50. Endocrine Disorders

A variety of endocrine disorders can complicate pregnancy and vice versa. The most common of these, diabetes mellitus, is discussed in [Chapter 51](#). Because thyroid disorders are also common in young women, they are encountered with some frequency during pregnancy. Other endocrinopathies, although less common, may have devastating effects on pregnancy outcome if unrecognized and untreated, for example, pheochromocytoma.

The pathogenic basis of most endocrine disorders is disordered autoimmunity. A number of autoantigens, autoantibodies, and cellular immune elements have been identified to cause destruction or stimulation of thyroid, pancreatic, or adrenal glandular tissue ([Baker, 1997](#)). Usually a nonspecific event—for example, viral infection—initiates an antigen and organ-specific response with subsequent immune-mediated glandular destruction. Frequently there is a genetic predisposition also, and inheritance of major histocompatibility complex antigens or increased target organ susceptibility plays a role. Finally, environmental factors predispose to development of some of these autoimmune endocrinopathies.

THYROID DISEASES

A number of thyroid disorders are common in the general population, especially in young women. The incidence of sporadic nontoxic goiter is estimated to be as much as 5 percent of the North American population. The incidence of hyperthyroidism, hypothyroidism, and thyroiditis probably approaches 1 percent for each condition.

The interactions between pregnancy and the thyroid gland are fascinating from at least three aspects. First, there are the now well-known and seemingly aberrant changes in tests of thyroid function induced by pregnancy; and indeed, there may be actual functional changes. Second, there is an intimate relationship between maternal and fetal thyroid function. Although the latter is largely autonomous even early in pregnancy, drugs that affect the maternal thyroid also affect the fetal gland. Third, there are a number of related abnormal pregnancy and thyroid conditions that at least appear to interact. For example, clinical thyrotoxicosis may be caused by gestational trophoblastic disease. Thyroid autoantibodies have been associated with increased early pregnancy wastage, and uncontrolled thyrotoxicosis and untreated hypothyroidism are both associated with adverse pregnancy outcomes. Finally, there is evidence that although the severity of some autoimmune thyroid disorders is ameliorated during pregnancy, these same disorders may be exacerbated postpartum.

THYROID PHYSIOLOGY. The impact of pregnancy on maternal thyroid physiology is substantial. There are changes in the structure and function of the gland that can cause confusion in the diagnosis of thyroid abnormalities. Consequently, evaluation of thyroid disorders and proper interpretation of thyroid function tests during pregnancy requires an understanding of these changes. These are discussed in detail in [Chapter 8 \(p. 192\)](#) and are now summarized.

Anatomically, there is moderate thyroid enlargement as a result of glandular hyperplasia and increased vascularity. Histologically, the appearance of the gland is consistent with active formation and secretion of thyroid hormone. Thyroid gland volume determined ultrasonographically increases during pregnancy, although its echostructure and echogenicity remain unchanged ([Rasmussen and colleagues, 1989](#)). Importantly, pregnancy does not cause impressive thyromegaly, and thus any goiter or nodule should be approached as if pathological.

During pregnancy, there is increased uptake of radioiodine by the maternal thyroid gland. Beginning as early as the second month, total serum thyroxine and triiodothyronine concentrations rise sharply. Daily thyroxine secretion is probably increased, perhaps due to increased placental degradation. Contrary to previous teaching, substantial amounts of thyroxine are transferred from mother to fetus, at least in those cases of fetal hypothyroidism due to enzyme defects or thyroid agenesis ([Vulsma and colleagues, 1989](#)). During pregnancy, the serum concentration of the major thyroid hormone carrier protein, *thyroid-binding globulin (TBG)*, is increased considerably. This is due to a combination of estrogen-stimulated hepatocyte production as well as altered glycosylation of the protein that inhibits degradation. *Thyrotropin-releasing hormone (TRH)* is undetectable in maternal serum, and its secretion does not appear to be altered during normal pregnancy. Beginning at mid-pregnancy, fetal serum TRH^1 is detectable, but does not increase. Injected TRH shows minimal placental transfer ([Bajoria and co-workers, 1998](#)).

Thyrotropin or *thyroid-stimulating hormone (TSH)* is a 28- to 30-kDa glycoprotein related to follicle-stimulating hormone (FSH), luteinizing hormone (LH), and chorionic gonadotropin (hCG). It is not bound by carrier proteins, its concentration is unchanged during pregnancy, and it does not cross the placenta. It appears that the thyrotropic substance isolated from human placenta, previously called *chorionic thyrotropin*, is in reality chorionic gonadotropin which has a very small crossover activity of 0.1 percent, but it is produced in prodigious quantities ([Grossman and associates, 1997](#)). Thus, in early pregnancy, coincidental with maximum chorionic gonadotropin levels, serum free thyroxine levels increase while thyrotropin levels decrease. Despite this, they usually are within the normal range. During most of pregnancy, however, levels of free thyroxine and triiodothyronine, as well as thyrotropin, are maintained within a narrow normal range, and thus there is not overt functional hyperthyroidism.

HYPERTHYROIDISM

Thyrotoxicosis, or hyperthyroidism, complicates about 1 in 2000 pregnancies ([Mestman and colleagues, 1995](#)). As perhaps expected, mild thyrotoxicosis is difficult to diagnose during pregnancy. Some helpful signs include:

1. Tachycardia that exceeds the increase associated with normal pregnancy.
2. An abnormally elevated sleeping pulse rate.
3. Thyromegaly.
4. Exophthalmos.
5. Failure in a nonobese woman to gain weight despite normal or increased food intake.

Confirmation has been made easier by assays to determine elevated serum free thyroxine levels along with the recent development of assays that reliably measure thyrotropin levels less than 0.1 mU/L. In fact, such accuracy has led to discovery of *subclinical hyperthyroidism* ([Utiger, 1994](#)). In younger persons, exogenous thyroxine replacement sometimes causes thyrotoxicosis, but as many as 5 percent of older persons may be affected spontaneously. Rarely, hyperthyroidism may be associated with normal serum thyroxine values but abnormally high serum triiodothyronine levels, so-called **T₃-toxicosis**.

THYROTOXICOSIS AND PREGNANCY. The overwhelming cause of thyrotoxicosis in pregnancy is **Graves disease**, an organ-specific autoimmune process usually associated with thyroid-stimulating antibodies. These autoantibodies mimic thyrotropin in its ability to stimulate thyroid function, and they appear to be responsible for both thyroid hyperfunction and growth in Graves disease. In an earlier classical study, [Amino and colleagues \(1982\)](#) reported that thyroid-stimulating antibody activity declined during pregnancy in 41 women with Graves disease. This was associated with chemical remission during almost all pregnancies. Between 1 and 4 months postpartum, many women had recurrence of antithyroid antibodies along with hyperthyroxinemia. Recently, [Kung and Jones \(1998\)](#) confirmed that the decline in antibody levels during pregnancy was accompanied by a mirror-image increase in thyroid stimulating-blocking antibody levels ([Fig. 50-1](#)). These changes were associated with corresponding decreased free thyroxine levels during pregnancy with a return to baseline at 4 months postpartum. Thus, it appears that any ameliorative effects of pregnancy on thyroid-stimulating antibodies is from production of blocking antibodies.

TREATMENT. Thyrotoxicosis during pregnancy is generally treated medically. Hyperthyroidism can nearly always be controlled by thioamide drugs ([Weetman, 2000](#)). Some prefer *propylthiouracil* because it partially inhibits the conversion of T₄ to T₃, it crosses the placenta less readily than *methimazole*, and it is not associated with **aplasia cutis**, which has been attributed to methimazole. [Wing and associates \(1994\)](#) have provided evidence in 185 pregnant thyrotoxic women that both drugs are effective and safe. Transient leukopenia manifests in about 10 percent of patients given thioamide drugs, but this does not require cessation of therapy. In about 0.2 percent, agranulocytosis develops suddenly and mandates discontinuance of the drug. It is not dose related, and because of its acute onset, serial leukocyte counts during therapy are not helpful ([Franklyn, 1994](#); [Mestman and colleagues, 1995](#)). If fever or sore throat develop, patients are instructed to discontinue medication immediately and to report for a complete blood count ([Vanderpump and associates, 1996](#)). Although either thioamide has the potential for causing fetal complications, it is difficult to ascribe all cases of neonatal thyroid abnormalities to them because thyrotropin-blocking antibodies also cross the placenta and may bind to the fetal thyroid gland.

A regimen employing propylthiouracil without replacement thyroid hormone has been followed at Parkland Hospital for four decades with very satisfactory pregnancy

outcomes for women who become euthyroid ([Davis and associates, 1989](#)). The dose of propylthiouracil is empirical, and for nonpregnant patients, the American Thyroid Association recommends an initial dose of 100 to 600 mg for propylthiouracil or 10 to 40 mg for methimazole ([Singer and colleagues, 1995](#)). In pregnant women, the [American College of Obstetricians and Gynecologists \(1993\)](#) recommends a starting dose of 300 to 450 mg daily for propylthiouracil. [Reinwein and associates \(1993\)](#) randomized 509 nonpregnant thyrotoxic patients to therapy with either 10 or 40 mg of methimazole. Of these, 68 and 83 percent, respectively, were euthyroid by 3 weeks. At 6 weeks, these numbers were 85 and 92 percent. In pregnant women, [Wing and colleagues \(1994\)](#) reported the median time to normalization of the free thyroxine index was 7 to 8 weeks with either methimazole or propylthiouracil.

In our experiences, metabolic control requires higher doses than most authorities recommend for pregnant women ([Davis and colleagues, 1989](#)). Of 52 women with thyrotoxicosis given an initial propylthiouracil dose that averaged 600 mg, about half underwent remission, and the dose was decreased to less than 300 mg within 8 weeks. In a third, however, it was necessary to increase the dose. In only 10 percent of these women could the dose be decreased to 150 mg by delivery. [Kriplani and colleagues \(1994\)](#) similarly found that the initial dose of carbimazole could be decreased in only a fourth of 32 pregnant thyrotoxic women. These clinical experiences are at variance with observations discussed earlier suggesting that remission is commonly induced by pregnancy.

Thyroidectomy may be carried out after thyrotoxicosis has been brought under medical control. Because of the increased vascularity of the thyroid gland during pregnancy, such surgery is more complicated than in the nonpregnant state. For women who cannot adhere to medical treatment or in whom drug therapy proves toxic, thyroidectomy may be appropriate. [Miccoli and co-workers \(1996\)](#) cite an incidence of about 2 percent for vocal cord palsy and 3 percent for hypoparathyroidism.

PREGNANCY OUTCOME. Pregnancy outcomes in thyrotoxic women depend upon whether metabolic control is achieved. In women who remain hyperthyroid despite therapy, and in those whose disease is untreated, there is a higher incidence of preeclampsia and heart failure, as well as adverse perinatal outcomes ([Table 50-1](#)). [Sherif and colleagues \(1991\)](#) reported perinatal mortality of 8 percent in 92 women with thyrotoxicosis, and [Kriplani and associates \(1994\)](#) reported 12 percent fetal mortality in 32 such women.

THYROID STORM OR HEART FAILURE. Thyroid storm is encountered only rarely in untreated women with Graves disease ([Davis and associates, 1989](#)). In some, storm is caused by a large functioning tumor ([Tewari and co-workers, 1998](#)). Heart failure is much more likely than thyroid storm, and it is caused by the profound myocardial effects of thyroxine ([Klein and Ojamaa, 1998](#)). This is characterized by a high-output state similar to constant exercising. Ironically, normal pregnancy causes a similar effect. Thus, it is not surprising that all of these effects are additive or even synergistic. In 239 women shown in [Table 50-1](#), heart failure developed in 3 percent. If thyrotoxicosis was not controlled, this rate was 8 percent and pulmonary edema commonly was precipitated by preeclampsia, anemia, or sepsis. In our experiences, and as shown in [Figure 50-2](#), thyroxine-induced cardiomyopathy is reversed with treatment over several weeks to months.

If thyroid storm develops, or if there is heart failure in the face of untreated or incompletely treated thyrotoxicosis, the woman should be managed in an intensive care unit. Specific treatment consists of 1 g of propylthiouracil given orally or crushed through a nasogastric tube. Propylthiouracil is continued in 200-mg doses every 6 hours. An hour later, iodide is given to inhibit the release of T₃ and T₄ from the thyroid gland. It is administered orally as 5 drops of supersaturated solution of potassium iodide (SSKI) every 8 hours; or Lugol solution, 10 drops every 8 hours. In the woman with a history of iodine-induced anaphylaxis, lithium carbonate, 300 mg every 6 hours, is given instead of iodide solution ([Burch and Wartofsky, 1993](#)). Blood levels of lithium should be monitored and kept within the range of 0.5 to 1.5 mmol/L. In addition, most authorities recommend dexamethasone, 2 mg intravenously every 6 hours for four doses, to further block peripheral conversion of T₄ to T₃. Some recommend intravenous administration of a β -blocker drug, but this should be approached cautiously if there is heart failure. Propranolol, labetalol, and esmolol have all been used intrapartum ([Bowman and colleagues, 1998](#)). A principal directive of therapy is supportive treatment and aggressive management of serious hypertension, infection, and anemia.

EFFECTS OF THYROTOXICOSIS ON THE NEONATE. The neonate may manifest transient thyrotoxicosis, which sometimes requires antithyroid drug treatment. Conversely, long-standing exposure in utero to these drugs may cause neonatal hypothyroidism. In either case, the fetus may develop a goiter ([Fig. 50-3](#)). Earlier estimates of adverse fetal effects induced by thiourea drugs were exaggerated, and their use during pregnancy carries an extremely small risk ([Momotani and associates, 1997](#); [O'Doherty and colleagues, 1999](#)). Of the 239 thyrotoxic women treated with thiourea shown in [Table 50-1](#), there was evidence for hypothyroidism in only four infants. [Davidson and colleagues \(1991\)](#) described a case of Graves disease in which the mother was overtreated with propylthiouracil, and the fetus developed a goiter by 28 weeks. Fetal blood sampling confirmed hypothyroidism, and thyroxine injected intra-amnionically at 35, 36, and 37 weeks caused rapid resolution of the goiter.

Finally, at least four long-term studies have been done to evaluate intellectual and physical development of children born to thyrotoxic mothers treated with thiourea drugs during pregnancy ([Mestman, 1998a](#)). No adverse effects on subsequent growth and development were found when compared with age-matched controls.

NEONATAL THYROTOXICOSIS AFTER MATERNAL THYROID ABLATION. Even after being rendered euthyroid by surgery or radiation, women with Graves disease occasionally give birth to infants with manifestations of thyrotoxicosis, including goiter and exophthalmos. [Watson and Fiegen \(1995\)](#) described nonimmune hydrops from fetal thyrotoxicosis. Neonatal thyrotoxicosis results from the transplacental passage of maternal thyroid-stimulating antibodies ([Wallace and collaborators, 1995](#)). Such fetal thyrotoxicosis can cause fetal demise ([Houck and associates, 1988](#); [Page and co-workers, 1988](#)). Fetal thyrotoxicosis is diagnosed by tachycardia in the appropriate clinical setting. Although this is adequate evidence to begin treatment, some have advocated cord blood sampling to assess fetal thyroid status ([Hatjis, 1993](#); [Wenstrom and colleagues, 1990](#)).

SUBCLINICAL THYROTOXICOSIS

This is defined as a low serum concentration of thyrotropin along with normal serum levels of T₃ and T₄. The overall prevalence in nine studies of community or clinic populations was about 4 percent ([Marqusee and colleagues, 1998](#)). About half of these patients were taking excessive thyroxine replacement therapy that suppressed thyrotropin. In the other half, the course of subclinical hyperthyroidism is variable, but many patients do not progress to overt thyrotoxicosis. Indeed, 40 percent of this half eventually have normal thyrotropin concentrations.

Long-term effects from subclinical thyrotoxicosis are for the most part currently unclear. It may cause cardiac arrhythmias and hypertrophy as well as osteopenia. Certainly, adverse effects on pregnancy have not been studied. Thus if there is no obvious cause of persistently depressed serum thyrotropin in an otherwise asymptomatic young woman, it seems reasonable at this time to periodically monitor for overt disease ([Marqusee and co-workers, 1998](#)).

THYROID DYSFUNCTION WITH GESTATIONAL TROPHOBLASTIC DISEASE. Serum thyroxine levels in women with molar pregnancy usually are elevated appreciably. Because many of these tumors are diagnosed early, clinically apparent hyperthyroidism is less common than in the past. In their review of earlier studies, [Goodwin and Hershman \(1997\)](#) estimate this was about 20 percent ([Chap. 32, p. 840](#)).

HYPOTHYROIDISM

Clinical hypothyroidism is diagnosed if free thyroxine levels are low and the thyrotropin level is elevated. Overt hypothyroidism complicating pregnancy is uncommon, probably because it is often associated with infertility. [Glincoer and colleagues \(1994\)](#) reported that euthyroid women with thyroid antibodies early in pregnancy go on to develop overt hypothyroidism in 40 percent of cases.

The experiences of [Davis and colleagues \(1988\)](#), as well as those of [Leung and associates \(1993\)](#), indicate that hypothyroid women who do become pregnant have a high incidence of preeclampsia and placental abruption with a correspondingly inordinate number of low-birthweight and stillborn infants ([Table 50-2](#)). [Wasserstrum and Anania \(1995\)](#) observed an inordinately high incidence of fetal distress (14 percent) during labor in 43 hypothyroid pregnancies. Heart failure is also encountered with increased frequency in hypothyroid women.

Replacement therapy is with thyroxine, 50 to 100 μ g daily. Serum thyrotropin is measured at 4 to 6 week intervals and thyroxine adjusted by 25- to 50- μ g increments. The goal is to keep the thyrotropin level at or slightly below normal. During pregnancy, thyrotropin is measured each trimester. [Mandel and colleagues \(1990\)](#), as well as [Tamaki and associates \(1990\)](#), presented evidence that pregnancy is associated with a 50- μ g increase in thyroxine requirements. Despite this, [Girling and de Swiet \(1992\)](#) reported that doses were unchanged in 80 percent of 35 pregnancies.

SUBCLINICAL HYPOTHYROIDISM

This condition is defined by an abnormally elevated serum thyrotropin and normal serum thyroxine in an asymptomatic patient. Its incidence in women between 18 and 45 is about 5 percent ([Canaris and colleagues, 2000](#); [Woeber, 1997](#)). Between 10 and 20 percent progress to overt hypothyroidism within 1 to 4 years. High-risk

factors include thyrotropin levels over 10 mU/L and antimicrosomal antibodies. The American Thyroid Association ([Singer and associates, 1995](#)) recommends that most patients be given treatment before they become symptomatic.

[Jovanovic-Peterson and associates \(1988\)](#) reported a high incidence of subclinical hypothyroidism in 51 pregnant women with type I diabetes, all of whom had normal thyroxine levels before conception. Effects of subclinical hypothyroidism on pregnancy outcome are not clear, but thyroxine replacement is recommended by most. There is a suggestion that these women are at greater risk for pregnancy-induced hypertension and preterm delivery ([Table 50-2](#)).

As discussed next, recent preliminary observations by [Haddow and colleagues \(1999\)](#) and [Pop and associates \(1999a\)](#) suggest diminished intelligence quotients (IQ) in children born to women with untreated subclinical hypothyroidism.

EFFECT OF HYPOTHYROIDISM ON THE FETUS AND INFANT. In the past, because most infants of hypothyroid mothers appeared healthy and without clinical evidence of thyroid dysfunction, it was presumed that they were euthyroid with normal fetal development. This is despite the fact that thyroid hormones are a known prerequisite for mental development ([Utiger, 1999a](#)). More recently, however, information is accruing that maternal hypothyroidism—either overt or subclinical—may cause subnormal mental development. [Pop and associates \(1999a\)](#) showed that maternal 12-week serum-free thyroxine levels below the 10th percentile were a significant risk factor for impaired psychomotor development. [Haddow and colleagues \(1999\)](#) evaluated children of 48 untreated women whose maternal serum thyrotropin values were above the 99.6th percentile. Serum samples had been stored following maternal serum alpha-fetoprotein screening in the early second trimester. As shown in [Table 50-3](#), elevated maternal thyrotropin values were associated with offspring with diminished school performance, reading recognition, and IQ scores when compared with matched controls.

It seems likely that the majority of women with hypothyroidism of this degree have antithyroid antibodies and impending autoimmune thyroid failure. For example, in the study by [Haddow and co-workers \(1999\)](#), at the time of follow-up 65 percent of the 48 untreated women had developed clinical hypothyroidism. In another study, [Dussault and Fisher \(1999\)](#) assessed thyroid function in mothers who had given birth to 259 hypothyroid newborns detected by the Quebec screening program. They found an increased incidence of maternal thyroid dysfunction in these women compared with controls (20 versus 13 percent).

These findings have led the [Endocrine Society \(2000\)](#) to recommend development of cost-effective screening programs for all pregnant women. Others emphasize the unknowns concerned with population screening ([Davies, 2000](#)). Moreover, it seems unlikely that effects of treatment given after the period of early cerebral development would be efficacious ([Pop and colleagues, 1999b](#); [Utiger, 1999a](#)). Because of this, the American Association of Clinical Endocrinologists ([Gharib and co-workers, 1999](#)) does not recommend routine antepartum thyrotropin screening. It does, however, recommend screening and appropriate treatment in women *considering* pregnancy. The [American Thyroid Association \(1999\)](#) recommends that the individual patient and her physician decide.

RADIOIODINE TREATMENT DURING PREGNANCY. If maternal hypothyroidism was caused by ablative radioiodine therapy (not tracer doses) during pregnancy, destruction of the fetal thyroid gland may have also resulted. Any exposed infant must be carefully evaluated and probably treated prophylactically for hypothyroidism ([Berg and colleagues, 1998](#)). Abortion should be considered. There is no evidence that therapeutic radioiodine causes fetal anomalies if pregnancy occurs after radiation effects have dissipated, and the woman is euthyroid. [Casara and colleagues \(1993\)](#) described outcomes in 70 pregnant women treated 2 to 10 years previously with radioiodine for thyroid cancer. Only 1 of 73 infants had an anomaly, and three were low birthweight. [Ayala and associates \(1998\)](#) reported three anomalous fetuses of 39 born to 26 women treated for thyroid cancer 2 months to 14 years before conception. They found no relationship to radioiodine but cautioned against pregnancy for 1 year after treatment.

IODIDE DEFICIENCY. Adequate iodide ingestion is extremely important for normal fetal thyroid and neurological development. Iodide deficiency may result in **endemic cretinism**, and the World Health Organization estimated in 1990 that 20 million people worldwide have varying degrees of preventable brain damage due to fetal iodide deficiency ([Hetzel, 1994](#)).

[Thilly and associates \(1978\)](#) studied a group of women from a region in Africa where severe endemic goiter is common because of iodine deficiency. Women whose iodine deficiency was corrected prenatally had significantly higher thyroxine levels and lower thyrotropin levels at delivery compared with nonsupplemented women. Mean cord serum thyrotropin levels in infants born to mothers not receiving supplementation was 19.6 mU/mL, compared with 9.4 mU/mL in newborns of treated mothers. [Cao and co-workers \(1994\)](#) studied these effects in a severely iodine-deficient region of China. They found that women given iodine supplementation in the first or second trimester had a 2 percent incidence of infants with moderate or severe neurological abnormalities. This was in contrast to an incidence of 9 percent in women not supplemented until the last trimester. Thus, iodine supplementation is necessary for pregnant women in areas of endemic iodine deficiency found in Latin America, Asia, and Africa ([Hetzel, 1994](#)). As emphasized by [Delange \(1996\)](#), iodide supplementation should ideally be given before conception.

CONGENITAL HYPOTHYROIDISM. The clinical diagnosis of hypothyroidism in neonates is difficult to make and is missed in nearly all cases. Because of this, newborn mass screening was introduced in 1974 and is now mandatory in all states. Early and aggressive thyroxine replacement therapy is critical for these infants. According to various reports based on these mass screening programs, congenital hypothyroidism is found in about 1 in 4000 to 7000 infants. The most common cause is thyroid agenesis (75 percent), followed by thyroid dyshormonogenesis (10 percent), and about another 10 percent have transient hypothyroidism ([Lindsay and Toft, 1997](#)). There are now 5- to 7-year follow-up data from infants identified by early screening programs who were treated promptly and adequately with thyroid hormone. Most, if not all, sequelae of congenital hypothyroidism—including intellectual impairment—were found to be preventable ([Burrow and colleagues, 1994](#)). Unfortunately, [Grant and colleagues \(1992\)](#) reported that 8 percent of 449 infants with congenital hypothyroidism also had other major associated anomalies.

PRETERM INFANTS. Transient hypothyroxinemia is common in preterm infants. It has been assumed that treatment was not necessary, and recently, [Van Wassenaer and colleagues \(1997\)](#) evaluated 157 infants born before 30 weeks and randomized to 8 ug/kg of thyroxine or placebo given daily. Follow-up at 6, 12, and 24 months with careful psychomotor and neurological testing showed no differences in the groups.

NODULAR THYROID DISEASE

Evaluation and management of a thyroid nodule during pregnancy depends on the stage of gestation. The likelihood that a solitary nodule will be malignant is from 5 to 30 percent. Even if malignant, the majority are low-grade neoplasms. Most authorities recommend against radioiodine scanning, although tracer doses used are associated with minimal fetal irradiation ([Chap. 42, p. 1153](#)). *Ultrasound* examination reliably detects nodules greater than 0.5 cm, and their solid or cystic nature also can be determined.

Fine-needle aspiration of thyroid nodules is an excellent method for assessment during pregnancy. [Mestman \(1999\)](#) recommends biopsy for nonfunctional solitary nodules before midpregnancy. This is performed for solid lesions over 2 cm and cystic lesions over 4 cm. In other cases, biopsy is done only if there is cervical lymphadenopathy or the nodule is growing. [Rosen and Walfish \(1986\)](#) and [Doherty and colleagues \(1995\)](#) provided data from a total of 53 pregnant women assessed for neoplasia because of nodular disease. Many of these underwent fine-needle aspiration, and 40 percent were found to have a malignancy.

Because most thyroid carcinomas are well differentiated and pursue an indolent course, some recommend that surgery be postponed until after delivery. [Moosa and Mazzaferri \(1997\)](#) studied 61 women with thyroid cancer diagnosed during pregnancy. In 75 percent, thyroidectomy was delayed until postpartum. In a long-term follow-up, these women had outcomes similar to nonpregnant control patients. In their review, [Driggers and co-workers \(1998\)](#) and [Morris \(1998\)](#) found minimal fetal loss related to thyroid cancer surgery. We are of the view that if pregnancy is less than about 24 to 26 weeks, that is, the time before surgery *might* stimulate preterm labor, then thyroidectomy surgery can be safely performed.

POSTPARTUM THYROIDITIS

The propensity for thyroiditis likely antedates pregnancy, and like other autoimmune endocrinopathies, a precipitating event such as a viral illness interplays with genetic and other factors. For example, [Pacini and associates \(1998\)](#) found serum thyroid antibodies in 30 percent of preadolescent girls exposed to radioactive fallout from the Chernobyl disaster, compared with 3 percent of a nonexposed control group.

Transient postpartum hypothyroidism or thyrotoxicosis associated with autoimmune thyroiditis is common. When women are carefully scrutinized postpartum, clinical and biochemical evidence of thyroid dysfunction has been found consistently in 5 to 10 percent regardless of their geographic locale ([Dayan and Daniels, 1996](#); [Lucas and colleagues, 2000](#)). In women with type I diabetes, up to 25 percent develop postpartum thyroid dysfunction ([Alvarez-Marfany and associates, 1994](#)). Nevertheless, postpartum thyroiditis is diagnosed infrequently, largely because it typically develops after the traditional postpartum examination and because it results in vague and nonspecific symptoms. These factors should not lead to an underestimation of its clinical importance. [Hayslip and colleagues \(1988\)](#) reported that such women were significantly more likely than euthyroid women to manifest depression, carelessness, and memory impairment 3 to 5 months after delivery. [Lucas and co-workers \(2000\)](#) documented a 9 percent incidence of depression at 6 months in women with thyroiditis.

PATHOGENESIS. Thyroiditis is thought to be caused by an initiating inflammatory event followed by a specific autoreaction from the immune system (Baker, 1997). It is characterized histologically as a destructive, lymphocytic thyroiditis. Many women who develop this disorder have antithyroid antibodies earlier during pregnancy. When postpartum thyroiditis develops, the majority of women are found to have a positive assay for microsomal autoantibodies (Jansson and co-workers, 1988). Other women at increased risk for postpartum thyroid dysfunction include those who have experienced it before and those who have a personal or family history of autoimmune disease. Iodine deficiency may also play a role (Glinoe and associates, 1992).

THYROID AUTOANTIBODIES. Thyroid microsomal autoantibodies have been identified in 7 to 10 percent of women either early in pregnancy or shortly following delivery (Jansson and associates, 1988; Kuijpers and co-workers, 1998). Stagnaro-Green and collaborators (1990) found that the incidence was 20 percent in 552 consecutive women studied before 13 weeks' gestation. Although 17 percent of these autoantibody-positive women aborted, only 8 percent of control women did so. Singh and co-workers (1995) reported similar observations.

When microsomal autoantibody titers are followed sequentially in seropositive women during pregnancy and the puerperium, a characteristic pattern emerges. As shown in Figure 50-4, titers decrease somewhat during pregnancy, rise to a peak 4 to 6 months after delivery, and then decline to early pregnancy levels by 10 to 12 months postpartum. Detection of microsomal autoantibodies either early in pregnancy or shortly after delivery helps to identify women at high risk for developing postpartum thyroid dysfunction (Hidaka and associates, 1994). Premawardhana and co-workers (2000) have shown that thyroid peroxidase antibodies are also associated with a high incidence of long-term thyroid dysfunction.

An association between maternal serum thyroid autoantibodies and fetal **Down syndrome** has long been suspected. Cuckle and colleagues (1988) identified both types of thyroid autoantibodies more frequently in pregnancies with Down syndrome versus normal controls, but the differences were not significant.

CLINICAL MANIFESTATIONS. There are two recognized clinical phases of postpartum thyroiditis (Table 50-4). Between 1 and 4 months after delivery, approximately 4 percent of all women develop transient **thyrotoxicosis** (Lucas and colleagues, 2000; Walfish and Chan, 1985). The onset is abrupt and a small, painless goiter is commonly found. Although there may be many symptoms, only fatigue and palpitations are more frequent in these thyrotoxic women compared with euthyroid postpartum controls.

In these cases, thyrotoxicosis results from excessive release of preformed hormone because of glandular disruption—*destruction-induced thyrotoxicosis*—rather than excessive hormone. Thus, antithyroid medications such as propylthiouracil and methimazole are ineffective, and they may even hasten the development of a subsequent hypothyroid phase. Treatment usually is not necessary, but if symptoms due to excessive thyroid hormone are severe, a β -adrenergic blocker may be useful. Approximately two thirds of these women return directly to a euthyroid state, but the other third subsequently experience hypothyroidism.

Between 4 and 8 months postpartum, 2 to 5 percent of all women develop **hypothyroidism** (Jansson and co-workers, 1988; Lucas and associates, 2000). At least a third of such women will previously have experienced the thyrotoxic phase of postpartum thyroid dysfunction. Goiters, as well as clinically significant symptoms, are common and are more prominent than during the thyrotoxic phase. Hypothyroidism can develop rapidly, sometimes within a month. Thus, women at risk for postpartum hypothyroidism should be evaluated regularly, and at least in selected situations, thyroid function tests should be performed. If hypothyroidism develops and the severity of symptoms warrants, thyroxine replacement is initiated. It has been suggested that thyroxine be continued for 6 to 12 months and then gradually withdrawn (Jansson and colleagues, 1988).

Women who experience postpartum thyroiditis are at high risk of developing permanent hypothyroidism. This incidence is about 25 percent (Dayan and Daniels, 1996; Lucas and colleagues, 2000; Premawardhana and associates, 2000). The incidence may be even greater if subclinical disease is considered. Permanent hypothyroidism is much more common in women with antiperoxidase antibodies (Kuijpers and colleagues, 1998). Premawardhana and co-workers (2000) found that almost half of women with postpartum thyroiditis associated with thyroid peroxidase antibodies developed hypothyroidism when followed for 6 to 7 years. The importance of long-term follow up in these women is apparent.

PARATHYROID DISEASE

The function of **parathyroid hormone (PTH)** is to maintain extracellular fluid calcium concentration. This 115 amino-acid hormone acts directly on bone and kidney and indirectly on small intestine through its effects on synthesis of vitamin D (1,25 (OH)₂D) to increase serum calcium. Parathyroid hormone secretion is regulated by serum ionized calcium concentration through a negative feedback system. **Calcitonin** is a potent hypocalcemic hormone produced by the thyroid gland. It acts in many ways as a physiological parathyroid hormone antagonist. The interrelationships between these hormones and calcium metabolism, as well as **PTH-related protein** produced by fetal tissue, are discussed in Chapter 8 (p. 193).

Because of substantive fetal calcium needs—300 mg/day in late pregnancy and a total of 30 g—and increased renal calcium loss from augmented glomerular filtration, parathyroid hormone levels were thought to be increased in pregnant women. With newer assay methods, however, Seely and co-workers (1997) observed a significant decrease in intact 1-84 parathyroid hormone longitudinally during pregnancy. They also demonstrated a twofold increase in serum concentrations of 1,25-dihydroxyvitamin D—presumably of placental and decidual origin. They speculate that this hormone increases gastrointestinal absorption to meet the needs of pregnancy. At the same time, total serum calcium levels decline during pregnancy, paralleling the decrease in serum albumin concentration (Power and associates, 1999). Ionized calcium levels, however, are unchanged in pregnancy (Dahlman and colleagues, 1994).

HYPERPARATHYROIDISM

Hypercalcemia is caused by hyperparathyroidism or cancer in 90 percent of cases. Primary hyperparathyroidism is relatively common with a prevalence rate of 0.15 percent, and its incidence peaks between the third and fifth decades (Potts, 1998). Because many automated laboratory systems include measurement of serum calcium, cases of hyperparathyroidism that previously would have been undiagnosed are being detected. Almost 80 percent of cases are caused by a solitary adenoma and another 15 percent by generalized chief cell hyperplasia. In most tumor-related cases, the malignancy and the cause of increased serum calcium are obvious. Parathyroid hormone produced by tumors is similar but not identical to the natural hormone and therefore is usually not detected by routine assays.

About half of patients with hyperparathyroid-induced hypercalcemia have minimal symptoms. Findings include fatigue, depression, and confusion; anorexia, nausea, and vomiting; constipation; nephrolithiasis; and peptic ulcer disease. Generally, symptoms are not apparent until the serum calcium exceeds 12 mg/dL in the nonpregnant person. **Hypercalcemic crisis** manifests as stupor, nausea, vomiting, weakness, fatigue, and dehydration.

There is controversy regarding management in nonpregnant patients. Silverberg and colleagues (1999) compared surgical excision with observation in 121 patients with primary hyperparathyroidism. Half of these were cured by parathyroidectomy, and bone density improved. Of the half observed, about a fourth had progression of disease, for example, six of eight had recurrence of nephrolithiasis. These findings led Utiger (1999b) to recommend surgical therapy for all patients.

HYPERPARATHYROIDISM IN PREGNANCY. This situation is uncommon, and reviews cite only about 100 pregnant women reported with this disease (Carella and Gossain, 1992; Kelly, 1991). It is presumed that many hypercalcemic pregnant women with hyperparathyroidism are either not detected or not reported. As in nonpregnant patients, hyperparathyroidism is usually caused by a parathyroid adenoma, but it can be due to ectopic parathyroid hormone production, or rarely to parathyroid carcinoma (Montoro and colleagues, 2000). Symptoms include hyperemesis, generalized weakness, renal calculi, pancreatitis, and psychiatric disorders.

Pregnancy will theoretically improve hyperparathyroidism because of significant calcium shunting to the fetus as well as augmented renal excretion (Power and colleagues, 1999). When the "protective effects" of pregnancy are withdrawn, however, there is significant danger of postpartum hypercalcemia and possible crisis.

Ludwig (1962) first described adverse pregnancy outcomes with hyperparathyroidism. He reported excessive stillbirths, preterm deliveries, and neonatal tetany. With earlier detection and better management, the incidence of adverse effects is much lower (Carella and Gossain, 1992; Shangold and associates, 1982). Certainly, if asymptomatic hypercalcemic women are included, adverse perinatal outcomes are less common.

MANAGEMENT. Surgical removal of the parathyroid adenoma has become preferable management during pregnancy (Mestman, 1998b). Elective neck exploration is well tolerated by pregnant women (Graham and associates, 1998; Kort and colleagues, 1999). In one woman, a mediastinal adenoma was removed at 23 weeks (Rooney and co-workers, 1998). An alternative is to treat the asymptomatic women with oral phosphate, 1 to 1.5 g daily in divided doses. This may lower serum calcium, thus allowing parathyroidectomy to be postponed until after delivery.

For women with dangerously elevated serum calcium levels, or in those who are mentally obtunded—*hypercalcemic crisis*—emergency treatment is instituted.

Intravenous hydration with normal saline to evoke diuresis is the first step. Urine flow should exceed 150 mL/hr. *Furosemide* given in conventional doses will block tubular reabsorption of calcium. Careful attention to prevent hypokalemia and hypomagnesemia is important. Adjunctive therapy includes *mithramycin*, which inhibits bone resorption; *calcitonin*, which decreases skeletal calcium release; and oral phosphorus.

NEONATAL EFFECTS. In the normal infant, cord blood calcium levels are higher than maternal levels. With hyperparathyroidism, abnormally elevated maternal levels further suppress fetal parathyroid function, resulting in a fall in newborn serum calcium levels, which reach a nadir at 24 to 48 hours. Accordingly, 15 to 25 percent of these infants develop severe hypocalcemia with or without tetany ([Molitch, 1992](#)). At times, neonatal tetany alone has led to a search that identified a maternal parathyroid adenoma ([Beattie and co-workers, 2000](#)).

HYPOPARATHYROIDISM

The most common cause of hypocalcemia is hypoparathyroidism that usually follows parathyroid or thyroid surgery. Chronically hypocalcemic pregnant women may have a fetus with skeletal demineralization. Treatment usually prevents symptomatic hypocalcemia. The woman is given 1,25-dihydroxyvitamin D₃ (calcitriol), dihydrotachysterol, or large doses of vitamin D (50,000 to 150,000 U/day); together with calcium gluconate or calcium lactate (3 to 5 g/day); and a diet low in phosphates. The fetal risks from large doses of vitamin D have not been established. [Caplan and Beguin \(1990\)](#) reported their experiences with treatment of five pregnant women and observed that whereas the calcitriol dose was increased during the second half of pregnancy, it was reduced during lactation.

PREGNANCY-ASSOCIATED OSTEOPOROSIS

In some women during pregnancy or lactation, idiopathic osteoporosis develops. The condition was first described in 1948 by Albright and Reifenshtein. While its cause is controversial, most believe that pregnancy unmasks preexisting bone disease ([Black and co-workers, 2000](#); [Henderson and collaborators, 2000](#)). [Dunne and colleagues \(1993\)](#) and [Smith and associates \(1995\)](#) described a total of 59 women with symptomatic osteoporosis during pregnancy. The most common symptom was back pain in late pregnancy or postpartum. Other symptoms were hip pain, either unilateral or bilateral, and difficulty in weight bearing. In 29 women, there was no apparent reason for osteopenia except pregnancy. Some known causes include long-term heparin or corticosteroid therapy during pregnancy. In a few cases, overt hyperparathyroidism or thyrotoxicosis eventually develop ([Khovidhunkit and Epstein, 1996](#)). Although overt osteonecrosis of the femoral head during normal pregnancy has been described ([Chang and associates, 1993](#)), we have seen this only as a complication of known causes. Examples include corticosteroid therapy as described by [Spencer and colleagues \(1999\)](#), sickle-cell disease, or heparin therapy.

Treatment is problematical, but most recommend calcium and vitamin D supplementation. Long-term follow-up indicates that while bone density improves, these women, as well as their offspring, may have chronic osteopenia ([Blanch and co-workers, 1994](#); [Carbone and colleagues, 1995](#)).

ADRENAL GLAND DISORDERS

Pregnancy has profound effects on adrenal gland cortical secretion and its control or stimulation. These interrelationships are discussed in detail in [Chapter 8 \(p. 194\)](#). Serum corticotropin levels increase after a marked reduction in early pregnancy, undoubtedly related to corticotropin-releasing hormone synthesized by the placenta ([Carr and Rainey, 1994](#)). The considerable increase in plasma cortisol is explained by increased transcortin production and binding. In addition, plasma renin increases, which increases angiotensin II and in turn aldosterone secretion. Baseline adrenal medullary hormone secretion is probably unaffected. Although there is no evidence that pregnancy causes any adrenal-specific disorders, a number of adrenal disorders may coexist with pregnancy.

PHEOCHROMOCYTOMA

These are chromaffin tumors that secrete catecholamines. Most are located in the adrenal medulla, but 10 percent are located in the sympathetic ganglia. In adults, they are called the *10-percent tumor* because 10 percent are bilateral, 10 percent are extra-adrenal, and about 10 percent are malignant. There is an association with medullary thyroid carcinoma and hyperparathyroidism in some of the autosomally dominant or recessive **multiple endocrine neoplasia syndromes (MENS)**, as well as neurofibromatosis and von Hippel-Lindau disease. Pheochromocytomas are common findings at autopsy but are frequently not diagnosed. Only 0.1 percent of hypertensive patients have a pheochromocytoma.

Symptoms are usually paroxysmal and manifest as hypertensive crisis, seizure disorders, or anxiety attacks. Hypertension is sustained in 60 percent of patients, but half of these also have paroxysmal crises. Other symptoms during paroxysmal attacks are headaches, profuse sweating, palpitations, and apprehension. Chest pain, nausea and vomiting, and pallor or flushing are also common. There is usually severe hypertension and tachycardia.

The standard screening test is quantification of catecholamine metabolites in a 24-hour urine specimen ([Keely, 1998](#)). Diagnosis is established by measurement of 24-hour urine vanillylmandelic acid (VMA), metanephrines, or unconjugated catecholamines. Determination of plasma catecholamine levels is not recommended.

Adrenal localization is usually successful with computed tomography or magnetic resonance imaging. Extra-adrenal tumors may be localized using these, but often abdominal arteriography (after a-blockade is accomplished) or ¹³¹I-metaiodobenzylguanidine (MIBG) scanning is necessary for localization.

PHEOCHROMOCYTOMA COMPLICATING PREGNANCY. These tumors are rare but dangerous complications of pregnancy. [Geelhoed \(1983\)](#) cited an earlier review of 89 cases in which 43 mothers died. Maternal death was much more common if the tumor was not diagnosed antepartum—58 versus 18 percent. With modern diagnostic methods and management, maternal survival has improved. [Ahlawat and colleagues \(1999\)](#) reviewed 42 cases reported from 1988 through 1999. Shown in [Table 50-5](#) are their results compared with the earlier review by [Harper and co-workers \(1989\)](#). Maternal mortality most recently had decreased from 16 to 4 percent, but **there were no maternal deaths when the diagnosis was made antepartum**. In more recent years, this proportion has increased. [Botchan and associates \(1995\)](#) reviewed available literature and stressed a team approach to management of these tumors.

[Grimbert and colleagues \(1999\)](#) described 56 pregnancies in 30 women with **von Hippel-Lindau disease**. Only two pregnancies were complicated by a pheochromocytoma.

There are several methods of tumor localization during pregnancy. From their review, [Ahlawat and colleagues \(1999\)](#) reported that 21 of 22 tumors were found using sonography, 10 of 11 with computed tomographic scanning, and 10 of 10 using magnetic resonance imaging ([Fig. 50-5](#)).

In some cases, the principal challenge is to differentiate preeclampsia from the hypertensive crises caused by a pheochromocytoma. Onset in early pregnancy may be a clue, and the lack of proteinuria with episodic hypertension may point to a pheochromocytoma. [Combs and colleagues \(1989\)](#) have shown that during paroxysmal hypertension, cardiac output falls substantially. They expressed appropriate concerns for adverse fetal effects of hypertensive paroxysms. [Bassoon-Zaltzman and associates \(1995\)](#) described a normotensive 20-week pregnant woman with intermittent ventricular tachycardia. Although pheochromocytoma was diagnosed by elevated catecholamine levels, the tumor was not found in the bladder until 4 months after uncomplicated delivery.

MANAGEMENT. Management of hypertension and symptoms with an α -adrenergic blocker such as *phenoxybenzamine* is imperative. The dose is 10 to 30 mg, two to four times daily. After α -blockade is achieved, β -blockers may be given for tachycardia if necessary. In some cases, surgical exploration and tumor removal may be performed during pregnancy. [Janetschek and associates \(1998\)](#) described laparoscopic surgical removal of an adrenal pheochromocytoma in 16- and 20-week pregnancies. Favorable outcomes were described for 10 of 26 women in whom the diagnosis was made in pregnancy and blood pressure controlled pharmacologically during cesarean delivery done along with tumor resection ([Ahlawat and colleagues, 1999](#)).

Recurrent tumors are troublesome. We have cared for three women in whom recurrent pheochromocytoma was identified during pregnancy. Hypertension was managed with phenoxybenzamine in all three. Two infants were healthy, but a third was stillborn in a mother with a massive tumor load who was receiving phenoxybenzamine, 100 mg daily. In all three women, tumor resection was done postpartum. One woman died of persistent metastases several years later. Other case reports suggest that even with good blood pressure control, dangerous peripartum hypertension may develop ([Lyons and Colmorgen, 1988](#); [Sweeney and Katz, 1994](#)).

CUSHING SYNDROME

Long-term exposure to glucocorticoids leads to Cushing syndrome, which may be corticotropin-dependent or independent ([Williams and Dluhy, 1998](#)). The most common cause is iatrogenic from corticosteroid treatment. Endogenous Cushing syndrome is caused by increased adrenal cortisol production. Most cases are due to bilateral adrenal hyperplasia stimulated by corticotropin-producing pituitary adenomas, and these cases are known as *Cushing disease*. Most of these are

microadenomas less than 1 cm. Occasionally, abnormal secretion of hypothalamic corticotropin-releasing factor may cause corticotrophic hyperplasia. Hyperplasia may also be caused by nonendocrine tumors that produce polypeptides similar to either corticotropin-releasing factor or corticotropin. About a fourth of cases of Cushing syndrome are corticotropin independent. Most are caused by an adrenal adenoma, which is usually bilateral, and half are malignant.

The typical body habitus is caused by adipose tissue deposition, which characteristically results in *moon facies*, a *buffalo hump*, and truncal obesity. Fatiguability and weakness, hypertension, hirsutism, amenorrhea, cutaneous striae, and easy bruisability are each encountered in 70 to 80 percent of cases. Diagnosis is made by elevated plasma cortisol that cannot be suppressed by dexamethasone. Free cortisol excretion in a 24-hour urine specimen is also elevated. Neither test is totally accurate, and both are harder to interpret in obese patients.

PREGNANCY AND CUSHING SYNDROME. Because most women with Cushing syndrome have amenorrhea, associated pregnancy is rare. [Buescher and co-workers \(1992\)](#) found only 70 or so cases in their review. [Kamiya and colleagues \(1998\)](#) cite 97 cases from the Japanese literature. Most cases were caused by adrenal tumors, of which 80 percent were benign. These reports stressed difficulties in diagnosis because of pregnancy-induced increases in plasma cortisol, corticotropin, and corticotropin-releasing factor.

Pregnant women usually have the classical findings of Cushing syndrome. In some, symptoms may be exacerbated. Maternal complications include hypertension in 60 to 90 percent and gestational diabetes in about half. Heart failure is common during pregnancy, and [Buescher and associates \(1992\)](#) reported three maternal deaths in 65 pregnancies. Perinatal morbidity and mortality are correspondingly high. Preterm delivery was reported in 60 percent, and perinatal mortality in about 25 percent.

MANAGEMENT. Long-term medical therapy for Cushing syndrome usually is ineffective. Ketoconazole blocks steroid production and it has been used successfully. Definitive therapy is resection of the pituitary or adrenal adenoma. Unfortunately, recurrences are difficult to manage. During pregnancy, management of hypertension in mild cases may suffice until delivery. Although pituitary adenomas are encountered less commonly during pregnancy, successful transsphenoidal resection at midpregnancy has been described ([Mellor and associates, 1998](#)). Removal of an adrenal adenoma can be curative ([Kamiya and colleagues, 1998](#)). Direct attempts to treat Cushing syndrome were reported in 16 cases summarized by [Aron and associates \(1990\)](#). In six women, unilateral adrenalectomy was done for an adenoma; in five, bilateral resection was done for hyperplasia; four were treated with *metirapone*, *aminoglutethimide*, or *cyproheptadine*; and one underwent pituitary irradiation. A few cases during pregnancy have been successfully treated with oral *ketoconazole* ([Berwaerts and co-workers, 1999](#)). The drug also blocks testicular steroidogenesis; therefore, treatment of a woman with a male fetus is worrisome.

ADDISON DISEASE

Primary adrenocortical insufficiency, or Addison disease, is rare. More than 90 percent of the glands must be destroyed for symptoms to develop. Whereas in the past chronic granulomatous diseases such as tuberculosis and histoplasmosis caused most cases, **idiopathic autoimmune adrenalitis** is now responsible for the majority. There is an increased incidence of concurrent Hashimoto thyroiditis, premature ovarian failure, type 1 diabetes, and Graves disease. These **polyglandular autoimmune syndromes** also include pernicious anemia, vitiligo, alopecia, nontropical sprue, and myasthenia gravis.

ADDISON DISEASE AND PREGNANCY. Before 1953, only 50 published cases of Addison disease in pregnancy had been identified, suggesting that untreated adrenal hypofunction caused infertility. With the synthesis of cortisone and related compounds, pregnancy has become much more common in these women. Fetal prognosis in general parallels maternal health. Because serum cortisol levels are increased during pregnancy, evaluation should include documentation of a lack of response to infused corticotropin ([O'Shaughnessy and Hackett, 1984](#)). [Seaward and colleagues \(1989\)](#) found only five cases published since 1972. They reported a woman with unrecognized Addison disease who suffered a placental abruption and fetal death associated with Addisonian crisis. [Albert and associates \(1989\)](#) reported six successful pregnancy outcomes in six women in whom adrenal insufficiency had been diagnosed before conception.

The woman with adrenal insufficiency is observed for evidence of either inadequate or excessive steroid replacement. Except at times of stress, replacement therapy need not be greater than in the nonpregnant state. There may be little need during pregnancy for potent mineralocorticoid compounds. During labor and after delivery or after a surgical procedure, steroid replacement must be increased appreciably to approximate the normal adrenal response. Hydrocortisone, 100 mg, is usually given intravenously every 8 hours. It is important that shock from causes other than adrenocortical insufficiency—for example, hemorrhage or sepsis—be recognized and treated promptly.

PRIMARY ALDOSTERONISM

Hyperaldosteronism is caused by an adrenal aldosteronoma in about 75 percent of cases, and idiopathic bilateral adrenal hyperplasia in the remainder ([Ganguly, 1998](#)). In view of the very high levels of aldosterone in normal pregnancies, it is not surprising that there may be amelioration of symptoms as well as electrolyte abnormalities during pregnancy ([Biglieri and Slaton, 1967](#); [Murakami and associates, 2000](#)). Unless there is an unequivocal adrenal adenoma localized by computed tomography or magnetic resonance imaging, medical therapy is given. In many cases, hypertension responds to *spironolactone*, but β -blockers or calcium-channel blockers also may be required.

PREGNANCY AND HYPERALDOSTERONISM. From their review, [Webb and Bayliss \(1997\)](#) reported 15 cases of primary aldosteronism associated with pregnancy. Most presented with hypertension and hypokalemia. Of the 12 with known causes, an adrenal adenoma was identified in 10. [Baron and associates \(1995\)](#) diagnosed an adrenal adenoma in a 14-week pregnant woman with mild hypertension and hypokalemia. Adrenalectomy was performed at 17 weeks with no further hypertension. [Nezu and co-workers \(2000\)](#) described two women found to have an aldosteronoma postpartum. Both were normotensive throughout pregnancy, but they developed severe hypertension 3 to 4 weeks postpartum. Tumor resection is curative, and as with other adrenal tumors, laparoscopic adrenalectomy is widely used in nonpregnant patients ([Ganguly, 1998](#)). This technique may prove to be useful during pregnancy.

PITUITARY DISEASES

The normal pituitary enlarges in pregnancy, predominately from lactotropic cellular hyperplasia. These effects arise from estrogen stimulation, as discussed in [Chapter 8 \(p. 191\)](#).

PROLACTINOMAS

With the advent of serum prolactin assays in the 1970s, the relative common frequency of prolactinomas was appreciated. Almost simultaneously, the ergot derivative, *bromocriptine*—a dopamine-receptor stimulator—was developed as a powerful prolactin inhibitor. Amenorrhea, galactorrhea, and hyperprolactinemia caused by pituitary microadenomas were found to be amenable to bromocriptine therapy. Many pregnancies have resulted from bromocriptine treatment, which does not appear to affect the fetus.

PROLACTINOMAS AND PREGNANCY. Prolactinomas are classified arbitrarily by their size determined by computed tomography or magnetic resonance imaging. By convention, a microadenoma is 10 mm or less, and a macroadenoma is greater than 10 mm. Because symptoms caused by pregnancy-induced pituitary enlargement are much more frequent with macroadenomas, most authorities recommend definitive therapy with surgery or irradiation before pregnancy ([Molitch, 1998](#)).

[Molitch \(1985\)](#) analyzed outcomes in almost 250 women with previously untreated **microadenomas** who became pregnant. Only four women developed symptomatic enlargement during pregnancy, and another 11, who were asymptomatic, had radiographic evidence for enlargement. In a review of 352 pregnancies, [Albrecht and Betz \(1986\)](#) reported 2.3 percent with visual disturbances, 4.8 percent with headaches, and 0.6 percent with diabetes insipidus.

Symptomatic tumor enlargement during pregnancy is more common with **macroadenomas**. According to [Molitch \(1985\)](#), 15 percent of 45 such women developed headaches or visual field defects during pregnancy. [Albrecht and Betz \(1986\)](#) reported that 15 percent of 144 women had visual disturbances, 15 percent had headaches, and 1.4 percent developed diabetes insipidus. [Kupersmith and colleagues \(1994\)](#) described visual loss during pregnancy in six of eight women with macroadenomas.

[Molitch \(1998\)](#) recommends that pregnant women with microadenomas be assessed regularly for headaches and visual symptoms. Those with macroadenomas should also have visual field testing during each trimester. Serial serum prolactin concentrations are not recommended because prolactin normally increases during pregnancy. Computed tomography or magnetic resonance imaging during pregnancy is recommended only if symptoms develop. Symptomatic tumor enlargement during pregnancy is treated immediately with bromocriptine. Relative resistance of macroprolactinomas has been described during pregnancy ([Shanis and Check,](#)

1996). Surgery is undertaken for women with no response. More than 6000 pregnant women have taken bromocriptine at some time during pregnancy and there have been no adverse effects ([Molitch, 1995](#)).

ACROMEGALY

Acromegaly is caused by excessive growth hormone, usually from an acidophilic or a chromophobic pituitary adenoma. In normal pregnancy, pituitary growth hormone levels decrease as placental epitopes are secreted. Diagnosis is confirmed by the failure of an oral glucose-tolerance test to suppress pituitary growth hormone ([Molitch, 1998](#)). Pregnancy is rare in acromegalic women, possibly because half are hyperprolactinemic. Management is similar for prolactinomas, with close monitoring for symptoms of tumor enlargement. From their review, [Prager and Braunstein \(1995\)](#) recommend that symptomatic tumor enlargement during pregnancy be treated with bromocriptine or surgery. [Herman-Bonert and associates \(1998\)](#) reported successful treatment of three pregnant women with *octreotide*.

DIABETES INSIPIDUS

Vasopressin deficiency is usually due to a hypothalamic or stalk disorder, rather than a pituitary lesion ([Lamberts and associates, 1998](#)). True diabetes insipidus is a rare complication of pregnancy. Only a few cases have been cared for in the last 45 years at Parkland Hospital, during which time there were nearly 350,000 deliveries. This incidence is remarkably close to that cited by [Hime and Richardson \(1978\)](#). As long as the woman takes vasopressin replacement therapy, there should be no serious pregnancy complications. Preferable therapy is intranasal administration of *desmopressin*, the synthetic analog of vasopressin, which is 1-deamino-8-D-arginine vasopressin (DDAVP). Most women require increased doses during pregnancy, likely because of an increased metabolic clearance rate stimulated by placental vasopressinase ([Lindheimer and Barron, 1994](#)). In a literature review, [Ray \(1998\)](#) found 53 cases in which DDAVP² was used during pregnancy with no adverse sequelae. Because of this same mechanism, **subclinical diabetes insipidus** may become symptomatic during pregnancy. [Krege and associates \(1989\)](#) reviewed 17 such cases. [Iwasaki and colleagues \(1991\)](#) showed that pregnancy unmasked subclinical forms of both nephrogenic as well as central diabetes insipidus.

Diabetes insipidus during pregnancy has been described as arising from a hemorrhage into a macroadenoma ([Freeman and co-workers, 1992](#)). One case followed an occluded ventriculoperitoneal shunt ([Goolsby and Harlass, 1996](#)). Another case that manifest during pregnancy as oligohydramnios, did not resolve postpartum ([Hanson and colleagues, 1997](#)).

In a few instances of diabetes insipidus, there appeared to have been an impairment of labor, possibly caused by diminished or absent endogenous oxytocin ([Hime and Richardson, 1978](#)). [Sende and associates \(1975\)](#) were unable to detect oxytocin by radioimmunoassay in plasma of a pregnant woman with diabetes insipidus before labor, but during labor and the puerperium there was an oxytocin surge. A woman described by [Chau and associates \(1969\)](#) lactated normally, with normal milk ejection pressures.

In our experience, transient secondary diabetes insipidus is more likely encountered with **acute fatty liver of pregnancy** ([Chap. 48, p. 1285](#)). This association was described by [Cammu and colleagues \(1987\)](#) as being nephrogenic; however, the syndrome may be due to altered vasopressinase clearance because of hepatic dysfunction. Thus, this type of diabetes insipidus should respond to DDAVP³. [Harper and associates \(1987\)](#) described transient disease in a 38-week pregnant woman with biopsy-proven viral hepatitis.

SHEEHAN SYNDROME

Pituitary ischemia and necrosis associated with obstetrical blood loss may cause hypopituitarism, referred to as Sheehan syndrome ([Chap. 25, p. 638](#)). Acutely, women may have persistent hypotension, tachycardia, hypoglycemia, and failure of lactation. Subsequent deficiencies of some or all pituitary-responsive hormones may develop. Diabetes insipidus with or without anterior pituitary deficiency has been described following massive obstetrical hemorrhage and prolonged shock ([Kan and Calligerous, 1998](#)). [Ammini and Mathur \(1994\)](#) described 12 cases seen from New Delhi. The average duration of onset of symptoms was 5 years.

LYMPHOCYTIC HYPOPHYSITIS

This autoimmune pituitary disorder is characterized by massive infiltration by lymphocytes and plasma cells with parenchymal destruction. The majority of cases have been associated with pregnancy ([Madsen, 2000](#); [Patel and associates, 1995](#); [Thodou and colleagues, 1995](#)). There are varying degrees of hypopituitarism or symptoms of mass effect, including headaches and visual field defects. Associated hypothyroidism is common. [Pressman and colleagues \(1995\)](#) reviewed 44 cases and found that 25 percent had other autoimmune diseases. Treatment is problematic, but the disease may be self-limited ([Gagneja and associates, 1999](#)). Surgery during pregnancy is warranted only in cases of severe chiasmal compression unresponsive to corticosteroid therapy. In nonpregnant women with disease, spontaneous pregnancies have been reported, and ovulation induction has also been successful ([Verdu and colleagues, 1998](#)).

51. Diabetes

This and the preceding 20 editions of *Williams Obstetrics* provide witness that the 20th century has been a remarkable time for the diabetic woman who becomes pregnant. At the beginning of the century, diabetic women suffered from infertility, and the rare woman achieving pregnancy faced a dismal prognosis. Maternal death was a real threat, and perinatal survival a mere 40 percent. The availability of insulin, beginning in 1922, restored fertility and virtually abolished maternal mortality. At the same time, perinatal survival did not change appreciably.

To improve this dismal perinatal mortality, obstetricians increasingly focused on both timing and mode of delivery, so that by the 1930s, awareness of fetal macrosomia and intrapartum deaths led to frequent cesarean delivery ([White and colleagues, 1939](#)). Some improvement followed, but unexplained late antepartum deaths continued to be a problem and led to early delivery with resultant neonatal immaturity and its consequences. The development of the White Classification in 1949, by which fetal risk was shown to be proportional to the severity of maternal diabetes, permitted individualized timing of delivery and helped reduce perinatal mortality. These management landmarks improved perinatal survival to about 85 percent by the late 1950s ([White, 1978b](#)). In the ensuing years, up to the present, several refinements in management of diabetic women and their fetuses or infants have resulted in a perinatal mortality rate, excluding malformations, nearly equivalent to that observed in normal pregnancies.

CLASSIFICATION

Diabetes is classified as type 1 (insulin dependent) or type 2 (noninsulin dependent) according to whether the patient requires exogenous insulin to prevent ketoacidosis. Some differentiating characteristics between types 1 and 2 are shown in [Table 51-1](#).

Type 1 diabetes is immune mediated and develops in genetically susceptible persons. This predisposition is permissive rather than causal and disease presumably is triggered by a viral infection. There is inflammatory *insulinitis* with lymphocytic infiltration of islets. Subsequently, there is immune stimulation of antibodies against the β -cell. The cell membrane then becomes susceptible to autoimmune cytotoxic antibodies, which leads to eventual cellular destruction and resultant diabetes. The genetics of type 1 diabetes is complex, but there is general agreement that there is an association with the HLA-D histocompatibility complex located on chromosome 6. There is a low vertical transmission rate in type 1 disease. Moreover, the concordance rate for diabetes in monozygous twins, rather than being nearly 100 percent if diabetes were solely genetic in origin, is less than 50 percent ([Foster, 1998](#)).

Type 2, noninsulin-dependent diabetes has no HLA association. The disease has a familial occurrence and concordance in monozygotic twins is 100 percent. Nearly 40 percent of siblings and a third of offspring develop abnormal glucose tolerance or obvious diabetes ([Foster, 1998](#)). Its pathophysiology is abnormal insulin secretion and insulin resistance in target tissues. Most patients are overtly obese, and there is speculation that peripheral insulin resistance induced by obesity leads to β -cell exhaustion.

Diabetes is the most common medical complication of pregnancy. Patients can be separated into those who were known to have diabetes before pregnancy (overt) and those diagnosed during pregnancy (gestational). In 1998, a total of 103,691 American women had pregnancies complicated by diabetes, representing 2.6 percent of all live births ([Ventura and colleagues, 2000](#)). It is estimated that 90 percent of all pregnancies complicated by diabetes are due to gestational diabetes. Thus, in 1998, approximately 10,000 American women with overt diabetes, and 90,000 with gestational diabetes, delivered live births.

CLASSIFICATION DURING PREGNANCY

[Table 51-2](#) gives a classification recommended by the [American College of Obstetricians and Gynecologists in 1986](#). This was replaced in 1994 because, according to the American College of Obstetricians and Gynecologists, "a single classification based on the presence or absence of good maternal metabolic control and the presence or absence of maternal diabetic vasculopathy is more helpful." In the 1986 classification, women diagnosed to have gestational diabetes are subdivided according to their degree of glycemia. Specifically, those with fasting hyperglycemia (105 mg/dL or greater) are placed into class A₂. Approximately 15 percent of women with gestational diabetes will exhibit fasting hyperglycemia (Sheffield and co-workers, 2000). Women in classes B to H, corresponding to the [White classification \(1978a\)](#), have overt diabetes antedating pregnancy. The White system emphasizes that end-organ derangements, especially involving the eyes, kidneys, and heart, have significant effects on pregnancy outcome.

DIAGNOSIS OF OVERT DIABETES DURING PREGNANCY

The woman with high plasma glucose levels, glucosuria, and ketoacidosis presents no problem in diagnosis. Similarly, women with a random plasma glucose level greater than 200 mg/dL plus classical signs and symptoms such as polydipsia, polyuria, and unexplained weight loss or fasting glucose of 126 mg/dL or higher, should be considered to have overt diabetes ([American Diabetes Association, 1999b](#)). The new diagnostic cutoff value for overt diabetes of a fasting plasma glucose of 126 mg/dL or higher is based on data that indicate the risk of retinopathy rises dramatically at that fasting level. The woman at the opposite end of the spectrum, with only minimal metabolic derangement, may be difficult to identify. The likelihood of impaired carbohydrate metabolism is increased appreciably in women who have a strong familial history of diabetes, have given birth to large infants, demonstrate persistent glucosuria, or have unexplained fetal losses.

Reducing substances are commonly found in the urine of pregnant women. Commercially available dipsticks may be used to identify glucosuria while avoiding a positive reaction from lactose. Even then, glucosuria most often does not reflect impaired glucose tolerance, but rather augmented glomerular filtration ([Chap. 8](#)). Nonetheless, the detection of glucosuria during pregnancy warrants further investigation ([Gribble and co-authors, 1995](#)).

DETECTION OF GESTATIONAL DIABETES

Gestational diabetes mellitus is defined as carbohydrate intolerance of variable severity with onset or first recognition during pregnancy. This definition applies regardless of whether or not insulin is used for treatment. Undoubtedly, some women with gestational diabetes have previously unrecognized overt diabetes. Sheffield and co-workers (2000) studied outcomes in 1190 diabetic women delivered at Parkland Hospital between 1991 and 1995. They found that women with fasting hyperglycemia diagnosed before 24 weeks had pregnancy outcomes similar to those for women in classes B through FR. This finding indicates that fasting hyperglycemia early in pregnancy likely represents overt diabetes rather than gestational diabetes. [Bartha and colleagues \(2000\)](#) also found that women diagnosed to have gestational diabetes early in pregnancy are a high-risk subgroup.

SCREENING. Despite more than 30 years of research, there is lack of consensus regarding the optimal approach to screening for gestational diabetes. The major issues include whether universal or selective screening should be used, as well as which 50-g glucose test threshold is best to identify women at risk for gestational diabetes ([Bonomo and colleagues, 1998](#); [Danilenko-Dixon and colleagues, 1999](#)).

Since 1980 there have been four international workshop-conferences on gestational diabetes held in Chicago, and these have attempted to provide consensus statements on screening for diabetes ([Metzger and Coustan, 1998](#)). At the most recent workshop, in 1997, prior recommendations for universal screening were changed to selective screening using the guidelines shown in [Table 51-3](#). It was recommended that screening for gestational diabetes should be performed between 24 and 28 weeks in those women not known to have glucose intolerance earlier in pregnancy. This evaluation may be done in one or two steps. In the two-step procedure, a 50-g oral glucose challenge test is followed by a diagnostic 100-g oral glucose tolerance test if results exceed a predetermined plasma glucose concentration. In the one-step approach, the diagnostic 100-g test is administered without the preceding 50-g test.

When the two-step method is used, plasma glucose is measured 1 hour after a 50-g glucose load without regard to the time of day or time of last meal. A value of 140 mg/dL (7.8 mmol/L) or higher will identify 80 percent of all women with gestational diabetes. Using a value of 130 mg/dL (7.2 mmol/L) or higher will increase the yield to over 90 percent; however, 20 to 25 percent of women will have positive tests compared with 14 to 18 percent when the 140 mg/dL or greater threshold is used. The recommended criteria for interpretation of the 100-g diagnostic glucose tolerance test are shown in [Table 51-4](#).

[Gabbe and co-authors \(1998\)](#) surveyed practicing obstetricians in the United States and found that 96 percent screened all pregnant women for gestational diabetes, usually between 25 and 29 weeks. Similarly, [Owen and colleagues \(1995\)](#) surveyed Obstetrics and Gynecology residency programs and found that 97 percent were using universal screening between 24 and 28 weeks. The [American College of Obstetricians and Gynecologists \(1994\)](#) has concluded that selective screening may be appropriate in some clinical settings and universal screening in other circumstances.

The day-to-day reproducibility of the 50-g screening test has also been tested ([Espinoza de los Monteros and co-workers, 1993](#)). While 90 percent of normal results

were reproducible the next day, only 83 percent of abnormal tests were reproducible. [Murphy and colleagues \(1994\)](#) studied the accuracy and precision of reflectance photometers (Accu-Check III) for screening. Use of the glucometer required redefining the circumstances for testing as well as threshold values for abnormal results. It seems best to avoid these devices for screening.

DIAGNOSTIC CRITERIA. There is not international agreement as to the optimal glucose tolerance test for the definitive diagnosis of gestational diabetes. The [World Health Organization \(1985\)](#) recommends the 75-g 2-hour oral glucose tolerance test and this approach is often used in Europe ([Weiss and colleagues, 1998](#)). In the United States, the 100-g 3-hour oral glucose tolerance test performed after an overnight fast remains the standard ([American College of Obstetricians and Gynecologists, 1994](#)). [Catalano and co-workers \(1993\)](#) found that the 100-g 3-hour test was not reproducible in 25 percent of women when repeated 1 week after the initial test. They attributed this to increased norepinephrine-mediated gluconeogenesis due to maternal stress at initial testing.

Thus, there is not a consensus as to which glucose threshold values to use for diagnosis of gestational diabetes. Plasma values suggested by the [American College of Obstetricians and Gynecologists \(1994\)](#) are shown in [Table 51-4](#). These permit use of normative data suggested by the [National Diabetes Data Group \(1979\)](#), as well as those of [Carpenter and Coustan \(1982\)](#). Diagnosis of gestational diabetes is generally made in either set of criteria when any two values are met or exceeded. [Schwartz and colleagues \(1999\)](#), however, suggest that replacing the National Diabetes Data Group criteria with the Carpenter and Coustan criteria would increase by 54 percent the number of pregnant women with a diagnosis of gestational diabetes. This would increase costs, while only minimally affecting the prevalence of macrosomia, which is the outcome of greatest importance. According to the survey by [Owen and colleagues \(1995\)](#), 77 percent of residency programs use the [National Diabetes Data Group \(1979\)](#) criteria, and 96 percent require two or more abnormal values. These are the diagnostic criteria in use at Parkland Hospital. The American Diabetes Association (1999) appears to endorse any of these approaches for screening or diagnosis of gestational diabetes.

GESTATIONAL DIABETES

"Gestational" diabetes implies that this disorder is induced by pregnancy, perhaps due to exaggerated physiological changes in glucose metabolism ([Chap. 8, p. 174](#)). An alternative explanation is that gestational diabetes is maturity-onset or type 2 diabetes unmasked or discovered during pregnancy. For example, [Harris \(1988\)](#) found that the prevalence of undiagnosed glucose intolerance in nonpregnant women between the ages of 20 and 44 years was virtually identical to the prevalence of gestational diabetes. [Catalano and colleagues \(1999\)](#) evaluated the longitudinal changes in insulin sensitivity, insulin response, and endogenous glucose production in women with normal glucose tolerance and in those with gestational diabetes before and during pregnancy. They found that women with gestational diabetes had abnormalities in glucose metabolism that are hallmarks of type 2 diabetes.

Use of the diagnostic term **gestational diabetes** has been encouraged in order to communicate the need for increased surveillance and to convince women of the need for further testing postpartum. The likelihood of fetal death with appropriately treated gestational diabetes has been found no different than in the general population ([Metzger and Coustan, 1998](#)). The most important perinatal concern is excessive fetal growth, which may result in birth trauma. **Importantly, more than half of women with gestational diabetes ultimately develop overt diabetes in the ensuing 20 years, and there is mounting evidence for long-range complications that include obesity and diabetes in their offspring.** Because of its strong link with obesity, prevention efforts are difficult.

MATERNAL AND FETAL EFFECTS

There has been an important shift in focus concerning adverse fetal consequences of gestational diabetes. Importantly, unlike in women with overt diabetes, fetal anomalies are not increased ([Reece and Hobbins, 1986](#)). Similarly, whereas pregnancies in women with overt diabetes are at greater risk for fetal death, this danger is not apparent for those with postprandial hyperglycemia only; that is, class A₁ ([Lucas and co-workers, 1993](#)). In contrast, gestational diabetes with elevated fasting glucose (class A₂), has been associated with unexplained stillbirth similar to overt diabetes ([Johnstone and colleagues, 1990](#)). The [American Diabetes Association \(1999a\)](#) has concluded that fasting hyperglycemia (> 105 mg/dL) may be associated with an increased risk of fetal death during the last 4 to 8 weeks of gestation. Adverse maternal effects include an increased frequency of hypertension and the need for cesarean delivery.

MACROSOMIA. The perinatal focal point is avoidance of difficult delivery due to macrosomia, with concomitant birth trauma due to shoulder dystocia. Except for the brain, most fetal organs are affected by macrosomia that commonly (but not always) characterizes the fetus of a diabetic woman. [Modanlou and colleagues \(1982\)](#) as well as [McFarland and associates \(2000\)](#) observed that macrosomic infants of diabetic mothers were anthropometrically different from other large-for-age infants. Specifically, those whose mothers had diabetes had excessive fat deposition on the shoulders and trunk ([Fig. 51-1](#)), predisposing these fetuses to shoulder dystocia. Similarly, [Bernstein and Catalano \(1994\)](#), using measurements of subscapular and triceps skinfold thickness, found that fat infants of diabetic women more often required cesarean delivery for cephalopelvic disproportion. Fortunately, shoulder dystocia is uncommon, even in women with gestational diabetes. For example, [Magee and colleagues \(1993\)](#) diagnosed shoulder dystocia in 3 percent of women with class A₁ diabetes. None of these infants sustained brachial plexus injuries.

Macrosomia in these infants is compatible with the long-recognized association between fetal hyperinsulinemia resulting from maternal hyperglycemia, which in turn stimulates excessive somatic growth. Similarly, neonatal hyperinsulinemia may provoke hypoglycemia within minutes of birth. The incidence varies greatly depending on the threshold used to define significant neonatal hypoglycemia. According to the [American Diabetes Association \(1995\)](#), values less than 35 mg/dL at term are abnormal. A lower value is considered abnormal in preterm infants, because glycogen stores have not reached term levels. [Magee and co-workers \(1993\)](#) reported that 4 percent of infants of women with gestational diabetes required intravenous glucose therapy for hypoglycemia.

There is extensive evidence that insulin and the insulin-like growth factors I (IGF-I) and II (IGF-II) have a role in the regulation of fetal growth ([Chap. 29, p. 744](#)). Insulin is secreted by fetal pancreatic β -cells primarily during the second half of gestation, and is believed to stimulate somatic growth and adiposity. These growth factors, which structurally are proinsulin-like polypeptides, are produced by virtually all fetal organs and are potent stimulators of cell differentiation and division. [Verhaeghe and co-workers \(1993\)](#) measured cord serum insulin-like growth factors and insulin (C-peptide) concentrations throughout gestation in women without diabetes and found that levels correlated with birthweight. Large-for-age infants had significantly increased levels of these factors.

Maternal obesity is an independent and more important risk factor for large infants in women with gestational diabetes than is glucose intolerance ([Leonardi and Bottoms, 1996](#); [Lucas and colleagues, 1993](#)). Moreover, maternal obesity is itself an important confounding factor in the diagnosis of gestational diabetes. [Johnson and colleagues \(1987\)](#) reported that 8 percent of 588 women who weighed more than 250 pounds had gestational diabetes compared with less than 1 percent of women who weighed less than 200 pounds. [Landon and colleagues \(1994\)](#) and [Zhang and co-workers \(1995\)](#) found that the risk of gestational diabetes was increased in women with truncal obesity.

MANAGEMENT

Women with gestational diabetes can be divided into two functional classes depending on their level of fasting glucose. Insulin therapy is usually recommended when standard dietary management does not consistently maintain the fasting plasma glucose at less than 105 mg/dL or the 2-hour postprandial plasma glucose at less than 120 mg/dL ([American College of Obstetricians and Gynecologists, 1994](#)). Whether insulin should be used in women with lesser degrees of fasting hyperglycemia, that is, 105 mg/dL or less, is unclear because there are no controlled trials to identify ideal glycemia targets for prevention of fetal risks. The Fourth International Workshop Conference on Gestational Diabetes ([Metzger and Coustan, 1998](#)), however, recommended that maternal capillary glucose levels be kept 95 mg/dL or less in the fasting state. The American Diabetes Association (1999) has recommended insulin therapy when nutritional management fails to maintain fasting blood glucose at or below 95 mg/dL or 2-hour postprandial blood glucose levels at or below 120 mg/dL.

DIET. Nutritional counseling is a cornerstone in management. The goals of such therapy are:

1. To provide the necessary nutrients for the mother and fetus.
2. To control glucose levels.
3. To prevent starvation ketosis.

Proposed daily caloric intakes and pregnancy weight gain for women with gestational diabetes are shown in [Table 51-5](#). These recommendations pertain to women treated with insulin as well as dietary restrictions. Significant caloric restriction to 1200 to 1800 kcal/day has been studied in overweight women with gestational diabetes ([Dornhorst and colleagues, 1991](#)). For obese women, an intake of about 1800 kcal/day has been shown to reduce hyperglycemia and plasma triglycerides with no increase in ketonuria ([Franz and co-authors, 1994](#)). [Major and colleagues \(1998\)](#) studied carbohydrate restriction in women weighing approximately 185 pounds at delivery and reported that this approach resulted in improved glucose control, less need for insulin, and a decreased incidence of macrosomia. Although maternal weight gain and fetal macrosomia may be decreased, the safety of this approach has not been established, and it is not recommended by the [American](#)

[College of Obstetricians and Gynecologists \(1994\)](#).

EXERCISE. A liberal exercise program is encouraged. [Jovanovic-Peterson and associates \(1989\)](#) have shown that a program of cardiovascular-conditioning exercise improves glycemic control when compared with diet alone. Appropriate exercises are those that use the upper-body muscles or place little mechanical stress on the trunk region during exercise ([Durak and co-workers, 1990](#)). It is proposed that when the lower body is kept from an excessive weight-bearing load, the work effort can be increased safely, permitting a cardiovascular workout without fear of fetal distress. [Jovanovic-Peterson and Peterson \(1990\)](#) reported that such upper body cardiovascular training resulted in lower glucose levels. The effects of exercise on glucose levels only become apparent after 4 weeks of exercise.

INSULIN. Most practitioners—93 percent according to [Owen and colleagues \(1995\)](#)—initiate insulin therapy in women with gestational diabetes if fasting hyperglycemia greater than 105 mg/dL persists despite diet therapy. Usually, institution of insulin therapy requires hospitalization to safely titrate the dosage and educate the woman on self-administration and measurement of capillary glucose levels.

Experts differ in their approach to insulin therapy in gestational diabetes. A total dose of 20 to 30 units given once daily, before breakfast, is commonly used to initiate therapy. The total dose is usually divided into two thirds intermediate-acting insulin and a third short-acting insulin.

Once insulin therapy has been initiated, it must be recognized that the level of glycemia necessary to reduce fetal and neonatal complications of gestational diabetes has not been established. [DeVeciana and colleagues \(1995\)](#) randomized 66 women with fasting hyperglycemia (class A₂ gestational diabetes) and treated with insulin to glucose surveillance using either preprandial or postprandial (1-hour after each meal) capillary blood glucose concentrations measured by glucometer. Postprandial surveillance was shown to be superior to preprandial because blood glucose control was significantly improved with less neonatal hypoglycemia (3 versus 21 percent), less macrosomia (12 versus 42 percent), and fewer cesarean deliveries for dystocia (24 versus 39 percent). [Bansal and co-authors \(1996\)](#), however, have challenged these conclusions, because the women analyzed had prestudy fasting glucose values consistent with overt diabetes.

Prophylactic insulin given to decrease complications related to macrosomia in women with fasting euglycemia (class A₁) has not been proven to be beneficial. [Langer and co-authors \(1994\)](#) reviewed 23 reports from 1979 through 1993 and found that none demonstrated improved perinatal outcomes related to any management approach, including prophylactic insulin given to the mother. There have been only three randomized studies to date. [Thompson and colleagues \(1990\)](#) randomized 108 women with gestational diabetes to diet alone or diet plus insulin and showed a significant birthweight reduction in the insulin-treated group. In contrast, [Nordlander and co-workers \(1989\)](#) randomized 261 gestational diabetics to diet or diet plus insulin and found no neonatal benefits from insulin therapy. [Garner and colleagues \(1997\)](#) randomized 300 gestational diabetics to strict glucose control versus routine obstetrical care. Intensive therapy had little effect on birthweight, birth trauma, operative delivery or neonatal complications.

[Langer and colleagues \(1994\)](#) managed 1145 women with gestational diabetes using an "intensified" approach guided by glucometer measurements seven times each day. Goals included fasting glucose levels between 60 and 90 mg/dL and postprandial levels less than 120 mg/dL. In contrast, another 1316 women in the "conventional" management group had the same glucose control goals, but without glucometers because there were insufficient instruments available. Women in both groups underwent glucose surveillance for an average of 12 weeks and a similar number of glucose measurements were performed in each study group—approximately 350 per patient. Although mean glucose values were not different between the "intensive" and "conventional" management groups, macrosomia, cesarean delivery, and shoulder dystocia were significantly reduced in women managed intensively.

ORAL HYPOGLYCEMIC AGENTS. Oral glucose-lowering agents are not recommended during pregnancy by the [American Diabetes Association \(1999a\)](#). [Langer and colleagues \(1999\)](#) randomized 257 women with gestational diabetes to insulin or glyburide therapy. Near normoglycemic levels were achieved equally well with either insulin or glyburide. There were no apparent neonatal complications attributable to the oral hypoglycemic agent.

OBSTETRICAL MANAGEMENT

In general, women with gestational diabetes who do not require insulin seldom require early delivery or other interventions ([American College of Obstetricians and Gynecologists, 1994](#)). There is no consensus regarding whether antepartum fetal testing is necessary, and if so, when to begin such testing in women without severe hyperglycemia ([Metzger and Coustan, 1998](#)). This is based on the low risk of fetal death. Elective induction, compared with spontaneous labor, is controversial in women with sonographic diagnosis of fetal macrosomia to prevent shoulder dystocia. [Conway and Langer \(1996\)](#) found that elective delivery reduced the rate of shoulder dystocia from 2.2 to 0.7 percent. In contrast, [Combs and colleagues \(1993b\)](#) and Adashech and associates (1996) found no advantages. Women who require insulin therapy for fasting hyperglycemia, however, typically receive fetal testing and are managed as if they had overt diabetes.

POSTPARTUM CONSEQUENCES

The Fourth Workshop-Conference recommended that women diagnosed to have gestational diabetes undergo evaluation with a 75-g oral glucose tolerance test at 6 to 12 weeks after delivery. The criteria for interpretation of this test are shown in [Table 51-6](#). Women whose 75-g test is normal should be reassessed at a minimum of 3-year intervals ([American Diabetes Association, 1999b](#)). Although postpartum follow-up of women diagnosed to have gestational diabetes has been recommended throughout the 1990s, reports on compliance have only recently become available. [Kaufmann and colleagues \(1999\)](#) measured physician and patient compliance rates during a 5-year postpartum follow-up period in 66 women with gestational diabetes. Compliance was poor and only 30 percent of the women reported receiving a yearly 2-hour glucose tolerance test although the risk of developing diabetes was 60 percent in others tested on an annual basis.

These recommendations for postpartum follow-up are based on the 50-percent likelihood of women with gestational diabetes developing overt diabetes within 20 years of delivery ([O'Sullivan, 1982](#)). If fasting hyperglycemia develops during pregnancy, diabetes is more likely to persist postpartum. For example, in women with fasting glucose levels of 105 to 130 mg/dL, 43 percent were found to be overtly diabetic ([Metzger and colleagues, 1985](#)). When fasting glucose exceeded 130 mg/dL during pregnancy, 86 percent of women became overtly diabetic. Similarly, [Dacus and co-workers \(1994\)](#) and [Greenberg and colleagues \(1995\)](#) have also concluded that insulin therapy during pregnancy, and especially before 24 weeks, is a powerful predictor of diabetes after the pregnancy.

Women with gestational diabetes are at risk not only for postpartum development of type 2 diabetes, but also for cardiovascular complications associated with abnormal serum lipids, and hypertension and abdominal obesity. [Pallardo and colleagues \(1999\)](#) evaluated cardiovascular disease risk factors in 788 women with gestational diabetes 3 to 6 months postpartum. The degree of postpartum glucose intolerance was significantly associated with obesity, plasma triglyceride levels, and hypertension. These results imply that identification of women with gestational diabetes also identifies those with risk factors for cardiovascular disease.

Recurrence of gestational diabetes in subsequent pregnancies was documented in 20 of 30 women reported by [Philipson and Super \(1989\)](#). Obese women were more likely to have impaired glucose intolerance in subsequent pregnancies. Thus, lifestyle behavioral changes, including weight control and exercise between pregnancies, could be a valuable strategy to prevent recurrence of gestational diabetes as well as type 2 diabetes later in life ([Pan, 1997](#)). Interestingly, perinatal outcomes in women with previous gestational diabetes but with normal glucose tolerance tests during a subsequent pregnancy were not improved with regard to birthweight, macrosomia, route of delivery, and neonatal complications ([Danilenko-Dixon and colleagues, 2000](#)).

Low-dose oral contraceptives may be used safely by women with recent gestational diabetes ([Chap. 58, p. 1526](#)). The rate of subsequent diabetes in oral contraceptive users is not significantly different than in those who did not use hormonal contraception ([Kjos and colleagues, 1990a](#)).

GESTATIONAL DIABETES AT PARKLAND HOSPITAL

Universal glucose screening was not performed at Parkland until recently. Selective screening was instead based on many of the risk factors previously enumerated. A standard 50-g oral glucose tolerance test was performed between 24 and 28 weeks without regard to recent meal status. The [National Diabetes Data Group \(1979\)](#) criteria shown in [Table 51-4](#) were used. Women diagnosed to have class A₁ gestational diabetes were seen weekly in a specific clinic designed to provide dietary counseling. Fasting plasma glucose measurements were obtained at each visit. Women without other complications such as hypertension or postterm gestation were permitted to enter spontaneous labor and antepartum testing was not used. Women diagnosed to have class A₂ gestational diabetes were managed as overt diabetics, as described later.

Beginning January 1997, universal screening for gestational diabetes was performed between 24 and 28 weeks using a standard 1-hour, 50-g oral glucose challenge test. All obstetrical management practices previously used during selective screening were continued during universal screening. The practice of universal screening doubled the number of women tested in one year from approximately 4300 to 8200 women. Despite this, the number of women actually diagnosed with gestational diabetes remained unchanged at approximately 225 per year. Importantly, universal screening for gestational diabetes did not increase or decrease obstetrical outcomes attributable to this diagnosis ([Casey and colleagues, 1999](#)).

OVERT DIABETES

Unlike gestational diabetes, it is unquestioned that overt diabetes has a significant impact on pregnancy outcome. Even the embryo, as well as the fetus and the mother, can experience serious complications directly attributable to diabetes. The likelihood of successful outcomes for the fetus-infant and the overtly diabetic mother are related somewhat to the degree of diabetes control, but more importantly, to the intensity of any underlying maternal cardiovascular or renal disease. Therefore, as the alphabetic classification shown in [Table 51-2](#) advances, the likelihood of a good pregnancy outcome lessens.

[Hanson and Persson \(1993\)](#) prospectively chronicled the effects of overt diabetes on pregnancy outcomes in Sweden. Their unique analysis included all deliveries between 1983 and 1985, during which period 491 insulin-dependent women in classes B or more advanced were identified. Their outcomes were compared with 279,000 pregnancies in nondiabetic women and are shown in [Table 51-7](#). Women with diabetic pregnancies experience significantly increased adverse pregnancy outcomes. As shown in [Table 51-8](#), Swedish women in the more advanced classes of overt diabetes increasingly developed preeclampsia. This complication occurred in 54 percent of women with diabetic nephropathy (class F). Similarly, [Sibai and colleagues \(2000\)](#) reported the risk of preeclampsia to be 11 percent in class B, 22 percent in class C, 21 percent in class D, and 36 percent in classes F-R.

FETAL EFFECTS

Improved fetal surveillance, neonatal intensive care, and maternal metabolic control have reduced perinatal losses with overt diabetes to 2 to 4 percent. These rates have seemingly plateaued because the two major causes of fetal death—congenital malformations and "unexplained" fetal death—remain unchanged by medical intervention ([Garner, 1995a](#)).

ABORTION. Several studies have shown that spontaneous abortion is associated with poor glycemic control during the first trimester ([Greene and colleagues, 1989](#); [Mills and associates, 1988b](#)). [Rosenn and colleagues \(1994\)](#) enrolled 215 women with type 1 diabetes for prenatal care before 9 weeks, and 24 percent experienced spontaneous abortions. Only those type 1 diabetic women with initial glycohemoglobin A_{1c} concentrations above 12 percent or persistent preprandial glucose concentrations above 120 mg/dL were at increased risk for abortion.

PRETERM DELIVERY. Overt diabetes antedating pregnancy is a risk factor for preterm birth. [Sibai and co-workers \(2000\)](#) from the Maternal-Fetal Medicine Units Network of the National Institute of Child Health and Development analyzed pregnancy outcomes in 461 women with pregestational diabetes and found that 9 percent of these women spontaneously delivered at 34 weeks or less compared with 4.5 percent of nondiabetic women. Moreover, 7 percent of diabetic women compared with 2 percent of normal women underwent indicated preterm delivery.

MALFORMATIONS. The incidence of major malformations in women with type 1 diabetes is 5 to 10 percent ([Rosenn and co-workers, 1994](#)). These account for almost half of perinatal deaths in diabetic pregnancies. Specific types of anomalies linked to maternal diabetes and their relative incidence are summarized in [Table 51-9](#). Diabetes is not associated with increased risk for fetal chromosomal abnormalities ([Henriques and colleagues, 1991](#)).

It is generally believed that increased severe malformations are the consequence of poorly controlled diabetes both preconceptionally as well as early in pregnancy (see [Chaps. 9](#) and [36](#)). The retrospective study of [Miller and co-workers \(1981\)](#) suggested that women with lower glycosylated hemoglobin values at conception had fewer anomalous fetuses compared with women with abnormally high values. [Lucas and colleagues \(1989\)](#) found that fetal anomalies correlated with high levels of glycosylated hemoglobin as well as diabetic vasculopathy and with duration of disease greater than 10 years. Data from [Mills and colleagues \(1988a\)](#) from the Diabetes in Early Pregnancy Study did not totally corroborate these findings. This investigation enrolled over 600 diabetic women, and it was concluded that a normal glycosylated hemoglobin did not guarantee that diabetes-associated anomalies would be avoided. Conversely, an elevated level did not necessarily indicate an increased risk. Despite this, these investigators observed that women in whom periconceptional glucose control was optimized had 5 percent fetal malformations compared with 9 percent in the group who did not present for care until after organogenesis was complete.

[Schaefer-Graf and associates \(2000\)](#) analyzed the pattern of congenital anomalies in pregnancies complicated by pregestational as well as gestational diabetes. The initial fasting glucose level was significantly higher in pregnancies with fetal malformations. Moreover, those with multiple organ system fetal anomalies had significantly higher initial fasting glucose levels (166 ± 64 mg/dL) compared with pregnancies in which only a single organ system was affected (141 ± 55 mg/dL) or with those with no anomalies (115 ± 38 mg/dL). The most common single-organ system anomalies were cardiac (38 percent), musculoskeletal (15 percent), and central nervous system (10 percent). The frequency of these specific organ system malformations was unrelated to the degree of glycemia.

[Kitzmler and associates \(1991\)](#) tested the effectiveness of intensive periconceptional glycemic management by comparing pregnancy outcomes in 84 women with well-controlled diabetes before conception with 110 diabetics who presented for care between 6 and 30 weeks. Only 1.2 percent of the preconceptionally controlled women had a fetus with a major anomaly compared with 11 percent of those who enrolled late.

ANIMAL STUDIES. Many investigators are conducting animal experiments to elucidate molecular mechanisms by which diabetes and/or hyperglycemia during embryogenesis induces fetal malformations. [Sivan and colleagues \(1996\)](#) and [Wiznitzer and associates \(1996\)](#) have found that the antioxidants vitamin E and lipoic acid, when given to pregnant diabetic rats, prevent fetal malformations. They hypothesize that hyperglycemia induces oxidative free-radical molecules that are embryotoxic and that antioxidants inhibit this process. Alternatively, [Reece and colleagues \(1996\)](#) demonstrated that hyperglycemia induces reduced specific gene activity, producing a state of arachidonic acid deficiency causally related to the development of neural-tube defects in rats.

"UNEXPLAINED" FETAL DEMISE. Stillbirths without identifiable cause are a phenomenon peculiar to pregnancies complicated by overt diabetes. They are declared "unexplained" because no factors such as obvious placental insufficiency, abruption, fetal growth restriction, or oligohydramnios are apparent. These infants are typically large for age and die before labor, usually at about 35 weeks or later ([Garner, 1995b](#)). The incidence of unexplained stillbirths in the Swedish study shown in [Table 51-7](#) was 1 percent.

Recent investigations using cordocentesis have provided new insights into acid-base metabolism in fetuses of diabetic mothers. [Salvesen and colleagues \(1992, 1993\)](#) reported decreased fetal pH, and increased PCO₂, lactate, and erythropoietin in diabetic pregnancies. Such findings lend credence to the long-held hypothesis that hyperglycemia-mediated chronic aberrations in transport of oxygen and fetal metabolites may account for these unexplained fetal deaths ([Pedersen, 1977](#)).

Between 1984 and 1993, [Richey and co-workers \(1995\)](#) were at the bedside in two pregnancies at Parkland Hospital where "unexplained" fetal deaths were seemingly in progress. In both of these rare clinical instances, the fetus was macrosomic and there was excessive amniotic fluid. Both fetuses were acidemic before labor and both placentae were hydropic due to edema of the chorionic villi. These features were linked to maternal hyperglycemia, and it was hypothesized that osmotically induced villous edema led to impaired fetal oxygen transport.

Explicable stillbirths due to placental insufficiency also occur with increased frequency in women with overt diabetes, usually in association with severe preeclampsia. This, in turn, is increased in women with advanced diabetes and vascular complications. Similarly, ketoacidosis can cause fetal death.

HYDRAMNIOS. Although diabetic pregnancies are often complicated by hydramnios, the cause is unclear. A likely, although unproven explanation is fetal polyuria resulting from fetal hyperglycemia ([Chap. 31, p. 819](#)). [Dashe and co-authors \(2000\)](#), in a study performed at Parkland Hospital, found that the amniotic fluid index parallels the amniotic fluid glucose level among women with diabetes. This finding suggests that the hydramnios associated with diabetes is a result of increased amniotic fluid glucose concentration.

NEONATAL EFFECTS

Before tests of fetal health and maturity became available, preterm delivery was deliberately effected to avoid unexplained fetal deaths. Although this practice has been abandoned, there is still an increased frequency of preterm delivery in women with diabetes. As shown in [Table 51-7](#), [Hanson and Persson \(1993\)](#) reported that 25 percent of Swedish women with classes B to F diabetes were delivered at 36 weeks or less. Most preterm births are associated with advanced diabetes and superimposed preeclampsia.

Modern neonatal care has largely eliminated neonatal deaths due to immaturity. [Cnattingius and colleagues \(1994\)](#) reported only one infant death due to immaturity in 914 singleton births to B to F diabetic women. However, neonatal morbidity due to preterm birth continues to be a serious consequence. Indeed, some of the morbidities in these infants of diabetic women are considered to be uniquely related to aberrations in maternal glucose metabolism.

RESPIRATORY DISTRESS. Conventional obstetrical teaching, at least until the late 1980s, generally held that fetal lung maturation was delayed in diabetic pregnancies, thus placing these infants at increased risk for respiratory distress ([Gluck and Kulovich, 1973](#)). Subsequent observations have challenged the concept of diabetes-altered fetal lung function. Gestational age, rather than overt diabetes, is likely the most significant factor governing the development of respiratory distress ([Berkowitz and colleagues, 1996](#); [Fadel and associates, 1988](#); [Kjos and colleagues, 1990b](#)).

HYPOGLYCEMIA. A rapid decrease in plasma glucose concentration after delivery is characteristic of the infant of a diabetic mother. This is attributed to hyperplasia of the fetal β -islet cells induced by chronic maternal hyperglycemia. Prompt recognition and treatment of the hypoglycemic infant has minimized sequelae.

HYPOCALCEMIA. Defined as serum calcium less than 7 mg/dL, hypocalcemia is one of the major metabolic derangements in infants of diabetic mothers. Its cause has not been explained. Theories include aberrations in magnesium-calcium economy unique to diabetic pregnancy, asphyxia, and preterm birth ([Cruikshank and co-workers, 1980](#)). [DeMarini and colleagues \(1994\)](#) randomized 137 pregnant women with insulin-dependent diabetes to strict glucose control versus customary control to test the effect of maternal glucose levels on neonatal hypocalcemia. Almost a third of infants in the customary control group developed hypocalcemia whereas this developed in only 18 percent of infants in the strict glucose control group. Gestational age and preeclampsia were also implicated.

HYPERBILIRUBINEMIA. The pathogenesis of hyperbilirubinemia in infants of diabetic mothers is uncertain. Factors implicated have included preterm birth and polycythemia with hemolysis. Venous hematocrits of 65 to 70 vol percent have been observed in as many as 40 percent of these infants ([Salvesen and associates, 1992](#)). Renal vein thrombosis has also been reported to result from polycythemia.

CARDIAC HYPERTROPHY. Infants of diabetic pregnancies may have hypertrophic cardiomyopathy that occasionally progresses to congestive heart failure ([Gandhi and co-authors, 1995](#); [Reller and Kaplan, 1988](#)). These infants are typically macrosomic and fetal hyperinsulinemia has been implicated in the pathogenesis of heart disease. [Way \(1979\)](#) reported that the cardiomyopathy in infants of diabetic mothers generally disappears by 6 months of age.

LONG-TERM COGNITIVE DEVELOPMENT. [Rizzo and colleagues \(1995\)](#) used multiple tests of intelligence and psychomotor development to assess 196 children of diabetic women up to 9 years of age. They concluded that maternal diabetes had a negligible impact on cognitive development.

INHERITANCE OF DIABETES. Offspring of women with overt diabetes have a low risk of developing insulin-dependent diabetes, with surveys suggesting an incidence of 1 to 3 percent ([Garner, 1995a](#)). The risk is 6 percent if only the father has overt diabetes. If both parents have type 1 diabetes, the risk is 20 percent. [McKinney and colleagues \(1999\)](#) studied 196 children with insulin-dependent diabetes and found older maternal age and maternal type 1 diabetes to be important risk factors.

ALTERED FETAL GROWTH. The incidence of macrosomia rises significantly when mean maternal blood glucose concentrations exceed 130 mg/dL ([Willman and co-authors, 1986](#)). Some authors have objected to classification of these infants as either "macrosomic" or "nonmacrosomic," because this ignores the observation that virtually all are *growth promoted* ([Bradley and associates, 1988](#)). This is discussed in [Chapter 29 \(p. 744\)](#). As shown in [Figure 51-2](#), the birthweight distribution of infants of diabetic mothers is skewed toward consistently heavier birthweights compared with normal pregnancies.

When in gestation macrosomia commences is of some interest. [Landon and co-workers \(1989\)](#) performed serial ultrasound examinations during the third trimester in 79 women with diabetes and observed that excessive fetal abdominal circumference growth was detectable by 32 weeks ([Fig. 51-3](#)), suggesting that excessive weight accrues primarily during the third trimester. [Keller and colleagues \(1990\)](#), however, reported that some macrosomic fetuses can be recognized before 24 weeks. Similarly, [Rey and co-authors \(1999\)](#) and [Raychaudhuri and Maresh \(2000\)](#) concluded that macrosomia was determined primarily by early pregnancy diabetes control.

MATERNAL EFFECTS

Diabetes and pregnancy interact significantly such that maternal welfare can be seriously jeopardized. With the possible exception of diabetic retinopathy, however, the long-term course of diabetes is not affected by pregnancy.

Maternal deaths have become rare in women with diabetes, although as emphasized by [Cousins \(1987\)](#), mortality is increased 10-fold, most often as a result of ketoacidosis, underlying hypertension, preeclampsia, and pyelonephritis. The rare woman with coronary artery disease (class H) is at particular risk of dying as a result of pregnancy ([Chap. 44, p. 1202](#)). [Pombar and colleagues \(1995\)](#) reviewed 17 women with class H diabetes and only half survived pregnancy.

DIABETIC NEPHROPATHY. As discussed in [Chapter 47 \(p. 1263\)](#), diabetic nephropathy is the leading cause of end-stage renal disease in the United States ([American Diabetes Association, 1999b](#)). The incidence of renal failure is nearly 30 percent with type 1 diabetes, and ranges from 4 to 20 percent in those with type 2 disease. Importantly, the incidence of nephropathy in individuals with type 1 disease declined during the 1980s, probably as a result of improved glucose control ([Bojestig and colleagues, 1994](#)). Indeed, [Krolewski and associates \(1995\)](#) have identified that subclinical diabetic nephropathy increases abruptly when hemoglobin A_{1c} values exceed 10 percent. The natural history of clinically detectable nephropathy in type 1 disease begins with microalbuminuria—30 to 300 mg of albumin per 24 hours. This may manifest as early as 5 years after the onset of diabetes ([Nathan, 1993](#)). After another 5 to 10 years, overt proteinuria—more than 300 mg of albumin per 24 hours—develops in patients destined to have end-stage renal disease. Hypertension invariably develops during this period, and renal failure ensues typically in the next 5 to 10 years.

The incidence of class F diabetes in recent large reports is approximately 5 percent ([Hanson and Persson, 1993](#); [Siddiqi and associates, 1991](#)). With nephropathy, preeclampsia and indicated preterm delivery increase substantially. As shown in [Table 51-8](#), approximately half of women in class F develop preeclampsia. [Combs and associates \(1993a\)](#) measured urinary protein excretion before 20 weeks in 311 diabetic women and preeclampsia developed in 38 percent with proteinuria exceeding 500 mg/day. Women with microproteinuria—defined as 190 to 500 mg/day—also had an increased risk of preeclampsia. Conversely, [How and colleagues \(2000\)](#) in an analysis of 460 women with classes B through F-R diabetes, did not find an increased rate of preeclampsia in women with 30 to 500 mg of proteinuria per day. Chronic hypertension with diabetic nephropathy increased the risk of preeclampsia to 60 percent. [Gordon and associates \(1996\)](#) have reported 100 percent perinatal survival in 46 pregnancies complicated by class F diabetes. Plasma creatinine values of 1.5 mg/dL or greater and protein excretion of 3 g per 24 hours or greater before 20 weeks were predictive for preeclampsia.

[Chaturvedi and associates \(1995\)](#) studied the relationship between pregnancy and long-term maternal complications in 1358 European women with type 1 diabetes, of whom 582 had been pregnant. The incidence of either microalbuminuria or macroalbuminuria was not increased in women with prior pregnancies compared with nulliparas. They concluded that pregnancy did not exacerbate or modify diabetic nephropathy. [Miodovnik and colleagues \(1996\)](#) found that a fourth of 46 class F diabetic women developed end-stage renal failure at a mean of 6 years after pregnancy.

DIABETIC RETINOPATHY. Retinal vascular disease is a highly specific complication of both type 1 and type 2 diabetes. The prevalence of retinopathy is related to duration of diabetes. After 20 years of diabetes, nearly all patients with type 1 diabetes have some degree of retinopathy and more than 60 percent of patients with type 2 diabetes have some degree of retinopathy ([American Diabetes Association, 1999b](#)). Diabetic retinopathy is now the most important cause of visual impairment in the United States in persons under 60 years of age ([Clark and Lee, 1995](#)).

The first and most common visible lesions are small microaneurysms followed by blot hemorrhages when erythrocytes escape from the aneurysms. These areas leak serous fluid that forms hard exudates. These features are termed *benign or background or nonproliferative retinopathy*. These findings would place a pregnant woman into class D ([Table 51-2](#)) regardless of the duration of diabetes. With increasingly severe retinopathy, the abnormal vessels of background eye disease become occluded, leading to retinal ischemia with infarctions that appear as *cotton wool exudates*. These are considered *preproliferative retinopathy*. In response to ischemia, there is neovascularization on the retinal surface ([Fig. 51-4A](#)) and out into the vitreous cavity, and these obscure vision when there is hemorrhage. Laser photocoagulation ([Fig. 51-4B](#)) before these vessels hemorrhage reduces by half the rate of progression of visual loss and blindness and is indicated during pregnancy for affected women. [Siddiqi and colleagues \(1991\)](#) reported that almost a third of 175 insulin-dependent pregnant women examined by 10 weeks had background retinal changes (class D) or proliferative retinopathy (class R). [Puza and Malee \(1996\)](#) reviewed routine ophthalmological surveillance during pregnancy.

There is continuing debate about the effect of pregnancy on proliferative retinopathy ([Garner, 1995a](#)). This complication is the one exception in which pregnancy is thought to possibly exert a detrimental effect on the long-term outcome of diabetes. [Klein and co-workers \(1990\)](#) concluded that pregnancy worsened proliferative retinopathy, but [Chaturvedi and co-authors \(1995\)](#) found equivalent prevalence of both background and proliferative retinopathy in women with prior pregnancies compared with nulliparous women. Most authors agree that laser photocoagulation and good glycemic control during pregnancy minimize the potential for deleterious effects of pregnancy ([Garner, 1995a](#)). There are case reports that link sudden institution of rigorous metabolic control during pregnancy to acute worsening of retinopathy ([Dahl-Jorgensen and colleagues, 1985](#); [Van Ballegooie and associates, 1984](#)). [Wang and co-workers \(1993\)](#) have observed that although retinopathy

worsened during the critical months of rigorous glucose control, in the longer term, the rate of deterioration of eye disease was slowed. [Lauszus and colleagues \(1998\)](#) reported that proliferative retinopathy, in the absence of nephropathy, did not endanger the fetus or newborn infant. In contrast, [McElvy and colleagues \(2000\)](#) found that a fourth of 253 women with retinopathy at the beginning of their pregnancies suffered progression of eye disease during pregnancy despite intensive glucose control. Moreover, progression of retinopathy was associated with reduced fetal weight.

In a preliminary report, [Kitzmilller and colleagues \(1999\)](#) implicated insulin lispro in the development of proliferative retinopathy during pregnancy. Conversely, [Buchbinder and associates \(2000\)](#), in a study of 13 pregnant women treated with insulin lispro, found no evidence that such therapy was linked to the development or progression of diabetic retinopathy.

DIABETIC NEUROPATHY. Although uncommon, some pregnant women will demonstrate peripheral symmetrical sensorimotor neuropathy due to diabetes. Another form, **diabetic gastropathy**, is very troublesome in pregnancy because it causes nausea and vomiting, nutritional problems, and difficulty with glucose control. Treatment with metoclopramide and H₂-receptor antagonists is sometimes successful.

PREECLAMPSIA. Hypertension induced or exacerbated by pregnancy is the major complication that most often forces preterm delivery in diabetic women. According to [Garner \(1995a\)](#), the perinatal mortality rate is increased 20-fold for preeclamptic diabetic women compared with those who are normotensive. Especial risk factors for preeclampsia include any vascular complications, preexisting proteinuria, and/or chronic hypertension. Interestingly, the occurrence of preeclampsia does not seem to be related to glucose control ([Garner and co-authors, 1990](#)). Preeclampsia is discussed in [Chapter 24](#).

KETOACIDOSIS. Although ketoacidosis affects only about 1 percent of diabetic pregnancies, it remains one of the most serious complications ([Garner, 1995a](#)). Diabetic ketoacidosis may occur as a result of hyperemesis gravidarum, use of β -sympathomimetic drugs for tocolysis, infections, and use of corticosteroids to induce fetal lung maturation. Fetal loss is about 20 percent with ketoacidosis.

[Kent and colleagues \(1994\)](#) found that only half of young women with recurrent ketoacidosis had successful pregnancies compared with 95 percent of women without ketoacidosis. A prominent factor implicated in recurrent ketoacidosis was noncompliance. Indeed, ketoacidosis and poor patient compliance have long been considered prognostically bad signs in pregnancy ([Pedersen and colleagues, 1974](#)).

INFECTIONS. According to [Stamler and co-authors \(1990\)](#), approximately 80 percent of insulin-dependent diabetics develop at least one episode of infection during pregnancy compared with 25 percent in nondiabetic women. Common infections include candida vulvovaginitis, urinary infections, puerperal pelvic infections, and respiratory tract infections. [Cousins \(1987\)](#) observed that antepartum pyelonephritis developed in 4 percent of women with type 1 diabetes compared with 1 percent in nondiabetics. They also reported that renal infection was associated with increased preterm delivery. Fortunately, these latter infections can be minimized by screening for asymptomatic bacteriuria ([Chap. 47, p. 1253](#)).

MANAGEMENT

The goals of management are tailored somewhat uniquely for pregnant women. Management preferably should begin before pregnancy and include specific goals during each trimester.

PRECONCEPTION. To prevent early pregnancy loss as well as congenital malformations in infants of diabetic mothers, optimal medical care and patient education are recommended before conception ([American Diabetes Association, 1999a](#)). This is also discussed in [Chapter 9](#). Unfortunately, unplanned pregnancies, thus preempting preconceptional care, continue to occur in approximately 60 percent of women with diabetes ([Holing and co-authors, 1998](#)). Thus, diabetic women begin pregnancy with suboptimal glucose control ([Casele and Laifer, 1998](#)). The [American Diabetes Association \(1999a\)](#) has defined optimal preconceptional glucose control using insulin to include self-monitored preprandial glucose levels of 70 to 100 mg/dL and postprandial values of less than 140 mg/dL and less than 120 mg/dL at 1 and 2 hours, respectively. Hemoglobin A₁ or A_{1c} measurement, which expresses an average of circulating glucose for the past 4 to 8 weeks, is useful to assess early metabolic control. Optimal preconceptional glycated hemoglobin values have been defined as those within or near the upper limit of normal for a specific laboratory or within three standard deviations of the normal mean ([American Diabetes Association, 1999a](#)). The most significant risk for malformations is with levels exceeding 10 percent ([American College of Obstetricians and Gynecologists, 1994](#)). Folate, 400 ug/day, given periconceptually and during early pregnancy, decreases the risk of neural-tube defects ([Milunsky and co-workers, 1989](#)).

FIRST TRIMESTER. Careful monitoring of glucose control is essential to management. For this reason, many clinicians hospitalize these women during early pregnancy to institute an individualized glucose control program and to provide education concerning the ensuing months of pregnancy. It also provides an opportunity to assess the extent of vascular complications of diabetes and to precisely establish gestational age.

Maternal glycemic control can usually be achieved with **multiple daily insulin injections** and adjustment of dietary intake. Oral hypoglycemic agents are not used because they may cause fetal hyperinsulinemia. [Piacquadio and colleagues \(1991\)](#) demonstrated increased rates of congenital malformations in infants of Mexican-American women treated during early pregnancy with oral hypoglycemic drugs.

Subcutaneous insulin infusion by a calibrated pump may be used during pregnancy. The pump has both advantages and disadvantages, and as emphasized by [Kitzmilller and associates \(1985\)](#) and [Leveno and colleagues \(1988\)](#), any salutary pregnancy effects have yet to be determined. The risk of nocturnal hypoglycemia is increased during pregnancy and, therefore, great care should be taken in selecting patients for this therapy ([American College of Obstetricians and Gynecologists, 1994](#)).

The goals of self-monitored capillary blood glucose control recommended during pregnancy are shown in [Table 51-10](#). Self-monitoring of capillary glucose levels using glucometers is strongly recommended as this involves the woman in her own care. [Campbell and co-workers \(1994\)](#) measured maternal glucose responses to standardized meals throughout normal pregnancies to better characterize plasma glucose goals for management of diabetic women ([Fig. 51-5](#)). These results correspond remarkably to the recommendations shown in [Table 51-10](#).

New technology is under development that offers the future possibility of noninvasive glucose monitoring. Such an automatic and painless means to obtain blood glucose information would undoubtedly greatly facilitate patient compliance with glucose control during pregnancy. [Tamada and colleagues \(1999\)](#) reported clinical results with such a monitoring device (Cygnus, Inc., Redwood City, California). The device extracts glucose through the skin using electrical potentials—a process known as iontophoresis. It then measures glucose concentrations in the extracted sample. The device provides up to three glucose readings per hour and causes only transient mild skin irritation at the sensor site. [Tamada and colleagues \(1999\)](#) found close agreement between these noninvasive glucose measurements and those obtained using repeated fingersticks to obtain blood samples.

The Committee on Maternal Nutrition of the National Research Council has recommended a total caloric intake of 30 to 35 kcal/kg of ideal body weight, given as three meals and three snacks daily ([Garner, 1995a](#)). An ideal dietary composition is 55 percent carbohydrate, 20 percent protein, and 25 percent fat with less than 10 percent saturated fat. There are no studies to support or refute these guidelines. Obese women may be managed with lower caloric intake as long as weight loss and ketonuria are avoided.

Although achieving euglycemia based on normal pregnancy blood glucose values is the goal in management of overtly diabetic women, achieving this goal is not always possible. Thus, individualized programs are often necessary to avoid both excessive hyperglycemia as well as frequent episodes of hypoglycemia. Diabetes tends to be unstable in the first trimester, followed by a stable period, and then by an increase in insulin requirement from about 24 weeks ([Steel and co-workers, 1994](#)). This rise is due to the increased production of pregnancy hormones, which are insulin-antagonists ([Chap. 6, p. 113](#) and [Chap. 8, p. 174](#)). The absolute increase in mean insulin requirement was 52 units in 237 women with type 1 diabetes, but there was wide variation ([Steel and associates, 1994](#)). The magnitude of increase was directly related to maternal weight and inversely related to diabetes duration.

[Rosenn and colleagues \(1995\)](#) assessed the impact of maternal hypoglycemia in 84 pregnant women with overt diabetes. Clinically significant hypoglycemia with glucometer values less than 35 mg/dL were documented in 70 percent of the women with a peak incidence between 10 and 15 weeks. Almost a fourth of these 84 women experienced unconsciousness and 15 percent developed seizures as a result of hypoglycemia. These investigators recommended caution in attempting euglycemia in women with recurrent episodes of hypoglycemia.

We have reported that good pregnancy outcomes can be achieved in women with mean preprandial plasma glucose values up to 143 mg/dL ([Leveno and associates, 1979](#)). Interestingly, the [Diabetes Control and Complications Trial Research Group \(1993\)](#) found that similar glucose values—intensive control was defined as mean values less than 155 mg/dL—delayed and slowed diabetic retinopathy, nephropathy, and neuropathy in nonpregnant patients. Thus, overtly diabetic women with

glucose values considerably above those defined as normal both during and after pregnancy can expect good outcomes.

SECOND TRIMESTER. As discussed in [Chapter 36](#), maternal serum alpha-fetoprotein concentration at 16 to 20 weeks is used in association with targeted ultrasound at 18 to 20 weeks in an attempt to detect neural-tube defects and other anomalies ([American College of Obstetricians and Gynecologists, 1994](#)). Maternal serum alpha-fetoprotein values may be lower in diabetic pregnancies, and interpretation is altered accordingly ([Martin and associates, 1990](#)). [Albert and colleagues \(1996\)](#) used sonography to identify 72 percent of 29 fetal anomalies in 289 diabetic pregnancies.

THIRD TRIMESTER. Weekly visits to monitor glucose control and to evaluate for preeclampsia are a typical recommendation. Serial ultrasonography at 3- to 4-week intervals is performed to evaluate both excessive and insufficient fetal growth as well as amniotic fluid volume. A program of fetal surveillance using some of the antepartum tests described in [Chapter 40](#) is usually begun between 26 and 32 weeks depending on clinical risk factors for fetal death ([Lagrew and co-workers, 1993](#)). According to the [American College of Obstetricians and Gynecologists \(1999\)](#), antepartum testing is recommended at least weekly. Some testing protocols in women with overt diabetes stipulate at least twice weekly testing ([Kjos and colleagues, 1995](#)).

Hospitalization is recommended for women whose diabetes is poorly controlled and for those with hypertension. Because of increased hospitalization costs, as well as reluctance of third-party payers, routine antepartum hospitalization for the overt diabetic woman is no longer commonly practiced. With a predominately indigent population at Parkland Hospital, conversion to outpatient management was associated with a doubling of the perinatal mortality rate. This doubling of mortality was due solely to unexplained fetal deaths that typically occurred at about 36 weeks. Consequently, most women with insulin-dependent diabetes currently accept hospitalization from 34 weeks until delivery.

Anecdotal reports of decreased insulin requirement during the last weeks of pregnancy have long been considered a warning sign of uteroplacental insufficiency. There is little objective evidence to support this concern. [Berria and colleagues \(2000\)](#) observed that decreased insulin requirement after 35 weeks was encountered in 5 percent of overtly diabetic women, and this was not associated with increased perinatal risks.

DELIVERY. Ideally, delivery of the diabetic woman should be accomplished near term. When the gestational age is certain, tests to determine fetal pulmonary maturation are not done, and delivery is planned after 38 completed weeks. For others, the lecithin-sphingomyelin ratio is measured at about 38 weeks and, if 2.0 or greater, delivery is effected. If severe hypertension develops, delivery is carried out even though the ratio is less than 2.0.

According to the [American College of Obstetricians and Gynecologists \(1994\)](#), if preterm labor occurs, tocolytic therapy with β -sympathomimetic drugs is best avoided in women with diabetes. These medications may significantly worsen maternal glucose control, causing ketoacidosis. Similarly, they advise caution in the use of corticosteroids to promote lung maturation.

In the overtly diabetic woman within class B or C White classification, cesarean delivery has commonly been used to avoid traumatic birth of a large infant at or near term. In women with more advanced diabetes, especially those with vascular disease, the reduced likelihood of successfully inducing labor remote from term has also contributed appreciably to an increased cesarean rate. Labor induction may be attempted when the fetus is not excessively large, and the cervix is considered favorable ([Chap. 20](#)). In the reports cited earlier with low perinatal mortality, the cesarean rate was more than 50 percent in Melbourne ([Martin and colleagues, 1987](#)), 55 percent in Los Angeles ([Gabbe and colleagues, 1977](#)), 69 percent in Boston ([Kitzmler and colleagues, 1978](#)), 70 percent in a midwestern multicenter study ([Schneider and co-workers, 1980](#)), and 81 percent in Dallas ([Leveno and associates, 1979](#)). At Parkland Hospital, the cesarean delivery rate for overtly diabetic women has remained at about 80 percent for the past 20 years.

It is important to considerably reduce or delete the dose of long-acting insulin given on the day of delivery. Regular insulin should be used to meet most or all of the insulin needs of the mother at this time, because insulin requirements typically drop markedly after delivery. We have found that constant insulin infusion by calibrated pump is most satisfactory ([Table 51-11](#)). During labor and after either cesarean or vaginal delivery, the woman should be hydrated adequately intravenously as well as given glucose in sufficient amounts to maintain normoglycemia. Capillary or plasma glucose levels should be checked frequently, and regular insulin administered accordingly. It is not unusual for the woman to require virtually no insulin for the first 24 hours or so and then for insulin requirements to fluctuate markedly during the next few days. Infection must be promptly detected and treated.

CONTRACEPTION

There is no single contraceptive method appropriate for all women with diabetes (see also [Chaps. 58](#) and [59](#)). Diabetes carries a risk of vascular disease, and the estrogens in oral contraceptives statistically increase the risk of thromboembolism, stroke, and myocardial infarction. Although many clinicians are reluctant to prescribe oral contraceptives for overtly diabetic women, recent investigations on their safety have yielded conflicting results. [Lidegaard \(1995\)](#) cautioned against use of oral contraceptives because of increased risk of strokes, whereas [Petersen and colleagues \(1994\)](#) concluded that contemporaneous low-dose pills did not increase cardiovascular risks in these women. The [American College of Obstetricians and Gynecologists \(1994\)](#) advises that use of low-dose oral contraceptives should probably be restricted to women without vasculopathy or additional risk factors such as a strong history of ischemic heart disease. The lowest dose of estrogen and progesterone should be prescribed. Low-dose combination oral contraceptive preparations do not increase the risk of type 2 diabetes in postpartum women with recent gestational diabetes ([Kjos and colleagues, 1990a](#)).

Progestin-only oral or parenteral contraceptives may also be used because of minimal effects on carbohydrate metabolism. Unfortunately, fear of litigation has largely removed the *progestin implant* system (Norplant) from current use.

Physicians have also been reluctant to recommend intrauterine devices in diabetic women, primarily because of a possible increased risk of pelvic infections. The Food and Drug Administration package insert for the Copper T 380A IUD (Paragard) lists diabetes as one of the contraindications. However, [Kjos and colleagues \(1994\)](#), based on their investigations and review of the literature, concluded that diabetic women are often ideal candidates for intrauterine devices.

For all of the reasons cited, many overtly diabetic women elect puerperal sterilization, and this should be made readily available.

TABLE 51-1. Some General Characteristics of Insulin-dependent (Type 1) and Noninsulin-dependent (Type 2) Diabetes Mellitus

Characteristics	Type 1 (Insulin Dependent)	Type 2 (Noninsulin Dependent)
Genetic locus ^a	Chromosome 6	Unknown
Age at onset	Usually < 40 ^b	> 40
Habitus	Normal to wasted	Obese
Plasma insulin	Low to absent	Normal to high
Plasma glucagon	High, suppressible	High, resistant
Acute complication	Ketoacidosis	Hyperosmolar coma
Insulin therapy	Responsive	Responsive/resistant
Sulfonylurea	Unresponsive	Responsive

^a Both are polygenic.

^b Most cases appear before age 20.

From Foster (1998), with permission.

TABLE 51-2. Classification of Diabetes Complicating Pregnancy

Class	Onset	Fasting Plasma Glucose	2-hour Postprandial Glucose	Therapy
A ₁	Gestational	< 105 mg/dL	< 120 mg/dL	Diet
A ₂	Gestational	> 105 mg/dL	> 120 mg/dL	Insulin
Class	Age of Onset (yr)	Duration (yr)	Vascular Disease	Therapy
B	Over 20	< 10	None	Insulin
C	10-19	10-19	None	Insulin
D	Before 10	> 20	Benign retinopathy	Insulin
F	Any	Any	Nephropathy ^a	Insulin
R	Any	Any	Proliferative retinopathy	Insulin
H	Any	Any	Heart	Insulin

^a When diagnosed during pregnancy: 500 mg or more proteinuria per 24 hours measured before 20 weeks' gestation.

From American College of Obstetricians and Gynecologists (1986).

**TABLE 51-3. Fourth International Workshop-Conference on Gestational Diabetes:
Recommended Screening Strategy Based on Risk Assessment for Detecting
Gestational Diabetes (GDM)**

Low Risk

Blood glucose testing not routinely required if all of the following characteristics are present:

Member of an ethnic group with a low prevalence of gestational diabetes

No known diabetes in first-degree relatives

Age less than 25 years

Weight normal before pregnancy

No history of abnormal glucose metabolism

No history of poor obstetrical outcome

Average Risk

Perform blood glucose testing at 24-28 weeks using one of the following:

Average risk—women of Hispanic, African, Native American, South or East Asian origins

High risk—women with marked obesity, strong family history of type 2 diabetes, prior gestational diabetes, or glucosuria

High Risk

Perform blood glucose testing as soon as feasible: If gestational diabetes is not diagnosed, blood glucose testing should be repeated at 24-28 weeks or at any time a patient has symptoms or signs suggestive of hyperglycemia

52. Connective-Tissue Disorders

Connective-tissue disorders, also referred to as collagen-vascular disorders, are a group of diseases that are not organ specific and thus cause generalized clinical findings. They are principally characterized by connective-tissue abnormalities that are immunopathologically mediated as the consequence of a variety of autoantibodies. These are also called *immune-complex disease* because many are mediated by deposition of immune complexes in specific organ or tissue sites, including the glomerulus and blood vessel walls. Some disorders that are characterized by sterile inflammation, especially of the skin, joints, blood vessels, and kidney, are referred to as *rheumatic diseases*. For inexplicable reasons, many of these rheumatic diseases mostly affect women.

Another major category of connective-tissue diseases includes inherited disorders of bone, skin, cartilage, blood vessels, and basement membranes. Examples of these are Marfan syndrome, osteogenesis imperfecta, and Ehlers-Danlos syndrome.

IMMUNE-MEDIATED CONNECTIVE-TISSUE DISEASES

Although the pathogenesis for all of these disorders has not been elucidated, they can be separated into those clearly associated with autoantibody formation and those without evidence of the rheumatoid factor, the so-called seronegative spondyloarthropathies (Hahn, 1997). The former category includes systemic lupus erythematosus, rheumatoid arthritis, Sjogren syndrome, progressive systemic sclerosis (scleroderma), mixed-connective tissue disease, dermatomyositis, polymyositis, and a variety of vasculitis syndromes. The seronegative spondyloarthropathies all are strongly associated with the presence of the HLA-B27 antigen but not the rheumatoid factor (Benjamin and Parkham, 1992; Moll, 1994). These include ankylosing spondylitis, psoriatic arthritis, Reiter disease, and likely the arthritis syndromes associated with ulcerative colitis and Crohn disease.

Because renal involvement is common with many of these syndromes, and because pregnancy is adversely affected by glomerulopathic syndromes, a search for co-existing renal involvement is paramount to evaluation. Hypertension likewise is common, and exacerbation during pregnancy frequently forces early delivery. In some of these immune-mediated diseases, *antiphospholipid antibodies* are formed that can cause injury to maternal vasculature and to the placenta. Conversely, they can arise de novo and do similar damage.

IMMUNOLOGICAL ASPECTS. The immune system basically protects cells, tissues, and organs perceived as *self* and attacks and destroys foreign or nonself antigenic material by the production of antibodies directed against foreign or *nonself* antigens. For some as yet unknown reason, the immune system may be stimulated to begin producing antibodies directed against self or normal tissues. These "misdirected" antibodies are called **autoantibodies** and are increased in many connective-tissue disorders. The stimulus responsible for their production is unknown, but a variety of inciting reasons are suspected that include bacterial or viral injury to genetically susceptible tissues.

Autoantibodies induce tissue destruction in susceptible tissues by at least two mechanisms, singly or in combination. The **cytotoxic mechanism** involves direct antibody attachment to a specific surface antigen, which results in cell injury or destruction. The **immune complex mechanism** results in tissue damage when the antigen-antibody complex itself attaches to a susceptible tissue. The complex is then believed to incite a complement response or "cascade," which results in the release of chemotactic substances that attract a variety of polymorphonuclear cells. The combination of any or all of the immune complexes, chemotactic substances, and leukocytes, either intra- or extracellularly, causes release of a variety of substances such as cytokines and lysosomal enzymes that attack tissues.

Both normal and abnormal immune responses are mediated through thymus-derived (T) and bone-marrow derived (B) lymphocyte production. Principal mediators are T, B, and large lymphocytes as well as monocytes-macrophages. *Cytokines* are soluble proteins that are stimulated by immune system activation. Such activation is regulated by the ordered production of a myriad of cytokines that control gene activation and functional cell surface molecule expression (Winchester, 1992). The large number of lymphocyte surface molecules is classified by their *cluster differentiation (CD)* antigens. Probably the best known of these is CD4, which is a 59-kd member of the immunoglobulin G superfamily. It is the receptor for the human immunodeficiency virus envelope gp120.

The **major histocompatibility complex (MHC)** is a series of 40 to 50 genes located on the short arm of chromosome 6, and it is known as the **human leukocyte-associated (HLA)** complex. These genetic loci code for distinct cell-surface glycoproteins, including transplantation antigens, and they are involved in self and nonself recognition. Class I antigens include HLA¹-A, -B, and -C. Class II antigens include HLA-DR, -DQ, and -DP. Through a variety of complex interactions, including T- and B-cell stimulation and interaction with immunoglobulins and the complement system, nonself antigens or, in the abnormal state, self antigens (normal tissue), are destroyed.

IMMUNE-MEDIATED DISEASE AND PREGNANCY. Very few immune disorders are definitely proven to arise only during pregnancy. Maternal isoimmunization from fetal red cell or platelet antigens is the most common (Chap. 39, p. 1057). Some theories of the cause of preeclampsia-eclampsia implicate an immunological basis (Chap. 24, p. 569). Some cases of recurrent abortion are also attributed to immunological causes (Chap. 33, p. 859).

There are some pregnancy-induced immunological alterations that potentially modulate connective-tissue disorders (Chap. 8, p. 179). They include depression of cell-mediated immunity and some antibody responses, increased immunoglobulin-secreting cells, decreased inflammatory response, abnormal lymphocyte stimulation, decreased T/B lymphocyte ratio, and increased levels of circulating immune complexes. Complement levels during pregnancy normally may be elevated, and there may be low-grade activation of the classical pathway. Serum levels of autoantibodies are not increased appreciably during normal pregnancy (Kutteh, 1996).

Although it is generally thought that these immunological changes have negligible effects on immune-mediated collagen-vascular disorders, the effects of large amounts of estrogen, progesterone, and prolactin cannot be ignored. For example, estrogens upregulate and androgens downregulate T-cell response, and a number of cytokines are regulated by sex hormones (Lockshin and Druzin, 1995). Also, recall that autoimmune rheumatic diseases mostly affect women. Lockshin (1998) postulates a modulating effect of hormones rather than a causative role.

SYSTEMIC LUPUS ERYTHEMATOSUS

Lupus is a disease(s) of unknown etiology in which tissues and cells are damaged by autoantibodies and immune complexes directed at one or more components of cell nuclei (Mills, 1994). Almost 90 percent of cases are in women, and its prevalence in childbearing-aged women is about 1 in 500 (Lockshin and Sammaritano, 2000). The 10- and 20-year survival rates are 75 and 50 percent (Jacobsen and colleagues, 1999). Infection, lupus flares, end-organ failure, and cardiovascular disease account for most deaths.

Some autoantibodies produced in patients with lupus are shown in Table 52-1. A number of genetic, environmental, and sex hormonal factors result in abnormal hormonal and cellular immune responses and inadequate clearing of antibodies and immune complexes. Genetic influences are indicated by a higher concordance with monozygotic compared with dizygotic twins and a 10 percent frequency in patients with one affected family member. The relative risk of disease is increased threefold if HLA-DR2 or -DR3 genes are found (Arnett, 1997). The lupus anticoagulant is associated with HLA¹ class II-DQB genes inherited with HLA-DR4 or DR7. In general, estrogens enhance disease and testosterone reduces antibody response. Thus, some individuals are genetically predisposed to lupus. Under the influence of multiple genes, often triggered by environmental stimuli and highly influenced by gender, a number of clinical syndromes may develop, fulfilling diagnostic criteria for lupus.

CLINICAL FINDINGS. Lupus is notoriously variable in its presentation, course, and outcome (Gladman and Urowitz, 1997). Clinical manifestations may be confined initially to one organ system, with other systems becoming involved as the disease progresses; or the disease may be manifested initially by multi-system involvement (Table 52-2). Common findings are malaise, fever, arthritis, rash, pleuropericarditis, photosensitivity, anemia, and cognitive dysfunction. At least half of patients have renal involvement. *Libman-Sacks endocarditis* was described with lupus, but likely is due to anticardiolipin antibodies (Hojnik and associates, 1996).

LABORATORY FINDINGS. Identification of antinuclear antibodies (ANA) is the best screening test; however, a positive test is not specific for lupus. For example, low titers are found in some normal individuals, other autoimmune diseases, acute viral infections, and chronic inflammatory processes; several drugs can also cause a positive reaction. Almost all patients with lupus have a positive test. Antibodies to double-stranded DNA (dsDNA) and to Sm (Smith) antigens are relatively specific for lupus, whereas other antibodies shown in Table 52-1 are not.

Anemia is common, and there may be leukopenia and thrombocytopenia. Proteinuria and casts are found in the half of patients with glomerular lesions, and there may be renal insufficiency. Other laboratory findings include false-positive syphilis serology, prolonged partial thromboplastin time, and rheumatoid factors.

DIAGNOSIS. The recently revised criteria of the American Rheumatism Association for diagnosis of systemic lupus are shown in [Table 52-3](#). If any four or more of these 11 criteria are present, serially or simultaneously, the diagnosis of lupus is made.

DRUG-INDUCED LUPUS. Numerous drugs have been reported to induce a lupus-like syndrome. This syndrome is rarely associated with glomerulonephritis, and disease usually regresses when the medication is discontinued ([Rubin, 1997](#)). Drugs associated with this syndrome include procainamide, quinidine, hydralazine, a-methyl dopa, phenytoin, and phenobarbital. Combination estrogen and progestin oral contraceptives have been implicated, but this has not been proven.

LUPUS AND MATERNAL OUTCOME. A number of factors apparently determine the effects of lupus on pregnancy outcome. Some that are important include the disease state at the beginning of pregnancy, age and parity, co-existence of other medical or obstetrical disorders, and antiphospholipid antibodies.

A number of investigators have attempted to ascertain the effects of lupus on maternal outcome. Their reports indicate lupus improved in a third of women followed during pregnancy; a third remained unchanged, and a third worsened. Importantly, in all their series, at least some of the women had disease that worsened. Thus, in any given pregnancy, the clinical condition can worsen or a flare can occur rapidly and often without biochemical or clinical warning ([Khamashta and colleagues, 1997](#); [Ruiz-Irastorza and co-workers, 1996](#)). [Petri \(1998\)](#) observed a 7 percent major morbidity during pregnancy and estimates a 1 in 20 chance of a life-threatening event. Generally these are due to renal impairment, myocarditis, or serositis, but complications associated with preeclampsia and antiphospholipid antibody syndrome are worrisome.

In studies in which women served as their own nonpregnant controls, investigators have universally reported increased disease activity during pregnancy ([Petri, 1991](#); [Ruiz-Irastorza, 1996](#); [Zulman, 1980](#), and all their co-workers). In a review of her extensive experiences at Johns Hopkins, [Petri \(1998\)](#) reported an increased incidence of renal and hematological flares during pregnancy. Despite this, there was not an increase in the overall severity of flares measured using several indices. **One fact is certain: lupus can be life threatening to both mother and her fetus-infant.** The clinician must remain vigilant about the development of such life-threatening dangers.

In general, pregnancy outcome is better if:

1. Lupus activity has been quiescent for at least 6 months.
2. There is no active renal involvement manifest by proteinuria or renal dysfunction.
3. Superimposed preeclampsia does not develop.
4. There is no evidence of antiphospholipid antibody activity.

LUPUS NEPHROPATHY. Women with nephropathy whose disease stays in remission usually have a good pregnancy outcome. [Packham and associates \(1992\)](#) described their experiences in 41 women and found similar outcomes in 64 pregnancies before and after nephritis was diagnosed. Hypertension developed during almost half of pregnancies, and it was frequently early and severe. Likewise, proteinuria worsened in half of these women during pregnancy. [Julkunen and colleagues \(1993b\)](#) reported similar findings. Of the 125 pregnancies reported by [Lockshin \(1989\)](#), 63 percent of women with preexisting renal disease developed preeclampsia compared with only 14 percent of those without underlying renal disease. The World Health Organization has identified six classes of lupus glomerulonephritis. While proliferative lesions generally are associated with a more severe clinical course than membranous or mesangial lesions, 5-year survival of the former is now over 80 percent with cytotoxic drugs ([Austin and Balow, 1999](#)).

Although most authorities recommend continuation of immunosuppressive therapy during pregnancy in women with nephritis, it is not clear whether the dosage should be increased peripartum. While it is often stated that this is the time that activation or exacerbations are most likely to develop, firm evidence for this is not conclusive.

LUPUS VERSUS PREECLAMPSIA-ECLAMPSIA. Preeclampsia is common in all women with lupus, and superimposed preeclampsia is encountered even more often in those with nephropathy. It may be difficult, if not impossible, to differentiate lupus nephropathy from severe preeclampsia ([Repke, 1998](#)). Central nervous system involvement with lupus may culminate in convulsions similar to those of eclampsia. Thrombocytopenia, with or without hemolysis, may further confuse the diagnosis. It has not been proven if decreased complement values or increased anti-DNA titers are useful to identify worsening lupus activity. If identified, these laboratory features support the diagnosis of a renal flare. According to [Petri \(1998\)](#), most women with renal flares during pregnancy do not develop hypertension. In such problem cases, management is identical as for preeclampsia-eclampsia described in [Chapter 24](#). Corticosteroid therapy is continued. The most common causes of death in these women when not pregnant are malignant hypertension with glomerulonephritis and neurological catastrophes such as seizures, strokes, and coma.

MANAGEMENT DURING PREGNANCY. Current management consists primarily of monitoring the clinical conditions of both maternal and fetal patients and a number of laboratory values in the mother. Monitoring of lupus activity and the identification of pending lupus flares by a variety of laboratory techniques has been recommended by some clinicians. The sedimentation rate is uninterpretable because of pregnancy-induced hyperfibrinogenemia. Although falling or low levels of complement components C₃, C₄, and CH₅₀ are more likely to be associated with active disease, higher levels provide no assurance against disease activation. [Varner and co-workers \(1983\)](#) found no correlation between clinical manifestations of disease and C₃ and C₄ complement levels in half of their pregnant patients. Our experiences, as well as those of [Lockshin and Druzin \(1995\)](#), have been similar.

Frequent hematological evaluation and assessment of renal and hepatic functions are done to detect changes in disease activity during pregnancy and the puerperium. Hemolysis is characterized by a positive Coombs test, anemia, reticulocytosis, and unconjugated hyperbilirubinemia. Thrombocytopenia, leukopenia, or both, may develop. According to [Lockshin and Druzin \(1995\)](#), chronic thrombocytopenia in early pregnancy may be due to **antiphospholipid antibodies**. It also may be caused by lupus activity. Finally, thrombocytopenia may indicate the onset of preeclampsia.

Increased serum transaminase activity reflects hepatic involvement, as does a rise in serum bilirubin. Azathioprine therapy also may induce enzyme elevations. Urine is tested frequently to detect new-onset or worsening proteinuria. Overt proteinuria that persists is an ominous sign and is even more ominous if accompanied by other evidence for the nephrotic syndrome or abnormal serum creatinine.

The fetus should be closely observed for adverse effects imposed by a hostile intrauterine environment. Fetal growth is monitored closely and careful attention is given to the development of hypertension. [Singsen and colleagues \(1985\)](#) and [Petri \(1998\)](#) recommend screening for anti-SS-A and anti-SS-B antibodies, and if found, a search for fetal cardiac dysfunction and arrhythmias should be made (see p. 1385). Although we routinely evaluate the fetus for an arrhythmia, we do not screen for these antibodies. Antepartum fetal surveillance is done as outlined by the American College of Obstetricians and Gynecologists (1999) and as discussed in [Chapter 40 \(p. 1107\)](#). [Farine and associates \(1998\)](#) reported an 11 percent incidence of absent end-diastolic umbilical artery velocity in 56 fetuses. Unless hypertension develops, or there is evidence for fetal compromise or retarded growth, pregnancy is allowed to progress to term. Delivery decisions are made using obstetrical criteria. Peripartum corticosteroids in "stress doses" are given to women who are taking these drugs or who recently have done so.

PHARMACOLOGICAL TREATMENT. There is no cure and complete remissions are rare. Approximately a fourth of patients have mild disease, which is not life-threatening, but may be disabling because of pain and fatigue. Arthralgia and serositis are managed by **nonsteroidal anti-inflammatory drugs**, including aspirin. Because of the risk of premature closure of the fetal ductus arteriosus, therapeutic doses probably should not be used after 24 weeks. Low-dose aspirin, however, can be used safely throughout gestation in the management of the antiphospholipid syndrome (see p. 1394). Life-threatening and severely disabling manifestations are managed with **corticosteroids** such as prednisone, 1 to 2 mg/kg per day. After the disease is controlled, this is tapered to a daily dose of 10 to 15 mg given each morning. Corticosteroid therapy can result in the development of gestational or even insulin-dependent diabetes.

Immunosuppressive and cytotoxic agents such as *azathioprine* and *cyclophosphamide* are beneficial in controlling active disease ([Hahn, 1998](#)). In nonpregnant patients, they are usually reserved for lupus nephritis or disease that is steroid resistant. Azathioprine is less toxic and recommended daily oral doses are 2 to 3 mg/kg. It is avoided during pregnancy unless life-threatening complications develop. Although [Ramsey-Goldman and associates \(1993\)](#) found that women exposed to either drug did not have more adverse pregnancy outcomes, [Enns and associates \(1999\)](#) reported that cyclophosphamide is teratogenic. **Antimalarials** help control skin disease, and [Parke and Rothfield \(1996\)](#) and [Petri \(1998\)](#) recommend their continuation if in use.

For **severe lupus flares**, [Petri \(1998\)](#) recommends pulse therapy consisting of methylprednisolone, 1000 mg per 24 hours for 3 days, then return to maintenance doses if possible.

LONG-TERM PROGNOSIS AND CONTRACEPTION. In general, women with lupus and chronic vascular or renal disease should limit family size because of morbidity associated with the disease as well as increased adverse perinatal outcomes. Tubal sterilization may be advantageous. It is performed with greatest safety postpartum or any other time when the disease is quiescent. Oral contraceptives must be used with caution in women with lupus because vascular disease is a relatively common component. Progestin-only implants and injections provide effective contraception with no known effects on lupus flares. Intrauterine devices probably should not be prescribed if the woman is receiving immunosuppressive therapy ([Chap. 58, p. 1539](#)).

EFFECTS OF LUPUS ON THE FETUS AND NEONATE. There is no doubt that fetal growth restriction and perinatal mortality and morbidity are increased significantly in pregnancies complicated by lupus ([Table 52-4](#)). Prognosis is worsened with a lupus flare, significant proteinuria, renal impairment, and with associated hypertension and/or the development of preeclampsia ([Aggarwal, 1999](#); [Carmona, 1999](#); [Rahman, 1998](#), and their associates).

The reasons at least partially responsible for adverse fetal consequences include decidual vasculopathy with placental infarction and decreased perfusion ([Hanly and colleagues, 1988](#); [Lubbe and Liggins, 1984](#)). [Magid and associates \(1998\)](#) reported that these effects occur in the absence of antiphospholipid antibodies. Anti-SS-A (Ro) and anti-SS-B (La) antibodies may damage the fetal heart and conduction system causing neonatal death ([Alexander and co-workers, 1992](#); [Tseng and Buyon, 1997](#)).

NEONATAL LUPUS. This unusual syndrome is characterized by skin lesions—*lupus dermatitis*—and a variable number of hematological and systemic derangements, and occasionally congenital heart block ([Tseng and Buyon, 1997](#)). The incidence is about 5 to 10 percent. [Lockshin and colleagues \(1988\)](#) prospectively followed 91 infants born to women with lupus; four had definite neonatal lupus and four had possible disease.

Cutaneous lupus, thrombocytopenia, and autoimmune hemolysis are transient and clear within a few months ([Lee and Weston, 1984](#)). [Weston and colleagues \(1999\)](#) stress that thrombocytopenia and hepatic involvement are present as frequently as cardiac disease and therefore should be investigated.

CONGENITAL HEART BLOCK. This is the consequence of diffuse myocarditis and fibrosis in the region between the atrioventricular node and bundle of His. [Miyagawa and associates \(1997\)](#) reported that in Japanese women, some maternal HLA-DR5 haplotypes (DRB1*1101, DQA1*0501, and DQB1*0301) were associated with neonatal cutaneous lupus and others with congenital heart block (HLA-DQB1*062). [Buyon and colleagues \(1993\)](#) reported that congenital heart block occurred almost exclusively in infants of women with antibodies to the SS-A or SS-B antigens. Even in the presence of such antibodies, however, the incidence of arrhythmia is only 3 percent ([Lockshin and associates, 1988](#)). The cardiac lesion is permanent and a pacemaker is generally necessary. Long-term outlook is not good, with a third of affected infants dying within 3 years ([Waltuck and Buyon, 1994](#)). The recurrence risk for neonatal cutaneous lupus is 25 percent and for congenital heart block it is 10 to 15 percent ([Julkunen and colleagues, 1993a](#)).

Maternal corticosteroid administration to treat fetal heart block is controversial. [Richards and associates \(1990\)](#) described such a fetus whose ascites cleared promptly with maternal corticosteroid therapy even though heart block and bradycardia persisted. [Shinohara and colleagues \(1999\)](#) reported no heart block in 26 neonates whose mothers received corticosteroid maintenance therapy before 16 weeks. By contrast, 15 of 61 neonates with heart block were born to women in whom corticosteroid therapy was begun after 16 weeks. [Saleeb and colleagues \(1999\)](#) recommend fluorinated steroids if therapy is given.

ANTIPHOSPHOLIPID ANTIBODIES

A number of antibodies directed against negatively charged phospholipids have been described and studied in detail over the past 25 years. These antiphospholipid antibodies include **lupus anticoagulant (LAC)** and **anticardiolipin antibodies (ACAs)**. They may be of IgG, IgM, and IgA classes, alone or in combination. Although they may be found in normal persons, they also are associated with the **antiphospholipid antibody syndrome**. This is characterized by recurrent arterial and/or venous thromboses, thrombocytopenia, and fetal losses—especially stillbirths, during the second half of pregnancy ([Meng and Lockshin, 1999](#); [Oshiro and associates, 1996](#)). The syndrome may occur alone or in association with systemic lupus erythematosus or other autoimmune disorders.

[Feinstein and Rapaport \(1972\)](#) introduced the term *lupus anticoagulant* in a review of acquired inhibitors of coagulation. This was based on the early recognition that certain patients with lupus had some tests of coagulation that were prolonged and thus suggested anticoagulant activity. Paradoxically, the so-called anticoagulant is powerfully thrombotic in vivo. This is despite that the lupus anticoagulant prolongs all phospholipid-dependent coagulation tests including the prothrombin time, partial thromboplastin time, and Russell viper venom time. Each of these tests requires a phospholipid surface to which other clotting factors attach and combine ([Fig. 52-1](#)).

Thus, detection of the lupus anticoagulant is based indirectly upon the prolongation of in vitro tests by this circulating antiphospholipid antibody. Anticardiolipin antibody usually is detected serologically using enzyme linked immunoabsorbent assays (ELISA). Most often IgM anticardiolipin antibodies found alone are stimulated by infections or drugs and are innocuous ([Silver and colleagues, 1996](#)).

PATHOPHYSIOLOGY. Many patients with lupus have circulating antibodies either specifically directed against cardiolipin(s) or against phospholipid binding proteins such as β_2 -glycoprotein I (apolipoprotein H). Anticardiolipin antibodies apparently bind directly to β_2 -glycoprotein I, and these proteins act as a co-factor in this antigen-antibody reaction ([Chamley, 1997](#)).

The major activity of β_2 -glycoprotein I appears to be its phospholipid-dependent anticoagulant inhibition of prothrombinase activity of platelets and adenosine diphosphate-induced platelet aggregation ([Shi and colleagues, 1993](#)). This results from the binding of this protein to negatively charged phospholipid surfaces such as activated platelets. Thus, β_2 -glycoprotein I competitively inhibits the binding of coagulation factors, especially factor XII and the prothrombinase complex to negatively charged phospholipid surfaces and prevents activation of the coagulation cascade ([Schousboe and Rasmussen, 1995](#)). An antibody directed against β_2 -glycoprotein I would bind and prevent it from acting as a phospholipid-dependent anticoagulant. This may not apply in all cases, because [Laszlo and colleagues \(1992\)](#) reported a patient with homozygous β_2 -glycoprotein I deficiency who had no evidence of thrombotic episodes.

Beta₂-glycoprotein I is found in high concentrations on the surface of the syncytiotrophoblast. This might be expected, because it is a critical area to ensure that coagulation does not occur. Beta₂-glycoprotein I also may be involved in implantation, because it is known that this protein binds heparin. Moreover, trophoblastic cells have heparin-like binding sites. Thus, a local loss of β_2 -glycoprotein I by an antibody directed against it might prevent implantation or result in intervillous-space thrombosis, or both ([Chamley, 1997](#)).

Lupus anticoagulant appears to require a co-factor for its in vitro anticoagulant function. Specifically, it does not bind directly to negatively charged phospholipids, but instead, it binds to phospholipid-bound prothrombin ([Bever and associates, 1991](#)).

There are other phospholipid-binding proteins that may be involved in the pathophysiology of the antiphospholipid antibody syndrome. These include **protein C** and **protein S**, both endogenous anticoagulants, and **annexin V**. The latter is also known as placental anticoagulant protein I or lipocortin V, and it coats the syncytiotrophoblast in high concentration ([Chamley, 1997](#)). Thus, an antibody that binds protein C or S would result in venous, arterial, or decidual thrombosis, while binding of annexin V would result in coagulation and thrombosis in the intervillous space ([Fig. 52-1](#)).

[Rand and co-workers \(1997b\)](#) reported that placental tissue from pregnancy complicated by the antiphospholipid antibody syndrome had significantly less apical membrane-associated annexin V than a normal placenta. Exposure of placental villous cultures to five different antiphospholipid IgGs also resulted in a significant reduction in apical membrane annexin V. In another study, [Rand and colleagues \(1997a\)](#) found a reduction in annexin V in endothelial cell tissue cultures exposed to antiphospholipid antibodies. The pathophysiology of this sequence of events is illustrated in [Figure 52-1](#).

These discoveries led to the development of direct assays to measure antibodies against β_2 -glycoprotein I and prothrombin. The latter are increased in and associated with pregnancies complicated by the antiphospholipid antibody syndrome ([Faden, 1997](#); [Falcon, 1997](#); [Forastiero, 1997](#); [Ogasawara, 1996](#), and their co-workers). Conversely, others have not observed a clinically significant association with these antibodies ([Caruso, 1999](#); [Cuadrado, 1998](#); [Lee, 1999](#); [Leroy, 1998](#); [Lynch, 1999](#), and all their associates).

ASSOCIATION OF ANTIPHOSPHOLIPID ANTIBODIES WITH LUPUS. There is considerable cross-reactivity with anticardiolipin and lupus anticoagulant antibodies and lupus. [Love and Santoro \(1990\)](#) reviewed 29 series that included over 1000 patients with lupus and reported an average frequency of 34 percent for lupus anticoagulant and 44 percent for anticardiolipin antibodies. In nearly half, both antibodies were found.

In general, patients with the lupus anticoagulant have higher levels of anticardiolipin antibodies, and about a third of those with biological false-positive tests for syphilis have anticardiolipin antibodies ([Branch, 1990](#)). Conversely, only about 20 percent of patients with identifiable anticardiolipin have the lupus anticoagulant.

Importantly, in patients with lupus, documentation of either anticardiolipin or lupus anticoagulant is a risk factor for thrombosis, neurological disorders, or thrombocytopenia ([Love and Santoro, 1990](#)). As discussed in [Chapter 33 \(p. 834\)](#), these antibodies have also been associated with pregnancy loss ([Kutteh and colleagues, 1999](#)). [Hojnik and colleagues \(1996\)](#) reported that *Libman-Sacks endocarditis* is much more prevalent in lupus patients who have antiphospholipid antibodies. There is also an association with antiphospholipid antibodies and dilated postpartum cardiomyopathy and giant cell (temporal) arteritis ([Airoldi and colleagues, 1996](#); [Duhaut and associates, 1998](#)). Finally, the association of these antibodies with the development of "primary" vaso-occlusive disease involving numerous different organs, but especially the kidney, has been documented by renal biopsy ([Nochy and colleagues, 1999](#)).

ANTIPHOSPHOLIPID ANTIBODIES IN NORMAL PREGNANCY. Nonspecific antiphospholipid antibodies in low titers have been found in 3 to 6 percent of all otherwise healthy nonpregnant populations screened. [Lockwood and colleagues \(1989\)](#) studied 737 normally pregnant women without a history of recurrent pregnancy loss. They found that two (0.27 percent) had a lupus anticoagulant and 16 (2.2 percent) had elevated concentrations of either IgM- or IgG-anticardiolipin antibodies. [Harris and Spinnato \(1991\)](#) studied 1449 consecutive pregnant women and found 1.8 percent positive for IgG-anticardiolipin and 4.3 percent for IgM-anticardiolipin antibodies. Most assays were low positive (see later discussion) and did not correlate with adverse outcome. [Pattison and co-workers \(1993\)](#) studied 933 consecutive prenatal patients and found nine (0.1 percent) with anticardiolipin antibody, 11 (1.2 percent) with lupus anticoagulant, and two women with both. [Yasuda and associates \(1995\)](#) found that 7 percent of 860 pregnant Japanese women had anticardiolipin antibodies, and they had an increased risk of abortion, preeclampsia, and fetal growth restriction.

DIAGNOSIS. A number of indications for testing are listed in [Table 52-5](#). [Lockshin and Druzin \(1995\)](#) recommend a conservative interpretation of results to be based on repeated tests from a reliable laboratory that are consistent with each clinical case. Because only approximately 20 percent of patients with the antiphospholipid antibody syndrome have a positive lupus anticoagulant reaction alone, both the clotting test to identify the lupus anticoagulant and the anticardiolipin [ELISA²](#) test must be performed.

Efforts have been made to standardize the anticardiolipin antibody by using [ELISA²](#). By agreement reached at the 1987 International Anti-Cardiolipin Workshop, values are reported in units and expressed as either *negative* or *low, medium, or high positive* ([Harris and colleagues, 1987](#)).

Tests for the lupus anticoagulant are nonspecific coagulation tests. The *partial thromboplastin time* is generally prolonged because the anticoagulant interferes with conversion of prothrombin to thrombin in vitro. Tests considered most specific are the *dilute Russell viper venom test (dRVVT)* and the *platelet neutralization procedure* ([Lockwood and Rand, 1994](#)). There is currently disagreement as to which of these is best for screening; but if any of the tests are positive after adding normal plasma, the diagnosis is confirmed.

[Harris and co-workers \(1998\)](#) developed two tests that they describe as more sensitive and specific for identifying the antiphospholipid antibody syndrome. These include an [ELISA²](#) using β_2 -glycoprotein I, which has a sensitivity from 40 to 90 percent and a specificity of 82 percent. The other is the APL Phospholipid Mixture (Louisville APL Diagnostics), which is a kit with sensitivity of 98 percent and specificity of more than 99 percent ([Merkel and colleagues, 1999](#)). The kit may serve as a follow-up study in patients identified to have a positive anticardiolipin ELISA.

There is a strong association between the lupus anticoagulant and anticardiolipin antibodies with decidual vasculopathy, placental infarction, fetal growth restriction, early-onset preeclampsia, and recurrent fetal death. Some of these women, like those with lupus, also have a high incidence of venous and arterial thromboses, cerebral thrombosis, hemolytic anemia, thrombocytopenia, and pulmonary hypertension ([Khamashta and colleagues, 1997](#); [Silver and associates, 1994](#)).

MECHANISM OF ACTION. Although it is not precisely known how these act, a number of mechanisms have been proposed. It seems reasonable to conclude that the actions of antiphospholipid antibodies are multifactorial. According to [Chamley \(1997\)](#), platelets may be damaged directly by antiphospholipid antibody, or indirectly by binding β_2 -glycoprotein I, which causes platelets to be susceptible to aggregation. [Rand and colleagues \(1997a, 1997b, 1998\)](#) propose that phospholipid-containing endothelial cell or syncytiotrophoblast membranes may be damaged directly by the antiphospholipid antibody or indirectly by antibody binding to either β_2 -glycoprotein I or annexin V (see [Fig. 52-1](#)). This prevents the cell membranes from protecting the syncytiotrophoblast and endothelium and results in exposure of basement membrane. It is known that damaged platelets adhere to exposed basement membrane of endothelium and syncytiotrophoblast and result in thrombus formation ([Lubbe and colleagues, 1983](#); [Lubbe and Liggins, 1984](#)).

There are other proposed mechanisms. [Pierro and co-investigators \(1999\)](#) reported that antiphospholipid antibodies decreased decidual production of the vasodilating prostaglandin E₂. Decreased fibrinolytic activity due to prekallikrein inhibition by lupus anticoagulant has been described ([Sanfelippo and Drayna, 1981](#)). Decreased protein C or S activity, as well as subtle increases in activation of prothrombin have been reported ([Ogunyemi and associates, 2001](#); [Zangari and colleagues, 1997](#)). [Amengual and co-workers \(1998\)](#) presented evidence that thrombosis with the antiphospholipid syndrome is due to activation of the tissue factor pathway.

ADVERSE PREGNANCY OUTCOMES. Although there is no doubt that these antibodies are associated with increased fetal wastage, it is unclear as to the extent of these adverse sequelae. In most studies in which recurrent abortions and fetal deaths are described, women were usually included because they had repeated adverse outcomes. In the previously cited studies, the incidence of antiphospholipid antibodies in the general obstetrical population is about 3 to 5 percent. Data are too limited to draw conclusions concerning the impact of these antibodies on bad outcomes. According to the Utah group, fetal deaths are now more characteristic of these antibodies than first-trimester miscarriages ([Ariel, 2001](#); Oshiro, 2000; [Roque, 2001](#), and all their associates).

Looking at the issue another way, the incidence of these antibodies may be increased in adverse obstetrical outcomes associated with the syndromes. [Polzin and colleagues \(1991\)](#) identified antiphospholipid antibodies in a fourth of 37 women with growth-restricted fetuses. None had evidence for lupus anticoagulant. [Branch and co-workers \(1989\)](#) found a 16 percent incidence of antiphospholipid antibodies in 43 women with severe preeclampsia before 34 weeks. Six of the seven women with antibodies also had lupus anticoagulant, and one woman had multiple cerebral infarctions. Similarly, [Moodley and associates \(1995\)](#) observed an incidence of antibodies in 11 percent of 34 women with severe preeclampsia before 30 weeks.

When otherwise unexplained fetal deaths are examined, anticardiolipin antibodies do not appear to play a significant role. [Haddow and co-workers \(1991\)](#) measured anticardiolipin antibodies in 309 pregnancies with fetal death and found no differences when compared with 618 viable pregnancies. Similarly, [Infante-Rivard and associates \(1991\)](#) did not find an increased incidence of lupus anticoagulant or IgG anticardiolipin antibodies in a case-control study of 331 women with spontaneous abortion or fetal death.

TREATMENT GUIDELINES. Women with high-titer anticardiolipin antibody or with the presence of the lupus anticoagulant and a previous second- or third-trimester fetal death not attributable to other causes should be treated ([Branch, 1998](#); [Lockshin and Druzin, 1995](#)). Similarly, some women with recurrent early-pregnancy loss and high titers of antibodies may benefit from therapy ([Kutteh, 1996](#)). A number of treatments for women with antiphospholipid antibodies have been evaluated, including low-dose aspirin, prednisone, heparin, and immunoglobulin ([Coulam, 1995](#)). These are thought to counteract the adverse action of antiphospholipid antibodies by affecting both the immune and coagulation systems.

Once daily **low-dose aspirin** (60 to 80 mg) blocks the conversion of arachidonic acid to thromboxane A₂ while allegedly sparing prostacyclin production ([Kaaja and co-workers, 1993](#); [Lellouche and colleagues, 1991](#)). This would result in reduced thromboxane A₂—which aggregates platelets and causes vasoconstriction—while sparing prostacyclin, which has the opposite effect. There appear to be no major side effects from low-dose aspirin other than a slight risk of small vessel bleeding during surgical procedures.

Heparin most often is used in doses of 5000 to 10,000 units administered subcutaneously every 12 hours. Some authors recommend measurement of heparin levels because clotting tests may be altered by lupus anticoagulant. According to [Cowchock \(1998\)](#), preinjection levels are monitored to ensure protection of patients most at risk of thromboembolism. The rationale for heparin therapy is to prevent thrombotic episodes in both venous and arterial circulations, especially in women with a history of such events. Heparin therapy also prevents thrombosis in the microcirculation, including the decidual-trophoblastic interface ([Toglia and Weg, 1996](#)). As discussed, heparin binds to β_2 glycoprotein I, which covers the syncytiotrophoblast. This prevents binding of anticardiolipin and anti- β_2 -glycoprotein I antibodies to their surfaces, which likely prevents cellular damage ([Chamley, 1997](#); [Schousboe and Rasmussen, 1995](#)). Heparin also binds to antiphospholipid antibodies in vitro, and likely in vivo as well ([Ernel and associates, 1995](#)).

Heparin therapy is associated with a number of complications. These are discussed in detail in [Chapter 46 \(p. 1237\)](#) and include bleeding, thrombocytopenia, osteopenia, and osteoporosis. Although **low-molecular weight heparin** preparations have fewer adverse effects, [Cowchock \(1998\)](#) does not recommend their use. This is because activated partial thromboplastin tests (APTT) are not prolonged by these heparins and thus factor Xa inhibition tests are mandatory for monitoring anticoagulation effectiveness. Also, each preparation has a different molecular weight, renal clearance, and most importantly, biological consequences.

Glucocorticoids likely should not be used in the so-called primary antiphospholipid antibody syndrome; that is, those conditions without associated connective-tissue disorders. Even so, some patients with these conditions can be expected to develop over time an associated disorder such as lupus ([Carbone and colleagues, 1999](#)). In instances of "secondary" antiphospholipid syndromes, the dose of prednisone should be maintained at the lowest effective level to prevent flares ([Kutteh, 1997](#)). Steroid therapy has significant adverse effects, including osteopenia, osteoporosis, and pathological fractures ([Shillette and associates, 1996](#)). Steroids also impede wound healing, and they induce gestational and overt diabetes ([Laskin and co-workers, 1997](#)).

Immunoglobulin therapy has usually been reserved for women with overt disease or heparin-induced thrombocytopenia, or both. It is also used when other first-line therapies have failed, especially when preeclampsia and fetal growth restriction were associated with these failures ([Cowchock 1996, 1998](#); [Petri, 1997](#); [Silver and Branch, 1997](#)). Immunoglobulin is administered intravenously in doses of 0.4 g/kg daily for 5 days (total dose of 2 g/kg). This is repeated monthly, or it is given as a single dose of 1 g/kg each month. Immunoglobulin has been evaluated in a preliminary placebo-controlled study by [Branch and colleagues \(2000\)](#), who showed that a definitive study was feasible. The drug costs the provider \$5000 to \$8000 for each 5-day course, and it may cause anaphylactic reactions, especially in women who have IgA deficiency due to anti-IgA antibodies. Aseptic meningitis also has been reported ([Sekul and colleagues, 1994](#)).

Immunosuppressive therapy has also not been well evaluated, but azathioprine and cyclosporine do not appear to improve standard therapies ([Silver and Branch, 1997](#)). Methotrexate and cyclophosphamide are contraindicated because of teratogenic potential ([Enns and associates, 1999](#); [Silver and Branch, 1997](#)).

RESULTS WITH TREATMENT. Although improved outcomes are reported with some of the preceding treatments, [Branch and associates \(1985\)](#) caution that fetal growth restriction and preeclampsia still are common. Low-dose aspirin and corticosteroid therapy are not universally successful, and some women with lupus and antiphospholipid antibodies have normal pregnancy outcomes without treatment ([Stafford-Brady and colleagues, 1988](#)). Similarly, women with lupus anticoagulant and prior bad pregnancy outcomes have had live-born infants without treatment ([Trudinger and associates, 1988](#)). [Lockshin and co-workers \(1989\)](#) reported that 23 of 32 women with a prior fetal death and antiphospholipid antibody greater than 40 IgG units, had a recurrent fetal death despite treatment with prednisone or aspirin, or both.

Current data suggests the most efficacious therapy to be low-dose heparin—7500 to 10,000 units administered subcutaneously, twice daily—given along with low-dose aspirin, 60 to 80 mg once daily. If active lupus also is present, then prednisone is usually also given.

RHEUMATOID ARTHRITIS

This is a chronic multisystem disease characterized by a variety of systemic manifestations. Its cause is unknown, but the pathogenesis is immunologically mediated. Infiltrating T cells secrete cytokines that mediate inflammation and systemic symptoms. Its prevalence is about 0.8 percent, and women are affected three times more often than men. The cardinal feature is inflammatory synovitis that usually involves the peripheral joints. It has a propensity for cartilage destruction, bony erosions, and joint deformities. Disease onset is generally between ages 35 and 50.

There is a genetic predisposition, and 20 percent of monozygous twins and 5 percent of dizygous twins are concordant ([Lipsky, 1998](#)). There is also an association with the class II major histocompatibility complex molecules (HLA-DR4), which are important in the immune response. A prolonged duration of cigarette smoking also appears to increase the risk of rheumatoid arthritis in women ([Karlson and colleagues, 1999](#)). [Hazes and colleagues \(1990\)](#) reported a protective effect of pregnancy in the development of rheumatoid arthritis. An excellent review of its pathophysiology was provided by [Firestein \(1997\)](#).

CLINICAL MANIFESTATIONS. Rheumatoid arthritis is a chronic polyarthritis. In addition to symptoms of synovitis, the majority of patients have fatigue, anorexia, weakness, weight loss, and vague musculoskeletal symptoms. The hands, wrists, knees, and feet are commonly involved. Pain, aggravated by movement, is accompanied by swelling and tenderness. Extra-articular manifestations include rheumatoid nodules, vasculitis, and pleuropulmonary symptoms. Fortunately, the kidney usually is spared. The 1987 revised criteria of the American Rheumatism Association have approximately a 90 percent specificity and sensitivity for the diagnosis ([Arnett and colleagues, 1988](#)).

MANAGEMENT. Treatment is directed at pain relief, reduction of inflammation, protection of articular structures, and preservation of function. Treatment is important before cartilage loss is irreversible. Physical and occupational therapy and self-management instructions are essential. Aspirin or another one of the nonsteroidal anti-inflammatory drugs are the cornerstone of therapy. Aspirin therapy for nonpregnant patients consists of 3 to 4 g per day contained in enteric coated capsules. A blood level of 15 to 20 mg/dL is the desired therapeutic level. Tinnitus develops with blood levels of approximately 25 mg/dL. While other nonsteroidal agents are not more effective, their gastrointestinal tolerance may make them a better choice.

Glucocorticoid therapy may be added, and 7.5 mg of prednisone daily for the first 2 years of active disease substantively reduces progressive joint erosions ([Kirwan and colleagues, 1995](#)). Otherwise, corticosteroids are avoided if possible, but low-dose therapy is used by some along with salicylates. A variety of disease-modifying drugs and immunosuppressive therapy are used for more severe disease. Some have considerable toxicity and include hydroxychloroquine, sulfasalazine, low-dose methotrexate, gold compounds, and penicillamine. High-dose cyclosporine is reserved for the most severe cases. Orthopedic surgery for joint deformities, including replacement, is commonly performed.

EFFECTS OF PREGNANCY. In 1938, Hench reported marked improvement in the inflammatory component of rheumatoid arthritis during pregnancy. Conversely, postpartum exacerbation is common ([Lockshin and Druzin, 1995](#)). Because cortisol levels in plasma were considered to be markedly increased in pregnancy, Hench used cortisone to treat rheumatoid arthritis, and there was a favorable effect. It was subsequently demonstrated that increased secretion of cortisol did not account for all of the remissions. Sex hormones supposedly interfere with a number of putative processes involved in arthritis pathogenesis, including immunoregulation and interactions with the cytokine system ([Masi and associates, 1999](#); [Ostensen, 1999](#); [Wildier and Elenkov, 1999](#)).

[Unger and associates \(1983\)](#) reported that amelioration of rheumatoid arthritis correlated with serum levels of **pregnancy-associated α_2 -glycoprotein**. This compound has immunosuppressive properties and likely suppresses at least one mediator of an inflammatory response, interleukin-2 ([Nicholas and colleagues, 1985](#)). [Nelson and co-workers \(1993\)](#) later reported that amelioration of disease was associated with a disparity in HLA¹ class II antigens between mother and fetus. They suggested that the maternal immune response to paternal HLA antigens may have a role in pregnancy-induced remission of arthritis.

[Silman and associates \(1992\)](#) performed a case-control study with 88 women with rheumatoid arthritis and reported that pregnancy had a "protective effect" for disease onset. Conversely, there was a sixfold increased likelihood of new-disease onset in the first 3 months postpartum. [Iijima and associates \(1998\)](#) observed only two new cases in 2547 postpartum women. [Barrett and co-workers \(2000a\)](#) reported that a flare was more common if women were breast feeding.

In a prospective study, [Ostensen and Husby \(1983\)](#) confirmed the amelioration of symptoms during early pregnancy in women with rheumatoid arthritis. They also described exacerbations within 3 months postpartum in 11 of 12 women. In a study from Leiden, [van der Horst-Bruinsma and colleagues \(1998\)](#) found that a favorable outcome was related to maternal-fetal MHC³ class II incompatibility. Conversely, [Barrett and co-workers \(2000b\)](#) performed a prospective study of 140 pregnant women recruited nationally in the United Kingdom and followed during the last trimester and at 1 and 6 months postpartum. There was only a modest fall in objectively assessed disease activity. Only 16 percent had complete remission. At least 25 percent had substantive levels of disability. Thus, while overall disease actually did not exacerbate postpartum, the mean number of inflamed joints increased significantly. Thus, most women with rheumatoid arthritis improve during pregnancy, some women develop disease during pregnancy, and others become worse ([Nelson and Ostensen, 1997](#)).

[Ostensen \(1991\)](#) reviewed outcomes of 76 pregnancies in 51 women with **juvenile rheumatoid arthritis**. Pregnancy had no effects on presentation of disease, but disease activity became quiescent or remained so during pregnancy. Postpartum flares were common, as discussed for rheumatoid arthritis. Joint deformities were common in these women, and 15 of 20 cesarean deliveries were done for contracted pelvis or joint prostheses. These observations are supported by the summary of similar results in 39 Polish women with a history of juvenile rheumatoid arthritis ([Musiej-Nowakowska and Ploski, 1999](#)).

PERINATAL OUTCOME. There are no obvious adverse effects of rheumatoid arthritis on pregnancy outcome, including preterm labor ([Klippel and Cecere, 1989](#)). Although [Kaplan \(1986\)](#) reported that women who go on to develop the disease have had a higher than expected incidence of spontaneous abortion, [Nelson and colleagues \(1992\)](#) did not observe this.

MANAGEMENT DURING PREGNANCY. In most instances, women with rheumatoid arthritis can be reassured that successful pregnancy outcome is likely. Large doses of aspirin or other nonsteroidal anti-inflammatory drugs typically used for nonpregnant patients might adversely affect the fetus and neonate ([Chap. 38, p. 1027](#)). Concerns include impaired hemostasis, prolonged gestation, and premature closure of the ductus arteriosus ([Briggs and colleagues, 1998](#)). Nonetheless, these drugs remain appropriate for treatment of symptomatic women during pregnancy. Corticosteroids are also used as indicated. Gold compounds have been used

in pregnancy, but their fetal effects are largely unknown. Immunosuppressive therapy with azathioprine, cyclophosphamide, or methotrexate is not routinely used during pregnancy. Of these, only azathioprine should be considered for use during pregnancy because the other agents are teratogenic ([Buckley and co-workers, 1997](#); [Enns and associates, 1999](#); [Ramsey-Goldman and Shilling, 1997](#)).

If cervical spine involvement exists, particular attention is warranted during pregnancy. Subluxation is common with such involvement, and pregnancy, at least theoretically, predisposes to this because of joint laxity, as discussed in [Chapter 8 \(p. 170\)](#). Intense involvement of certain joints may interfere with delivery; for example, severe hip deformities may preclude vaginal delivery.

CONTRACEPTION. Combination oral contraceptives are a logical choice because of their effectiveness, and the possibility they might improve rheumatoid arthritis ([Bijlsma and associates, 1992](#)). In fact, all reversible methods of contraception discussed in [Chapter 58](#) are appropriate except that the intrauterine device should not be used in women receiving immunosuppressive therapy.

SYSTEMIC SCLEROSIS (SCLERODERMA)

This is a multisystem disorder of unknown etiology characterized by fibrosis of skin, blood vessels, and visceral organs. Its prevalence averages 1 in 10,000, with a 3 to 1 female dominance. This strong prevalence for women and the increased incidence in the years following childbirth has led to the hypothesis that microchimerism may be involved in the pathogenesis of systemic sclerosis ([Maloney and associates, 1999](#); [Nelson and colleagues, 1998](#)). [Artlett and co-workers \(1998\)](#) demonstrated Y-chromosomal DNA in 32 of 69 women (46 percent) with systemic sclerosis compared with 4 percent of controls. These investigators showed that low concentrations of male DNA may normally remain in the maternal circulation for decades after birth of a male infant ([Chap. 37, p. 992](#)). The reverse of this may occur in which maternal cells have been observed to engraft and persist in some immunodeficient infants. [Maloney and colleagues \(1999\)](#) have shown persistent maternal microchimerism in six of nine immunocompetent women with systemic sclerosis. Whether this contributes to the development of systemic sclerosis currently is unresolved ([Russo-Stieglitz and colleagues, 2001](#)).

CLINICAL COURSE. Symptoms in systemic sclerosis involve its attacks upon the gastrointestinal tract, heart, lungs, and kidneys. **Overlap syndrome** refers to the presence of systemic sclerosis with features of other connective-tissue disorders. **Mixed connective-tissue disease** is a term used for the syndrome involving features of lupus, systemic sclerosis, polymyositis, rheumatoid arthritis, and high titers of anti-RNP antibodies (see [Table 52-1](#)).

The hallmark of the disease is overproduction of normal collagen. This results in fibrosis of skin and the gastrointestinal tract, especially the distal esophagus. Pulmonary interstitial fibrosis along with vascular changes may cause pulmonary hypertension. Antinuclear antibodies are found in 95 percent of patients, and immunoincompetence is common. Common symptoms are Raynaud phenomenon (95 percent) and swelling of the distal extremities and face. Half of patients have symptoms from esophageal involvement, especially fullness and epigastric burning pain. Pulmonary involvement is common and causes dyspnea. Renal failure causes half of the deaths caused by systemic sclerosis. Mortality is high with renal or pulmonary involvement, and 10-year survival is less than 50 percent. There is, however, a small subset of patients who have a better prognosis. Women with CREST—calcinosis, Raynaud phenomenon, esophageal involvement, sclerodactyly, and telangiectasia—have milder disease.

There is no effective treatment. Therapy is symptomatic and directed at end-organ involvement. Corticosteroids are helpful only for inflammatory myositis and hemolytic anemia. The use of **angiotensin converting enzyme (ACE) inhibitors**, however, can be lifesaving ([Steen, 1997, 1999](#)). These agents should always be considered in the face of developing renal compromise or severe unresponsive hypertension. [Steen \(1999\)](#) reported the use of ACE⁴ inhibitors under such conditions during pregnancy without fetal effects, but these agents have been associated with severe fetal consequences.

The use of **recombinant human relaxin** in patients with systemic sclerosis was reported by [Seibold and co-workers \(1998\)](#). The results of this initial study, however, were inconclusive.

EFFECTS ON PREGNANCY. Pregnancy outcome with scleroderma probably is related to the severity of underlying disease. From their review of 94 cases, [Maymon and Feigin \(1989\)](#) found that a third of women had exacerbations of symptoms during pregnancy; 15 percent died of hypertension, renal failure, or cardiopulmonary complications; and there was a 20 percent fetal mortality rate. The majority of maternal deaths have been case reports and do not accurately reflect the risks involved.

[Steen and colleagues \(1989, 1999\)](#) reported more optimistic outcomes in 214 women with scleroderma, 45 percent of whom had had diffuse disease. Major complications included *renal crisis* in three women characterized by malignant hypertension and renal failure. One woman died at 25 weeks; another was delivered preterm and died during hemodialysis 3 years later. The incidence of renal crisis was not considered different from that of nonpregnant women over the same period. They did not find an increased incidence of preeclampsia or hypertension. Infertility also was not a problem ([Steen and Medsger, 1999](#)).

In these studies by [Steen and associates \(1989, 1999\)](#), the risks for preterm delivery, fetal growth restriction, and perinatal mortality were increased, but not dramatically so. As some have reported for rheumatoid arthritis, a higher incidence of prediagnosis early pregnancy wastage was observed in these women in a case-controlled study ([Silman and Black, 1988](#)).

As perhaps expected, dysphagia and reflux esophagitis are aggravated by pregnancy ([Steen, 1999](#)). Treatment is described in [Chapter 48 \(p. 1276\)](#). [Chin and colleagues \(1995\)](#) described a woman with scleroderma who developed a Mallory-Weiss tear at 28 weeks from persistent vomiting despite therapy. Women with diffuse scleroderma or with hypertension, renal or cardiac involvement, or pulmonary fibrosis do poorly. Women with renal insufficiency and malignant hypertension have an increased incidence of superimposed preeclampsia. In the presence of rapidly worsening renal or cardiac disease, pregnancy termination should be considered.

Vaginal delivery may be anticipated, unless the soft-tissue changes wrought by scleroderma produce dystocia requiring abdominal delivery. Tracheal intubation for general anesthesia has special concerns because these women typically have limited ability to open their mouths ([Black and Stevens, 1989](#)). Because of esophageal dysfunction, aspiration is also more likely, and epidural analgesia is preferable.

[Steen and Medsger \(1999\)](#) emphasized that with careful timing of pregnancy in women without renal, pulmonary, or cardiac disease and with careful monitoring, successful pregnancy outcomes are achievable for both mother and fetus.

CONTRACEPTION. Due to the progressive and often unrelenting nature of this disease, permanent sterilization should be considered. Other forms of reversible contraception are acceptable, but hormonal agents, especially combination oral contraceptives, probably should not be used especially in women with pulmonary, cardiac, or renal involvement.

VASCULITIS SYNDROMES

Inflammation and damage to blood vessels may be primary or due to another disease. Most cases are presumed to be caused by immunopathogenetic mechanisms, specifically, immune-complex deposition. These syndromes are difficult to classify because of overlap. One current classification includes polyarteritis nodosa, hypersensitivity angiitis, Wegener granulomatosis, giant cell arteritis, and arteritis of collagen disease or miscellaneous arteritis ([Valente and associates, 1997](#)). [Sneller and Fauci \(1997\)](#) have presented a more extensive classification along with a scholarly review of the role of adhesion molecules and cytokines in the pathogenesis of these diffuse syndromes.

POLYARTERITIS NODOSA. Polyarteritis (periarteritis) nodosa is a rare disease with protean manifestations. The pathological lesion is necrotizing vasculitis of small- and medium-sized arteries. The classical variety is one of the progressive vasculitis syndromes characterized clinically by myalgia, neuropathy, gastrointestinal disorders, hypertension, and renal disease. Up to a third of cases are associated with hepatitis B antigenemia.

Symptoms are nonspecific and vague. Fever, weight loss, and malaise are present in over half of cases. Renal failure, hypertension, and arthralgias are common ([Rao and associates, 1998](#)). The diagnosis of polyarteritis nodosa is from classical findings of vasculitis on biopsy material of involved organs.

Treatment is largely ineffective and currently consists of high-dose prednisone and possibly cytotoxic medications ([Allen and Bressler, 1997](#)). Even with corticosteroid and immunosuppressive treatment, almost half of patients die within a year of diagnosis.

PREGNANCY. Only a few documented cases of polyarteritis nodosa in association with pregnancy have been reported. While definitive conclusions are unclear, certainly if active arteritis is identified during pregnancy, mortality is high. [Owen and Hauth \(1989\)](#) reviewed the courses of 12 pregnant women. In seven, polyarteritis

first manifested during pregnancy, and it was rapidly fatal by 6 weeks postpartum. The diagnosis was not made until autopsy in six of the seven women. Five other women were in remission at conception. Four of these women continued pregnancy, resulting in one stillborn and three successful outcomes. [Aya and co-workers \(1996\)](#) described a woman with hepatitis B-associated polyarteritis who developed severe preeclampsia at 31 weeks.

WEGENER GRANULOMATOSIS. This is a necrotizing granulomatous vasculitis of the upper and lower respiratory tract and kidney. According to [Sneller \(1995\)](#), common lesions include sinusitis and nasal disease (90 percent), pulmonary infiltrates or nodules (85 percent), glomerulonephritis (75 percent), and musculoskeletal lesions (65 percent). It is uncommon and usually encountered after age 50. There have been only a few cases reported in association with pregnancy ([Fields and colleagues, 1991](#); [Palit and Clague, 1990](#)). [Pauzner and associates \(1994\)](#) reviewed 15 pregnancies in 10 women with Wegener granulomatosis. In eight women with known disease preceding pregnancy, five had a relapse and two died. [Luisiri and associates \(1997\)](#) reviewed 13 cases associated with pregnancy and reported similar results.

ARTERITIS SYNDROMES. These uncommon syndromes involve medium- and large-sized arteries.

TEMPORAL OR GIANT CELL ARTERITIS. The diagnosis is usually established by biopsy of the temporal artery, but more recently, [Schmidt and associates \(1997\)](#) have reported that by utilizing color duplex ultrasonography of the temporal artery, a diagnosis can be made. They describe the specific image to be a dark halo that likely is due to edema of the artery wall. This sign was present in 73 percent of 30 patients with temporal arteritis.

TAKAYASU ARTERITIS. This is so-called *pulseless disease*, which is most prevalent in young women. When compared with temporal arteritis, the onset of Takayasu arteritis occurs almost exclusively in patients younger than 40 years of age. This form of arteritis also is associated with abnormal angiography of the upper aorta and its main branches, resulting in upper extremity vascular impairment ([Michel and co-workers, 1996](#)). Today, noninvasive methods, including computed tomography or magnetic resonance angiography, or both, can be used to detect this disorder prior to the development of severe vascular compromise ([Numano and Kobayashi, 1999](#)). There is no known serological test specific for Takayasu arteritis ([Hoffman and Ahmed, 1998](#)).

Takayasu arteritis may respond to corticosteroid therapy; however, surgical bypass sometimes is required to reestablish circulation. Severe renovascular hypertension, cardiac involvement, and pulmonary hypertension frequently preclude a good pregnancy outcome. Conversely, from their review of 14 cases, [Nagey and colleagues \(1983\)](#) reported good pregnancy outcomes. Other case reports and one series of four patients reported by [Railton and Allen \(1988\)](#) substantiate this optimism.

Most authors advise that blood pressure be taken in the lower extremity. Hemodynamic monitoring may be helpful if severe hypertension is identified ([Winn and associates, 1988](#)). Epidural analgesia has been advocated for labor and delivery ([Crofts and Wilson, 1991](#)).

DERMATOMYOSITIS AND POLYMYOSITIS (IDIOPATHIC INFLAMMATORY MYOSITIS)

These are uncommon acute, subacute, or chronic inflammatory diseases of unknown cause involving skin and muscle, in particular. Prevailing theories are that the syndromes are caused by either viral infections or autoimmune disorders. At least a third of cases are associated with one of the connective-tissue disorders, including rheumatoid arthritis, lupus, mixed connective-tissue disease, or scleroderma. The disease may manifest as a severe generalized myositis with a cutaneous eruption, fever, and a fatal outcome within a few days or weeks. It may also assume a chronic form, characterized by the gradual development of paresis with little, if any, cutaneous or systemic involvement. Laboratory manifestations include elevated muscle enzymes in serum, and an abnormal electromyogram. Confirmation is by biopsy. The disease usually responds to high-dose corticosteroid therapy, and cytotoxic drugs such as azathioprine, cyclophosphamide, and methotrexate are reserved for refractory cases ([Kofteridis and colleagues, 1999](#); [Solomon and D'Alton, 1996](#)).

About 15 percent of adults developing dermatomyositis have an associated malignant tumor. The time of appearance of the two diseases may be separated by several years. Extirpation of the malignant lesion sometimes is followed by a permanent remission of the dermatomyositis. The most common sites of associated cancer are breast, lung, stomach, and ovary. The uterus and cervix also have been reported as primary sites.

There are only a few reports of dermatomyositis complicating pregnancy. [King and Chow \(1985\)](#) reported five uneventful pregnancies in three women with dermatomyositis. In four of these, disease was inactive. [Gutierrez and colleagues \(1984\)](#) reviewed outcomes in 10 pregnancies among seven women with active disease. They reported three abortions, three perinatal deaths, and five preterm deliveries. [Rosenzweig and colleagues \(1989\)](#) reviewed 24 pregnancy outcomes in 18 women with primary polymyositis-dermatomyositis. In half, the diagnosis preceded pregnancy. Although they were in remission at conception, one fourth had an exacerbation in the second or third trimester. Excluding abortions, there were two perinatal deaths and two growth-restricted neonates. In the other half in whom disease became manifest first during pregnancy, outcomes were less favorable. One woman died 6 weeks postpartum when she suffered a severe exacerbation. Excluding abortions, half of the eight pregnancies resulted in perinatal death. Two fetuses developed ascites, and two were growth restricted. [Ohno and associates \(1992\)](#) described two women with established dermatomyositis who had evidence of disease activity during pregnancy but with good maternal and fetal outcomes. [Papapetropoulos and co-workers \(1998\)](#) reported two successful pregnancies and a therapeutic abortion in one of their patients. The therapeutic abortion was performed during an acute exacerbation.

The best form of contraception for these women is not known. Contraceptives containing hormones probably should not be used, especially combination estrogen-progestin contraceptives. Unfortunately, little data are available. While sterilization might seem at first to be an obvious choice, some women have mild chronic disease, and others may experience a permanent remission if an associated malignancy is identified and cured.

INHERITED CONNECTIVE-TISSUE DISORDERS

MARFAN SYNDROME

Marfan syndrome is an autosomal dominant connective-tissue disorder that affects both sexes equally. There appears to be no racial or ethnic basis for the syndrome. There are many mild cases in which the intrinsic connective tissue lesion is subclinical with no effect on longevity. Although the specific defect is still controversial, there is a degeneration of the elastic lamina in the media of the aorta. The cardiovascular lesion is the most serious abnormality, involving most of the ascending aorta and predisposing to aortic dilatation or dissecting aneurysm. Early death in Marfan syndrome is ultimately caused by either valvar insufficiency and congestive heart failure or rupture of a dissecting aneurysm. [Mor-Yosef and colleagues \(1988\)](#) report an increased frequency of dissecting and ruptured aneurysms during pregnancy. These were more likely in the last trimester. The syndrome was recently reviewed by [Elkayam and associates \(1995\)](#) and is discussed in detail in [Chapter 44, \(p. 1201\)](#).

EHLERS-DANLOS SYNDROME

This disease is characterized by a variety of changes in connective tissue, including hyperelasticity of the skin. In the more severe types of the syndrome, there is a strong tendency for fatal rupture of any of several arteries, causing strokes or bleeding. Rupture of the colon or uterus has been described. There are at least 11 types of disease based on skin, joint, or other tissue involvement. They include some autosomal dominant, some recessive, and some X-linked types. Their estimated aggregate prevalence is about 1 in 5000 ([Prockop and colleagues, 1998](#)). There is overlap between these types, and in most, the underlying molecular defect of collagen or procollagen is unknown. Types I, II, and III are autosomally dominant, and each accounts for about 30 percent of cases.

Women with Ehlers-Danlos syndrome have an increased frequency of preterm rupture of membranes and preterm delivery. There is also increased antepartum and postpartum hemorrhage, and tissue fragility makes episiotomy repair and cesarean delivery difficult. Multiple musculoskeletal abnormalities may develop or worsen during pregnancy, and back pain may be exacerbated ([Klippel and Riordan, 1989](#)). [Sorokin and colleagues \(1994\)](#) surveyed women members of the Ehlers-Danlos National Foundation, who reported a stillbirth rate of 3 percent, preterm delivery rate of 23 percent, cesarean delivery rate of 8 percent, and postpartum bleeding problems in 15 percent. Case reports and literature reviews have been provided by [Hordnes \(1994\)](#) and [Sakala and Harding \(1991\)](#).

TABLE 52-1. Some Autoantibodies Produced in Patients with Systemic Lupus Erythematosus

Antibody	Incidence (%)	Clinical Associations
Antinuclear	98	Multiple antibodies; repeat negative test makes lupus unlikely
Anti-DNA	70	Associated with nephritis and clinical activity
Anti-Sm	30	Specific for lupus
Anti-RNP	40	Polymyositis, scleroderma, lupus, mixed-connective tissue disease
Anti-Ro (SS-A)	30	Sjogren syndrome, cutaneous lupus, neonatal lupus, ANA-negative lupus, congenital heart block
Anti-La (SS-B)	10	Always with anti-Ro; Sjogren syndrome
Antihistone	70	Common in drug-induced lupus (95%)
Antiphospholipid	50	Lupus anticoagulant and anticardiolipin associated with thrombosis, fetal loss, thrombocytopenia, valvar heart disease; false-positive test for syphilis
Antierythrocyte	60	Overt hemolysis uncommon
Antiplatelet	—	Thrombocytopenia

ANA = antinuclear antibody.

TABLE 52-2. Clinical Manifestations of Systemic Lupus Erythematosus

Organ System	Clinical Manifestations	Percent
Systemic	Fatigue, malaise, fever, weight loss	95
Musculoskeletal	Arthralgias, myalgias, polyarthritis, myopathy	95
Hematological	Anemia, hemolysis, leukopenia, thrombocytopenia, lupus anticoagulant	85
Cutaneous	Malar (butterfly) rash, discoid rash, photosensitivity, oral ulcers, alopecia, skin rashes	80
Neurological	Cognitive dysfunction, organic brain syndromes, psychosis, seizures	60
Cardiopulmonary	Pleuritis, pericarditis	60
Renal	Proteinuria, casts, nephrotic syndrome	60
Gastrointestinal	Anorexia, nausea, pain, diarrhea	45
Thrombosis	Venous (10%), arterial (5%)	15
Ocular	Conjunctivitis	15
Fetal loss	Recurrent abortion, early preeclampsia, stillbirths	30

TABLE 52-3. 1997 Revised Criteria of the American Rheumatism Association for Systemic Lupus Erythematosus^a

Criteria	Comments
Malar rash	Malar erythema
Discoid rash	Erythematous patches, scaling, follicular plugging
Photosensitivity	
Oral ulcers	Usually painless
Arthritis	Nonerosive involving two or more peripheral joints
Serositis	Pleuritis or pericarditis
Renal disorders	Proteinuria > 0.5 g/day or > 3+ dipstick, or cellular casts
Neurological disorders	Seizures or psychosis without other cause
Hematological disorders	Hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia
Immunological disorders	Anti-dsDNA or anti-Sm antibodies, or false-positive VDRL, abnormal level of IgM or IgG anticardiolipin antibodies, or lupus anticoagulant
Antinuclear antibodies	Abnormal titer of ANAs

ANAs = antinuclear antibodies; dsDNA = double-stranded DNA; Sm = Smith antigens; VDRL = Venereal Disease Research Laboratories test for syphilis.

^a If four criteria are present at any time during course of disease, systemic lupus can be diagnosed with 98 percent specificity and 97 percent sensitivity.

TABLE 52-4. Maternal and Perinatal Effects of Systemic Lupus Erythematosus

Outcome	Description
Maternal	
Lupus flare	Overall a third flare during pregnancy
Preeclampsia	Controversial if incidence is increased Flare can be life threatening (1 in 20 chance) Flares associated with worse perinatal outcomes Prognosis worse if antiphospholipid antibodies Increased incidence common with nephritis
Preterm labor	Increased
Perinatal	
Preterm delivery	Increased with preeclampsia
Growth restriction	Increased
Stillbirth	Increased, especially with antiphospholipid antibodies
Neonatal lupus	About 10 percent incidence—transient except for heart block

FIGURE 52-1.

Mechanisms of the reduction of annexin V levels and acceleration of coagulation associated with antiphospholipid antibodies. **A.** Anionic phospholipids (-) on the surface of the cell-membrane bilayer serve as potent co-factors for assembly of three coagulation complexes: tissue-factor-VIIa (TF-VIIa) complex, IXa-VIIIa complex, and Xa-Va complex. The phospholipids thus accelerate blood coagulation by generating factors IXa and Xa. Factor Xa yields factor IIa (thrombin) and in turn cleaves fibrinogen to form fibrin. **B.** When antiphospholipid antibodies are absent, annexin V forms clusters that bind to the surface of anionic phospholipids and inhibit coagulation. **C.** Directly or through an interaction with protein-phospholipid co-factors, antiphospholipid antibodies disrupt the ability of annexin V to cluster on the phospholipid surface. This reduces binding affinity of annexin V, which permits more anionic phospholipid to be available to form complexes with coagulation proteins. Coagulation is thus accelerated and thrombosis promoted. (From [Rand and colleagues, 1997a](#), with permission.)

53. Neurological and Psychiatric Disorders

NEUROLOGICAL DISORDERS

Neurological diseases are relatively common in women of childbearing age. Many of these disorders are physically and mentally disabling, and in the past precluded childbearing. Therapeutic advances have changed that, however, and currently many women with chronic neurological disease become pregnant. Although the majority of such conditions are compatible with successful pregnancy outcome, most also require special therapies and entail specific risks with which the clinician should be familiar.

DIAGNOSIS OF NEUROLOGICAL DISEASE DURING PREGNANCY. Most women with chronic neurological disease have been diagnosed before pregnancy. Occasionally, however, new neurological symptoms arise during gestation and must be distinguished from complications of pregnancy. Because neurological symptoms are complex and may involve cognitive as well as neuromuscular functions, they must also be distinguished from psychiatric disorders. In general, the pregnant woman should receive the same evaluation as anyone else, and should not be penalized for her pregnancy. If indicated, the techniques discussed subsequently should not be withheld from the pregnant woman.

CENTRAL NERVOUS SYSTEM IMAGING. Various imaging techniques have been developed during the past 30 years that have revolutionized the visualization of anatomical lesions responsible for neurological disease. Computed-tomography scanning and magnetic resonance imaging have opened new vistas for the diagnosis, classification, and management of many neurological and psychiatric disorders.

Cranial computed tomography is safe during pregnancy (see [Table 42-8](#)). In some diseases, it is used preferentially to magnetic resonance imaging, while in others it is complementary. Certainly it is more widely available, and is commonly used whenever rapid diagnosis is necessary to differentiate between medical and surgical management of an acute neurological catastrophe. In hemorrhagic lesions, tomography may be superior to magnetic resonance imaging.

Magnetic resonance imaging is also believed to be safe in pregnancy and, in fact, may be the imaging modality of choice because of its low associated risk. It is helpful in diagnosing demyelinating diseases, screening for arteriovenous malformations, evaluating congenital and developmental nervous system abnormalities, identifying posterior fossa lesions, and diagnosing spinal cord diseases. A relative disadvantage is the limited space available within the scanner, which makes it difficult to monitor critically ill patients. Because the claustrophobic conditions of the scanner may be difficult for some pregnant women to tolerate, premedication may be beneficial. For both magnetic resonance imaging and computed tomographic scanning, the woman should be positioned in left lateral tilt with a wedge under her right hip to avoid hypotension and aortic pulsations, which can degrade the image.

Cerebral angiography with contrast injection, usually via femoral artery access, is a valuable adjunct to the diagnosis and treatment of some cerebrovascular diseases. Careful abdominal shielding may be used to limit x-ray exposure during fluoroscopy and film exposure (see [Table 42-7](#)).

HEADACHE

[Table 53-1](#) lists the prevalence of the most common neurological disorders, and headache is by far the most common neurological complaint during pregnancy.

TENSION HEADACHES. More than 90 percent of headaches are caused by tension, or they are migraine headaches ([Paulson, 1995](#)). Tension headaches are characterized by tightness and pain in the back of the neck and head that can persist for hours. There are no associated neurological disturbances, and the pain usually responds to rest, massage, application of heat or ice, anti-inflammatory medications, or a mild tranquilizer. The patient with recurrent tension headaches may benefit from counseling about stress management. Headaches may also be a symptom of depression.

MIGRAINE HEADACHES. The term *migraine* describes periodic, hemicranial, throbbing headaches that are often accompanied by nausea and vomiting. There are four types of migraine headaches. *Common migraine* is often familial and it is characterized by a usually unilateral headache, nausea and vomiting, and scalp tenderness of several hours duration. *Classical migraine* has similar symptoms but is preceded by premonitory neurological phenomena such as visual scotoma or hallucinations. This type of migraine can sometimes be averted if medication is taken at the first premonitory sign. *Basilar migraine* includes vertigo, dysarthria, and diplopia. *Complicated migraine* includes more severe transient neurological symptoms, and thus may mimic an ischemic event. Because migraine is frequently a diagnosis of exclusion, the initial attack should prompt a full neurological workup to rule out other more serious pathology.

Migraines may begin in childhood, adolescence, or young adulthood and tend to diminish both in frequency of recurrence as well as severity with advancing years. [Stewart and colleagues \(1992\)](#) reported that 18 percent of women and 6 percent of men suffer from migraine headaches at some time. Such headaches are especially common in young women, and several studies have indicated an as yet unclear relationship between hormone levels and migraine. The exact pathophysiology is uncertain, but prodromal neurological symptoms are believed to be caused by cerebral artery vasoconstriction and decreased blood flow. Presumably, vasodilation follows and is responsible for the headache. Serotonin has been implicated in this mechanism ([Olesen, 1994](#)). In some cases, migraines are associated with stroke ([Tietjen, 2000](#)). [Tzourio and colleagues \(1995\)](#) have shown a three- to sixfold increase in ischemic stroke in young women with migraines, although the absolute risk is small, from 10 to 20 per 100,000. Migraineurs who smoked or used oral contraceptives, however, were particularly vulnerable and had a 10- to 14-fold increased risk.

EFFECTS OF PREGNANCY. Several studies in which over 1500 pregnant women were surveyed indicate that approximately 70 percent of women with migraines experience a dramatic improvement during pregnancy ([Uknis and Silberstein, 1991](#); [Welch, 1994](#)). Menstrual migraines typically improve, most likely because they are provoked by the drop in estrogen levels just before menstruation and are thus relieved by the high estrogen levels of pregnancy ([Aube, 1999](#); [Fettes, 1997](#)). Women with menstrual migraines can expect a relapse postpartum. The remainder perceive either no change or worsening of symptoms.

About 15 percent of migraine headaches appear for the first time during pregnancy. These migraines are more likely to be preceded by an aura than not, and often appear in the first trimester when hormone levels are rising ([Aube, 1999](#)). Because migraine symptoms are similar to those of other more serious disorders, a complete evaluation, including neuroimaging as necessary, should be performed.

MANAGEMENT. Most migraine headaches respond to simple analgesics such as aspirin or acetaminophen, with or without caffeine or butalbital, especially if given early. Antiemetics frequently are needed. For severe headaches, codeine or meperidine is given along with promethazine for its antiemetic and sedative effects. Although almost half of classical migraines can be aborted by ergotamine taken in the prodromal period, ergotamine preparations are potent vasoconstrictors that should be avoided in pregnancy because of concerns about their effect on uteroplacental blood flow and vasoconstriction of fetal vessels. Ergotamine-induced uterine hypertonicity may also be responsible for fetal demise ([Au and colleagues, 1985](#)). Moreover, several case reports have described anomalies in exposed infants ([Graham, 1983](#); [Hughes, 1988](#); [Verloes, 1990, and their colleagues](#)). Ergotamine may be associated with maternal myocardial infarction, pulmonary edema, bronchospasm, bowel infarction, and stroke when given peripartum ([Reprotox, 1998](#)).

Sumatriptan is an agonist for a specific vascular serotonin receptor found in the cranial arteries and dura mater. It relieves headaches by causing vasoconstriction and is highly effective in the treatment of migraine attacks ([Bateman, 1993](#)). According to [Welch \(1993\)](#), a 6-mg subcutaneous dose results in improvement of over 80 percent of patients within 2 hours. The drug also relieves nausea and vomiting and greatly reduces the need for analgesics. Although previously administered only by injection, it is now available as a nasal spray and in pill form. Whether or not sumatriptan can be given safely in pregnancy is controversial, and some authors consider it to be contraindicated ([Pfaffenrath and Rehm, 1998](#)). It causes embryo lethality when given to animals at doses toxic to the mother, but does not appear to cause structural abnormalities. Sumatriptan has not been studied extensively in pregnancy, but a registry of 150 cases and two series totaling 162 exposures have not shown any teratogenic effects ([Eldridge, 1997](#); [O'Quinn, 1999](#); [Shuhaiber, 1998](#), and their colleagues).

For women with frequent migraine attacks, prophylactic therapy is indicated ([Welch, 1993](#)). Amitriptyline, 10 to 150 mg/day, propranolol, 20 to 80 mg three times daily, or atenolol, 50 to 100 mg/day, are safe in pregnancy and have been used with success.

SEIZURE DISORDERS

Approximately 0.5 to 2.0 percent of the population—including as many as 1.1 million American women of childbearing-age—have epilepsy, which complicates 1 in 200 pregnancies ([Brodie and Dichter, 1996](#); [Yerby, 1994](#)). Convulsive disorders are the second most prevalent and certainly the most serious common neurological conditions encountered in pregnant women. Epilepsy can affect the course of pregnancy, labor, and delivery and can alter fetal development, and pregnancy can

exacerbate epilepsy. The metabolism of antiepileptic medications during pregnancy is changed, and teratogenic effects of several anticonvulsant medications are unquestioned.

PATHOPHYSIOLOGY. A seizure is defined as a paroxysmal disorder of the central nervous system characterized by an abnormal neuronal discharge with or without a loss of consciousness. Epilepsy is defined as a condition characterized by a tendency for two or more recurrent seizures unprovoked by any known proximate insult. This excludes seizures due to acute systemic metabolic derangement or to an acute central nervous system insult.

A standard classification of seizures is shown in [Table 53-2](#). Partial seizures originate in one localized area of the brain, and affect a correspondingly localized area of neurological function. They are believed to result from a lesion caused by trauma, abscess, tumor, or perinatal factors, although a specific lesion is rarely demonstrated. Simple motor seizures start in one region of the body and progress toward other areas on the same side, producing tonic and then clonic movements. Simple seizures can also affect sensory function or produce autonomic dysfunction or psychological changes. Consciousness is usually not lost and recovery is rapid. Partial seizures can secondarily generalize, producing loss of consciousness and convulsions. Complex partial seizures, also called temporal lobe or psychomotor seizures, usually involve clouding of the consciousness and a feeling of disassociation or a dyscognitive state.

Generalized seizures involve both hemispheres of the brain simultaneously, and may be preceded by an aura before an abrupt loss of consciousness. In grand mal seizures, loss of consciousness is followed by tonic contraction of the muscles and rigid posturing, and then by clonic contractions of all extremities while the muscles gradually relax. Loss of bowel or bladder control is common. Return to consciousness is gradual, and the patient may be confused and disoriented for some time.

Absence seizures, also called petit mal, involve a loss of consciousness without muscle activity, are very brief, and are characterized by immediate recovery of consciousness and orientation. Appropriate selection of an anticonvulsant is based on accurate seizure classification ([Table 53-3](#)).

SPECIFIC CAUSES. Some identifiable causes of convulsive disorders in adolescents and young adults include trauma, alcohol and other drug-induced withdrawals, brain tumors, or arteriovenous malformations. A search for all of these, including biochemical abnormalities, is necessary when a new-onset seizure disorder is encountered in a pregnant woman. The diagnosis of idiopathic seizures is one of exclusion. Lumbar puncture, skull x-rays, and arteriography have been largely replaced by evaluation with computed tomography, magnetic resonance imaging, or both. The pregnant woman should receive the same evaluation as a nonpregnant individual.

EPILEPSY DURING PREGNANCY. The major pregnancy-related threats to women with epilepsy are an increase in seizure frequency and risk of congenital malformations in their offspring. [Hollingsworth and Resnik \(1988\)](#) reviewed studies including 2385 pregnancies and found increased seizure frequency in 35 percent, decreased frequency in 15 percent, and no change in 50 percent. Increased seizure frequency is often associated with subtherapeutic anticonvulsant levels, a lower seizure threshold, or both. Subtherapeutic levels are caused by a variety of factors, some of which are amenable to therapeutic intervention. Nausea and vomiting leads to skipped doses; decreased gastrointestinal motility and the use of antacids reduces drug absorption; expanded intravascular volume lowers serum drug levels; the induction of hepatic, plasma, and placental enzymes increases drug metabolism; and increased glomerular filtration hastens drug clearance. These changes are offset somewhat by the fact that decreased protein binding increases free drug levels. An important factor that can be averted by appropriate counseling is that women often self-discontinue medication because they think it can harm the fetus. The seizure threshold can also be affected by various factors, including exhaustion from sleep deprivation and hyperventilation during labor. Women with the most severe disease are most susceptible to increased seizure frequency during pregnancy, probably because their seizure control is more difficult and thus susceptible to minor changes.

The offspring of epileptic women are at increased risk to have certain congenital malformations caused by the epilepsy itself, the anticonvulsant medications, or a combination of both. On average, 7 percent of the offspring of epileptic women have major congenital abnormalities compared with 3 percent of the general population. Some seizure disorders are inheritable, and almost 10 percent of children develop a seizure disorder later in life. The specific drug-related risks are discussed in [Chapter 38 \(p. 1007\)](#).

Older data suggested that epileptic women were at increased risk to have a variety of pregnancy complications other than seizures. This is controversial, however, because of ascertainment bias, and because these findings did not address the confounding effects of alcohol and drug abuse and socioeconomic factors. [Nelson and Ellenberg \(1982\)](#), using data from the Collaborative Perinatal Project, reported an increased incidence of preeclampsia, perinatal mortality, cesarean delivery, and preterm birth among epileptic women, as well as increased low birthweight, congenital malformations, cerebral palsy, seizures, and mental retardation in the offspring. In contrast, [Olafsson and colleagues \(1998\)](#) performed a population-based study of all epileptic women delivered in Iceland over a 19-year period. Although these women had a twofold increased cesarean delivery rate, the risk of other adverse obstetrical events was similar to that for the general population. While the risk of major congenital malformations was increased 2.7-fold in the offspring of epileptic women, mean birthweight and perinatal mortality were not different.

MANAGEMENT DURING PREGNANCY. For a number of reasons, epileptic women will benefit from counseling prior to pregnancy.

PRECONCEPTIONAL COUNSELING. As discussed in [Chapter 9 \(p. 205\)](#), preconceptional counseling is preferable for optimal anticonvulsant management. In addition to issues addressed in that chapter, postpartum contraception should be discussed. Co-administration of oral contraceptives and anticonvulsants such as phenobarbital, primidone, phenytoin, and carbamazepine may cause breakthrough bleeding and contraceptive failure because they induce hepatic P₄₅₀ microsomal enzyme systems, which in turn increase estrogen metabolism. Although an increased failure rate is speculative, the [American College of Obstetricians and Gynecologists \(1990\)](#) recommends that oral contraceptives containing 50 ug of estrogen be used in epileptic women taking anticonvulsants. Oral contraceptives are not associated with exacerbation of seizures ([Table 58-6](#)).

PRENATAL CARE. The major goal of pregnancy management is to keep the woman seizure free. To accomplish this, she may need treatment for nausea and vomiting, she should avoid seizure-provoking stimuli, and compliance is urged for medication. In general, antiepileptic medication should be maintained at the lowest dose associated with seizure control. While some clinicians routinely monitor serum drug levels during pregnancy, we recommend that they be measured only when seizures occur, or if noncompliance is suspected. Altered protein binding of antiepileptic drugs during pregnancy makes standard values for therapeutic serum levels unreliable in pregnancy. [Lander and Eadie \(1991\)](#) reported that seizure control was not improved by routine monitoring. While determination of free or unbound drug levels may be more helpful, it currently is not widely available and has not been studied.

Women taking antiepileptic medication should take folic acid as most of these agents deplete this nutrient. Some investigators recommend vitamin K for women ingesting phenytoin because it has been implicated in functionally defective neonatal vitamin K-dependent clotting factors II, VII, IX, and X. [Cornelissen and associates \(1993\)](#) demonstrated diminished levels in half of cord blood samples in women taking anticonvulsants compared with 20 percent of control infants. It is unclear, however, whether vitamin K crosses the placenta. Moreover, hemorrhage in the newborn is usually prevented by prompt parenteral administration of vitamin K. For these reasons, we do not administer vitamin K to the epileptic mothers.

A midpregnancy targeted ultrasound examination may identify anomalies. Other than this, fetal monitoring because of epilepsy may not be necessary. Tests of fetal well-being might be indicated if there is poor fetal growth, inadequate seizure control, or co-morbid maternal conditions.

CEREBROVASCULAR DISEASES

In the United States, cerebrovascular disease is the eighth leading cause of death in women 25 to 44 years old. Cerebrovascular disease refers to disorders of one or more blood vessels of the brain, with the majority of lesions in the arterial system. The resultant pathological lesion is a stroke, which is an acute neurological injury due to ischemia caused by embolization, occlusion, or rupture of a vessel ([Easton and colleagues, 1998](#)). Although distinctly uncommon in young women, disorders of cerebral circulation have continued to be a prominent cause of maternal deaths in the United States. The Maternal Mortality Collaborative ([Rochat and associates, 1988](#)) reported that 10 percent of 507 direct maternal deaths from 1980 to 1985 were caused by strokes.

Fortunately, stroke and intracranial thrombosis are relatively rare complications of pregnancy. [Lanska and Kryscio \(1998\)](#) used the National Hospital Discharge Survey to identify all pregnancy-related strokes and intracranial thromboses in the United States from 1979 to 1991. They reported 17.7 cases of stroke and 11.4 cases of intracranial venous thrombosis per 100,000 deliveries. [Kittner and co-workers \(1996\)](#) reported similar rates when they analyzed data from a regional hospital-based registry of strokes in the Baltimore-Washington area. They found 11 cerebral infarctions and 9 hemorrhages per 100,000 deliveries.

Some causes of stroke in young women are listed in [Table 53-4](#). There is evidence that inherited thrombophilias also contribute to cerebrovascular disease, although the appropriate prophylaxis or therapy for these conditions is as yet unknown. The postpartum period is a time of greatest risk. [Kittner and colleagues \(1996\)](#) reviewed records of all women aged 15 to 44 in the Central Maryland and Washington, D.C., area who had the diagnosis of stroke between 1988 and 1991. Among 254 cases, there were 31 associated with pregnancy. The relative risk of 0.7 for cerebral infarction during pregnancy was increased to 8.7 postpartum. The relative risk of

intracerebral hemorrhage was significantly increased 2.5-fold during pregnancy and increased to 28-fold postpartum. Causes of strokes included preeclampsia-eclampsia, carotid dissection, thrombotic thrombocytopenic purpura, cortical vein thrombosis, postherpetic vasculitis, arteriovenous malformation, primary central nervous system vasculopathy, and cocaine use.

ISCHEMIC STROKES. These strokes may result from thrombosis of an artery or vein, or from arterial embolism.

CEREBRAL ARTERY THROMBOSIS. The vast majority of strokes afflict older individuals, result from cerebral artery thrombosis caused by atherosclerosis, and are preceded by transient ischemic attacks. The patient usually presents with sudden onset of severe headache, hemiplegia or other neurological deficits, or seizures. A thorough workup should be performed, that includes serum lipid profile, echocardiography, and cranial computed tomographic scanning or angiogram as necessary. Therapy includes rest, analgesia, and aspirin. There is evidence that prompt treatment with low-molecular-weight heparin or tissue plasminogen activator (t-PA) may improve outcomes with acute ischemic stroke ([Kay and colleagues, 1995](#); [National Institute of Neurological Disorders and Stroke Study Group, 1995](#)).

Unfortunately, the [Multicenter Acute Stroke Trial Europe Study Group \(1996\)](#) reported that early streptokinase for ischemic stroke resulted in increased mortality from hemorrhage. To be effective, t-PA must be given without delay, and this can result in its being given before radiological evaluation confirms arterial occlusion. [Caplan and colleagues \(1997\)](#) estimate that among every 100 patients who are eligible for thrombolysis according to current guidelines, 25 or more will not have arterial occlusions, and they have a 5 to 10 percent risk of hemorrhage from the therapy. Accurate diagnosis is thus essential before initiating therapy, and the evaluation of pregnant women should not be delayed if they are to be candidates for thrombolysis.

Arterial thrombosis during pregnancy is probably not more common than stroke from cerebral embolism or intracranial hemorrhage ([Table 53-4](#)). In over 29,000 consecutive births at the Mayo Clinic, [Wiebers and Whisnant \(1985\)](#) identified only one case each of cerebral thrombosis and intracranial hemorrhage. In almost 90,000 pregnant women, [Simolke and colleagues \(1991\)](#) identified only two cases of cerebral artery thrombosis. One of these women had other features of connective-tissue disease. Cerebral thrombosis and other thrombotic complications occur more frequently in women who have antiphospholipid antibodies. According to [Branch \(1990\)](#), as many as a third of ischemic strokes in otherwise healthy patients under 50 years of age are caused by these antibodies ([Chap. 52, p. 1391](#)). Conversely, [Voetsch and colleagues \(2000\)](#) found no relationship with arterial ischemic strokes and inherited thrombophilias in young Brazilian women.

CEREBRAL VENOUS THROMBOSIS. Lateral or superior sagittal venous sinus thromboses usually occur in the puerperium. There appears to be an association with preeclampsia, sepsis, and thrombophilias. Symptoms include severe headache, drowsiness, confusion, convulsions, and focal neurological deficits, along with hypertension and papilledema. As discussed in [Chapter 46 \(p. 1234\)](#), venous thrombosis is more common in patients with inherited thrombophilias. These include factor V Leiden mutation (activated protein C resistance), methylene tetrahydrofolate reductase deficiency, deficiencies of proteins C and S, antithrombin III, and plasminogen, as well as lupus anticoagulant and antiphospholipid antibodies.

Cerebral venous thrombosis is not common in the United States and Europe. [Cross and colleagues \(1968\)](#) reported the incidence to be 1 in 20,000 pregnancies in Scotland. In the series from Parkland Hospital, two women with sagittal sinus thrombosis were identified, for an incidence of 1 in 45,000 deliveries ([Simolke and co-workers, 1991](#)). Likely because of the link with sepsis and preeclampsia, cerebral venous thrombosis remains common in undeveloped countries. [Srinivasan \(1984\)](#) reported its incidence in Madurai, India, to be 1 in 250 deliveries.

Venous thrombosis of the cerebral circulation is more common in the puerperium. [Cantu and Barinagarrementeria \(1993\)](#) described 72 cases associated with pregnancy from Mexico City over a 20-year period. All but five occurred postpartum. Headaches were the most common presenting symptom (73 percent) and 10 percent had convulsions. Magnetic resonance is the imaging procedure of choice ([Cartledge, 2000](#)). Management includes anticoagulants to control seizures and antimicrobials if septic thrombophlebitis is suspected. Heparin anticoagulation is controversial because bleeding may develop spontaneously. [Donaldson and Lee \(1994\)](#) recommend that heparin be risked, especially if there is no hemorrhagic infarction demonstrated by tomography. In a small randomized study, [Einhaupt and associates \(1991\)](#) described improved outcomes in nonpregnant patients given heparin therapy. In all cases the prognosis is guarded.

CEREBRAL EMBOLISM. This most commonly involves the middle cerebral artery. This type of stroke is more common during the latter half of pregnancy or early puerperium. The source of arterial occlusion may be unclear at first, but a diligent search may determine that emboli are associated with heart disease.

Management of embolic stroke consists of supportive measures and consideration for anticoagulation once hemorrhage or infarction has been excluded. Because infarction follows cerebral embolization, it is sometimes confused with cerebral artery thrombosis. Many cases of cerebral embolism in young women never are found to have an underlying cause, and the risk of recurrence therefore is speculative. On the other hand, if an underlying cause is identified, recurrence is more common unless treatment or prophylaxis can be given. Thus, it is important to aggressively pursue an etiology when these lesions are identified during pregnancy. The most commonly found origin of emboli is a cardiac arrhythmia, especially atrial fibrillation associated with rheumatic valvular disease. They also may arise from rheumatic heart disease without arrhythmia or mitral valve prolapse. Finally, emboli from infective endocarditis must be considered ([Cox and associates, 1988](#)).

HEMORRHAGIC STROKES. Hemorrhagic and ischemic strokes occur with about equal frequency during pregnancy ([Table 53-4](#)). *Intracerebral hemorrhage* into the substance of the brain may complicate chronic essential hypertension (often in older women), hypertension with superimposed preeclampsia, or may be associated with pure preeclampsia. It can also be caused by crack cocaine abuse ([Mercado and colleagues, 1989](#); [Witlin and associates, 2000](#)). This is in contrast to *subarachnoid hemorrhage*, which is more likely to be due to an underlying malformation and associated with an otherwise normal pregnancy. According to [Cartledge \(2000\)](#), intracerebral hemorrhage has a high mortality rate because of its location ([Fig. 53-1](#)). In 13 women shown in [Table 53-4](#), six died and most of the others suffered permanent neurological sequelae. These experiences underscore the importance of proper management for acute hypertension to prevent cerebrovascular pathology ([Lanska and Kryscio, 2000](#)).

SUBARACHNOID HEMORRHAGE. Intracranial vascular anomalies can become symptomatic during pregnancy. Rupture of a cerebral aneurysm or angioma or bleeding from an arteriovenous malformation occurs in 1 in 75,000 gestations. The cardinal feature is sudden severe headache, along with visual changes, cranial nerve abnormalities, focal neurological deficits, or altered consciousness. The patient typically has signs of meningeal irritation, tachycardia, hypertension, slight fever, leukocytosis, and proteinuria. According to [Dias and Sekhar \(1990\)](#), bleeding from aneurysms is more common than from arteriovenous malformations, with a ratio of 3 to 1 during pregnancy. The incidence during pregnancy supposedly does not differ from that in the general nonobstetrical population ([Minielly and associates, 1979](#)). The mortality rate is reported to be as high as 35 percent ([Dias and Sekhar, 1990](#)).

RUPTURED ANEURYSM. Bleeding from a ruptured aneurysm reportedly is more common during the second half of pregnancy, but about 20 percent bleed before midpregnancy ([Dias and Sekhar, 1990](#)). There likely is a relationship between pregnancy-associated hypertension and ruptured aneurysms. [Henderson and Torbey \(1988\)](#) described a case temporally related to crack cocaine smoking.

Prompt evaluation is important because re-bleeding can be fatal and early neurosurgical clip ligation can prevent this. If the computed tomographic scan of the head is normal, but the clinical picture strongly suggests intracranial hemorrhage, the cerebrospinal fluid can be examined to confirm the presence of blood and this is followed by angiography to locate the lesion. We agree with [Giannotta and colleagues \(1986\)](#) who recommend that the workup be pursued as aggressively as if these women were not pregnant.

Treatment includes bed rest, analgesia, and sedation. Whether to attempt repair of potentially accessible vascular lesion during pregnancy is controversial. The risk of recurrent hemorrhage is difficult to estimate, but appears to depend on the rate of aneurysm growth. [Kamitani and co-workers \(1999\)](#) reported that four of six fast-growing aneurysms (more than 8 percent increase in size per year) bled again, while none of the 14 slow-growing aneurysms had recurrent bleeding. Immediate surgical correction obviates the need to monitor growth and thus has clear advantages. The potential for adverse fetal effects from the surgery is real. While the fetus generally tolerates hypothermia well, hypotension is problematic and should be avoided. If the woman requires surgery near term, cesarean delivery followed by craniotomy is a consideration. If remote from term, there appears to be no advantage to pregnancy termination.

Vaginal delivery is not prohibited following surgical repair, although some authorities perform vaginal delivery only after 2 months from the event. A major obstetrical problem concerns the management of delivery in women who survive intracranial hemorrhage, but in whom repair is not done. Some authorities, but certainly not all, recommend against bearing down, and thus favor cesarean delivery. On the basis of a review of 142 cases of intracranial aneurysms that ruptured before or during pregnancy, [Hunt and co-workers \(1974\)](#) concluded that there is no contraindication to vaginal delivery. With an unrepaired aneurysm, [Wiebers \(1988\)](#) recommends cesarean delivery only if bleeding occurred in the third trimester. We agree with [Cartledge \(2000\)](#) who recommends cesarean delivery if the aneurysm has not been repaired.

ARTERIOVENOUS MALFORMATIONS. Vascular malformations causing subarachnoid hemorrhage are uncommon. According to [Horton and co-workers \(1990\)](#), the incidence of bleeding from cerebral arteriovenous malformations is not increased during pregnancy. [Simolke and associates \(1991\)](#) encountered only one case in

nearly 90,000 deliveries cared for at Parkland Hospital ([Fig. 53-2](#)). Conversely, bleeding from these lesions caused 8 percent of strokes listed in [Table 53-4](#). Although it is commonly accepted that bleeding from these malformations occurs with similar frequency throughout gestation, [Dias and Sekhar \(1990\)](#) reported an increased frequency with advancing gestational age.

There is no general agreement in nonpregnant patients about whether all of these lesions should be resected, even if they are accessible. However, the risk of recurrent hemorrhage in unoperated lesions is high. Without surgical therapy, about 5 to 7 percent will bleed again within the first year, and perhaps 2 to 3 percent per year thereafter ([Itoyama and associates, 1989](#)). In nonpregnant patients, the mortality rate is 10 percent after the first hemorrhage, 13 percent after the second hemorrhage, and approximately 20 percent after subsequent hemorrhages ([Wilkins, 1985](#)). [Dias and Sekhar \(1990\)](#) reported a mortality rate of 28 percent after the first bleeding event in pregnant women.

In pregnancy, management decisions to operate should be based on neurosurgical considerations ([Finnerty and associates, 1999](#)). Because of the high risk of recurrent hemorrhage, the conduct of labor and delivery following a bleeding episode during pregnancy from an inoperable lesion is critical. Although [Dias and Sekhar \(1990\)](#) found no evidence to support better maternal outcome with cesarean delivery, it seems best to avoid vaginal delivery if the malformation was not corrected surgically.

DEMYELINATING AND DEGENERATIVE DISEASES

Demyelinating diseases comprise a group of neurological disorders that involve focal or patchy destruction of central nervous system myelin sheaths accompanied by an inflammatory response. The degenerative diseases frequently are inherited, and are characterized by gradually evolving and progressive neuronal death from unknown causes.

MULTIPLE SCLEROSIS. This disease is the most common chronic demyelinating neurological disorder. Multiple sclerosis (MS) usually begins in young adults and is most common in 20- to 40-year-old white women. The etiology is unknown, but it likely involves a combination of heredity and environmental factors. One theory is that it is caused by a virally triggered autoimmune phenomenon in genetically susceptible individuals. There are four forms of the disease which are recognized primarily for research classification ([Confavreux and colleagues, 2000](#); [Lublin and Reingold, 1996](#)). *Relapsing-remitting MS*¹ is characterized clinically by unpredictable recurrent attacks of focal or multifocal neurological dysfunction. Early in the disease, attacks typically last 2 to 3 days, followed by complete recovery over several weeks. As attacks become more frequent, recovery may not be complete, and permanent deficits can accrue. In *secondary progressive MS*, the disease pursues a progressive downhill course after each relapse. *Primary progressive MS* is characterized by gradual progression of disability from the initial diagnosis. *Progressive-relapsing MS* refers to primary progressive MS with apparent relapses.

Classical symptoms include loss of vision and diplopia, and over 40 percent of patients have optic neuritis during the course of disease. In fact, 75 percent of women who have isolated optic neuritis will go on to develop multiple sclerosis within 15 years. Other common symptoms are weakness, hyperreflexia, spasticity, paresthesia, ataxia and intention tremor, nystagmus, dysarthria, diminished vibratory sense, and bladder dysfunction. The diagnosis is one of exclusion, and is confirmed by cerebrospinal fluid analysis and magnetic resonance imaging. The characteristic multifocal white matter lesions, termed plaques, are present in more than 90 percent of patients and represent discrete areas of demyelination ([Hauser and Goodkin, 1998](#)).

The goal of treatment is to arrest the disease or its symptoms. Corticosteroids may diminish the severity of acute flares, but they have no effect on permanent disability. Symptomatic relief can be provided by analgesics; carbamazepine, phenytoin, or amitriptyline (for neurogenic pain); baclofen (for spasticity); α -adrenergic blockade (to relax the bladder neck); and cholinergic and anticholinergic drugs (to stimulate or inhibit bladder contractions). Immunosuppressive therapy with cyclosporine, azathioprine, and cyclophosphamide is often prescribed for aggressive cases but has not been accepted by all as efficacious ([Ebers, 1994](#)).

Both interferon- β 1a and 1b have been shown to favorably modify the course of disease ([McDonald, 1995](#)). The [PRISMS \(Prevention of Relapses and Disability by Interferon beta-1a Subcutaneously in Multiple Sclerosis\) Study Group \(1998\)](#) prospectively randomized 560 patients with MS¹ from 22 centers to one of two different doses of interferon or placebo. They found that both doses of interferon significantly lowered the relapse rate, prolonged the time to first relapse, and delayed both the progression to disability and the accumulated disability. Because depression, thrombotic thrombocytopenic purpura, and various autoimmune reactions are side effects of treatment, patients receiving interferon- β should be closely monitored ([Walther and Hohlfeld, 1999](#)).

EFFECTS OF PREGNANCY. There is no evidence that pregnancy precipitates MS¹, and in most cases pregnancy has no deleterious effect on its course. In fact, several studies indicate that women who have been pregnant have less deterioration than those who have not ([Damek and Shuster, 1997](#)). However, acute exacerbation during the first few months postpartum is common, possibly due to the reversal of the relative immune suppression of pregnancy ([Cartledge, 2000](#); [Schneider and associates, 1996](#)). [Abramsky \(1994\)](#) summarized eight retrospective studies of over 1000 pregnancies and found that the disease worsened during pregnancy in only 10 percent, but 30 percent had worsening in the puerperium. In a prospective study of 125 women, [Roulet and associates \(1993\)](#) confirmed a 43 percent postpartum exacerbation rate. Conversely, in a prospective investigation of 58 pregnancies, [Sadovnick and co-workers \(1994\)](#) found that postpartum relapses were no more common than in nonpregnant controls.

If uncomplicated, MS¹ usually has no adverse effects on pregnancy outcome. [Schneider and colleagues \(1996\)](#) reported increased preterm delivery and a slight increase in the rate of congenital malformations. Women may become fatigued more easily, and those with bladder dysfunction are prone to urinary infection. Labor is unaffected, and the indications for cesarean delivery are obstetrical. Women with lesions at or above T₆ are at risk for autonomic dysreflexia, and they should receive epidural anesthesia accordingly. Although spinal analgesia has anecdotally been associated with exacerbations, some authorities consider epidural analgesia to be safe ([Weinreb, 1994](#)). [Bader \(1994\)](#) rightfully emphasizes the high incidence of postpartum exacerbation regardless of analgesia or anesthesia.

Perinatal outcome is not altered significantly, but the incidence of multiple sclerosis in offspring is increased nearly 15-fold. Although breast feeding is not associated with an increased risk of postpartum exacerbation, such an exacerbation may prevent the woman from breast feeding. Exacerbation may also limit a woman's ability to provide general infant care, and the need for assistance during this period should be anticipated ([Nelson and colleagues, 1988](#)).

HUNTINGTON DISEASE. This degenerative disease of the cerebral cortex and basal ganglia is characterized by a combination of choreoathetotic movements and progressive dementia. Since the mean age of onset is 40 years, Huntington disease rarely complicates pregnancy. Because it is inherited as an autosomal dominant trait, a family history of the disease does arouse interest during pregnancy. With the development of several DNA probes, as well as the use of the polymerase chain reaction, prenatal diagnosis is now possible ([Chap. 36, p. 966](#)). Prenatal diagnosis is highly controversial because termination is often not considered in view of the late age of disease onset. Also, prenatal diagnosis could prejudice health insurance carriers and others against the child.

MYASTHENIA GRAVIS

BR>This disease is an immune-mediated neuromuscular disorder that affects about 1 in 10,000 persons and has a predilection for women of childbearing age. The etiology is unknown, but genetic factors play a role as it is more common in those with the HLA-B8 antigen. The disease is characterized by weakness resulting from IgG-mediated destruction of postsynaptic striated muscle acetylcholine receptors. Even though acetylcholine is released normally, without adequate receptors it produces diminished endplate action potentials that do not always trigger muscle action potentials and thus results in weakened muscle contractions.

Myasthenia gravis is characterized by easy fatigability of facial, oropharyngeal, extraocular, and limb muscles. Cranial muscles are involved early and disparately, and diplopia and ptosis are common. Facial muscle weakness causes difficulty in smiling, chewing, and speech. In 85 percent of patients the weakness becomes generalized. The course of the disease is variable, but it tends to be marked by exacerbations and remissions, especially when it first becomes clinically apparent. Remissions seldom are complete or permanent. Systemic diseases, concurrent infections, and even emotional upset may precipitate myasthenic crises, of which there are three types: myasthenic crises, characterized by severe muscle weakness, inability to swallow, and respiratory muscle paralysis; refractory crises, characterized by the same symptoms but unresponsive to the usual therapy; and cholinergic crises, in which excessive cholinergic medication leads to nausea, vomiting, muscle weakness, abdominal pain, and diarrhea. All three crisis types can be life threatening, but a refractory crisis is a medical emergency. Women with bulbar myasthenia are at particular risk during a crisis because they may be unable to swallow or even ask for help.

Myasthenia is manageable but not curable. About 75 percent of patients have thymic hyperplasia or a thymoma. Young women are more likely to respond to thymectomy with remission ([Cartledge, 2000](#)). Anticholinesterase medications bring about improvement by impeding degradation of acetylcholine, but seldom produce normal muscle function. Pyridostigmine, an analog of neostigmine, is the most commonly used preparation. Ironically, the side effects of overdosage are increased weakness, which is sometimes difficult to differentiate from myasthenic symptoms. Nearly all patients respond to immunosuppressive therapy with corticosteroids, azathioprine, and cyclosporine ([Cartledge, 2000](#)). Cyclophosphamide is used for refractory cases. Short-term clinical improvement has been reported following intravenously administered immunoglobulin or plasmapheresis.

EFFECTS OF PREGNANCY. Pregnancy does not appear to affect the course of myasthenia gravis, which may be marked by exacerbations and remissions just like any other 9-month period. The enlarging uterus may compromise respiration, and diminished energy levels common to most pregnancies may be tolerated poorly. [Plauche \(1991\)](#) found that 30 percent of women improve, 30 percent are unchanged, and 40 percent worsen during pregnancy. Although the disease has no adverse general effects on pregnancy outcome, he reported nine maternal deaths among 322 pregnancies. Most of these were due to complications of myasthenia or its treatment. Because the greatest period of risk is within the first year following diagnosis, [Cartledge \(2000\)](#) recommends that pregnancy be postponed until there is sustained symptomatic improvement.

Management during pregnancy includes close observation with liberal bed rest and prompt treatment of infection. Most patients respond well to pyridostigmine administered every 3 to 4 hours. Those in remission who become pregnant while taking corticosteroids or azathioprine should continue these medications. Acute onset of myasthenia or its exacerbation demands prompt admission and supportive care. Plasmapheresis should be used for emergency situations, taking care not to provoke maternal hypotension or hypovolemia ([Drachman, 1994](#)). There is at least one report of thymectomy performed in a 17-week pregnant woman ([lp and colleagues, 1986](#)).

Most women with myasthenia gravis tolerate labor without difficulty. Because the disease does not affect smooth muscle, labor usually proceeds normally. Oxytocin can be administered as necessary. Careful observation and prompt respiratory support are essential. Narcotics must be used with care, and any drug with a curare-like effect must be avoided—examples include magnesium sulfate, muscle relaxants used with general anesthesia, and aminoglycoside antibiotics. Amide-type local anesthetic agents are used for epidural analgesia for labor ([Bader, 1994](#)). Cesarean delivery is for obstetrical indications, with regional analgesia preferred unless there is significant bulbar involvement or respiratory compromise. During second-stage labor, some women may have impairment of voluntary expulsive efforts, and forceps delivery may be necessary.

NEONATAL EFFECTS. Acetylcholine-receptor antibodies have been detected in most myasthenic patients, and these IgG antibodies can be transferred to the fetus. Fortunately, only about 10 to 20 percent of neonates develop symptoms. [Vernet-der Garabedian and colleagues \(1994\)](#) have shown that newborns are more likely to have symptoms if their mothers produce autoantibodies directed against embryonic rather than adult acetylcholine receptors. Transient symptomatic myasthenia gravis in the affected infant is typically demonstrated by a feeble cry, poor suckling, and respiratory distress, which are corrected by parenteral neostigmine or small doses of edrophonium. Although symptoms resolve within 2 to 6 weeks as the antibodies are cleared, the perinatal death rate among offspring of myasthenic mothers was considerably higher than the background rate at 68 per 1000 ([Plauche, 1991](#)).

NEUROPATHIES

Peripheral neuropathy is a general term used to describe a disorder of peripheral nerve(s) due to a variety of causes. Its discovery should prompt a search for an etiology. Polyneuropathies are often associated with systemic diseases, such as diabetes and drugs, environmental toxins, and an imposing list of genetic diseases. Mononeuropathies signify focal involvement of a single nerve trunk and imply local causation such as trauma, compression, or entrapment.

GUILLAIN-BARRE SYNDROME. This is an acute demyelinating polyradiculoneuropathy. In over two thirds of cases, it follows clinical or serological evidence for viral infections, especially cytomegalovirus and Epstein-Barr virus. Approximately 10 percent of cases develop within weeks following a surgical procedure. In 1977, there was an epidemic of Guillain-Barre syndrome following immunization against swine influenza. The disease is thought to be immune mediated, but its pathogenesis is unclear. The pathological finding is a primary T-cell lymphocytic infiltration of cranial nerves, ventral and dorsal roots, dorsal root ganglia, peripheral nerves, lymph nodes, and liver, heart, spleen, and other organs, apparently occurring aberrantly in response to a precipitating infection ([Ropper, 1992](#)).

Clinical features include areflexic paralysis with mild sensory disturbances, and sometimes evidence of autonomic dysfunction. The full syndrome takes 1 to 3 weeks to develop. Management is supportive, but patients should be hospitalized because about 25 percent will need ventilatory assistance, and the mortality rate for this complication is high. Corticosteroids have not been effective, although plasmapheresis or intravenous high-dose immunoglobulin (2 g/kg over 5 days) have been shown to be of benefit if begun within 1 to 2 weeks of symptoms ([van der Meche and colleagues, 1992](#)). Almost 85 percent of patients will have full recovery, but about 3 percent will die from complications of the acute condition.

EFFECTS OF PREGNANCY. There does not appear to be an increased incidence of Guillain-Barre syndrome during pregnancy; however, the incidence is significantly increased postpartum. [Cheng and co-workers \(1998\)](#) reviewed all cases of Guillain-Barre occurring in Swedish reproductive-age women between 1978 and 1993 and found that the age-adjusted rate ratio was unchanged during pregnancy but was significantly increased threefold in the first 30 days after delivery. The first 2 weeks postpartum was a time of particularly increased risk.

Management is not changed by pregnancy. [Hurley and colleagues \(1991\)](#) described three pregnancies complicated by this syndrome and reviewed 31 others. As in nonpregnant patients, after an insidious onset, paresis and paralysis most often continued to ascend, and respiratory insufficiency then became a common and serious problem. About a third ultimately required ventilatory support, and overall maternal mortality was 13 percent. [Bravo and associates \(1982\)](#) successfully ventilated a mother for 5 weeks before delivery of a healthy infant. [Kuller and associates \(1995\)](#) and [Rockel and co-workers \(1994\)](#) described successful outcomes in pregnant women in whom plasmapheresis was performed. High-dose immunoglobulin may also be administered safely in pregnancy.

BELL PALS. This is an acute idiopathic peripheral facial paralysis of unknown etiology. It is thought to be a viral-induced mononeuropathy and is relatively common, especially in reproductive-age women. Women are affected two to four times more often than men of the same age, and pregnant women are affected three to four times more commonly than nonpregnant women ([Cohen and colleagues, 2000](#)). [Falco and Eriksson \(1989\)](#) reported an incidence of 1 in 2500 births at Brigham and Women's Hospital. Increased extracellular fluid, viral inflammation, and the relative immune suppression of pregnancy are thought to be predisposing factors. The onset is usually abrupt and painful, with maximum weakness within 48 hours. In some cases, hyperacusis and loss of taste accompany varying degrees of facial muscle paralysis. Electromyography may be helpful in determining prognosis—if denervation extends beyond 10 days, healing will be delayed and likely incomplete.

EFFECTS OF PREGNANCY. Pregnancy does not alter the overall good prognosis for spontaneous recovery from Bell palsy, and nearly 90 percent of affected women will recover function within a few weeks to months. Poor prognostic markers for incomplete recovery are bilateral disease and recurrence in a subsequent pregnancy ([Cohen and associates, 2000](#)). [Shapiro and co-workers \(1999\)](#) noted that hypertension or preeclampsia was present in over 20 percent of cases of Bell palsy, compared to only 5 percent in the general population. Treatment with short-term corticosteroids remains controversial, but the bulk of evidence suggests that these drugs do not hasten resolution. Surgical decompression is seldom indicated. Supportive care includes prevention of injury to the constantly exposed cornea, facial muscle massage, and reassurance. [Dorsey and Camann \(1993\)](#) have provided evidence that regional analgesia does not exacerbate the neuropathy.

CARPAL TUNNEL SYNDROME. This syndrome is characterized by hand and wrist pain extending into the forearm and sometimes into the shoulder. It is caused by compression of the median or (less frequently) ulnar nerve, which are especially vulnerable to compression within the carpal tunnel at the wrist. Typically, the woman awakens with burning, numbness, or tingling in the inner half of one or both hands, and the fingers feel numb and useless. Symptoms are bilateral in 80 percent of cases, and often exhibit a diurnal pattern ([Seror, 1998](#)). Although some symptoms of carpal tunnel syndrome are experienced by a fourth of pregnant women, new onset of the full syndrome is much less frequent. [Stolp-Smith and colleagues \(1998\)](#) made the diagnosis in less than 1 percent of nearly 11,000 pregnant women. [Ekman-Ordeberg and colleagues \(1987\)](#) verified carpal tunnel syndrome in 2.3 percent of almost 2400 pregnant women.

Carpal tunnel syndrome is self-limited, and treatment is symptomatic. A splint applied to the very slightly flexed wrist and worn during sleep usually provides relief. [Ekman-Ordeberg and colleagues \(1987\)](#) and [Courts \(1995\)](#) reported that this relieved pain in 80 percent of 132 women. Only three required surgical decompression. The signs and symptoms most often regress after delivery, although surgical decompression and corticosteroid injections are occasionally necessary ([Dammers and associates, 1999](#)). In the report by [Stolp-Smith and co-workers \(1998\)](#), 11 percent of women underwent surgery postpartum. In rare instances, symptoms may recur long after pregnancy and surgical release is necessary ([Al Qatten and colleagues, 1994](#)).

The syndrome should be distinguished from De Quervain tendinitis caused by swelling of the conjoined tendons and sheaths near the distal radius. [Schumacher and colleagues \(1985\)](#) described six women with tendinitis during pregnancy, and two also had carpal tunnel syndrome. Nerve conduction studies may be helpful in distinguishing these entities. [Seror \(1998\)](#) reported that two thirds of women with carpal tunnel syndrome had evidence of an acute median nerve lesion at the wrist with motor or sensory conduction blocks, or both, and approximately 10 percent had signs of severe denervation.

SPINAL CORD INJURY

Trauma, especially motor vehicle accidents, accounts for most spinal cord injuries. With well-organized trauma systems, almost 95 percent of patients with cord injuries survive the initial hospitalization ([Ditunno and Formal, 1994](#)). Most patients are young adults, who typically injure the cervical or thoracic spine. Lesions

caused by trauma or tumor do not prevent conception, and pregnancy outcome is usually good. In a survey of 472 reproductive-age women with spinal cord injury, [Jackson and Wadley \(1999\)](#) found that approximately 67 percent of affected women had intercourse after the injury, and almost 14 percent became pregnant. Women with spinal cord injury had lower birthweight infants and experienced more pregnancy complications than unaffected women. Complications included urinary tract infections, anemia, pressure necrosis of skin, and aggravation of constipation ([Baker and associates, 1992](#); [Hughes and colleagues, 1991](#)). Over half of women have significant bowel dysfunction ([Glickman and Kamm, 1996](#)). [Westgren and co-workers \(1993\)](#) described 49 pregnancies in 29 women with traumatic cord injuries. Three fourths developed urinary infections, there was a 20 percent preterm delivery rate, and perinatal mortality was 3.8 percent.

There are two serious and life-threatening complications that can develop. If the lesion is above T₁₀, the cough reflex will be impaired and respiratory function may be compromised. Pulmonary function should be determined before or early in pregnancy, and carefully monitored throughout gestation. In some cases, women with high lesions may need ventilatory support in late pregnancy or in labor. In women with lesions above T₅₋₆, autonomic hyperreflexia can occur. In this potentially life-threatening event, splanchnic nerves are excited by some stimulus and are not dampened because of lack of central inhibition. The resultant sudden sympathetic stimulation of nerves below the cord lesion causes a throbbing headache, facial flushing, sweating, bradycardia, and paroxysmal hypertension. A variety of stimuli including urethral, bladder, rectal, or cervical distention, catheterization, cervical dilatation, uterine contractions, or examination of pelvic structures may precipitate dangerous hypertension, which must be treated immediately. In the report by [Westgren and colleagues \(1993\)](#), 12 of 15 women at risk suffered at least one episode of autonomic hyperreflexia. Spinal or epidural analgesia can prevent or avert dysreflexia, and should be instituted at the start of labor. General anesthesia is not preferred because the depth of anesthesia necessary to control the spasms and dysreflexia can cause hypotension and respiratory dysfunction ([Hambly and Martin, 1998](#)).

Uterine contractions are not affected by cord lesions. Indeed, labor is often easy, even precipitous, and comparatively painless. If the lesion is below T₁₂, then contractions are felt normally. There is great concern that women with lesions above T₁₂ may deliver at home unattended before they realize that labor has begun. However, these women can be taught to palpate uterine contractions, or home tocodynamometry can be used. Serial examinations with admission for advanced cervical dilatation or effacement may also be helpful, and some authorities recommend weekly cervical examinations beginning at about 28 weeks. [Hughes and associates \(1991\)](#) recommend elective admission between 36 and 37 weeks.

Delivery is preferably vaginal. The [American College of Obstetricians and Gynecologists \(1993b\)](#) recommends continuous cardiac rhythm monitoring along with intra-arterial pressure monitoring. Epidural or spinal analgesia is used to minimize autonomic hyperreflexia. In some cases, second-stage labor may be prolonged due to diminished expulsive efforts. [Westgren and colleagues \(1993\)](#) cited a cesarean rate of 63 percent, but concluded that this was because of inexperience of the health-care providers.

SHUNTS FOR MATERNAL HYDROCEPHALUS

Many cases of pregnancy have been described in women with ventriculoperitoneal, ventriculoatrial, or ventriculopleural shunts for hydrocephalus. Pregnancy outcomes have usually been satisfactory. Although [Landwehr and colleagues \(1994\)](#) reported no shunt complications during eight pregnancies in four women with ventriculoperitoneal shunts, others have reported shunt obstruction, typically late in pregnancy. [Wisoff and associates \(1991\)](#) described 21 pregnancies in 18 women with various shunts. Neurological complications developed in 13 of 17 pregnancies in women with preexisting shunts, including headaches (60 percent), nausea and vomiting (35 percent), lethargy (30 percent), ataxia (20 percent), and gaze paresis (20 percent). Most responded to conservative management. Computed tomography discloses acute hydrocephaly, which can be relieved by tapping the shunt or pumping it several times daily. Surgical revision may be necessary.

In women with shunts, vaginal delivery is preferred, and unless there is a meningomyelocele, epidural analgesia is permitted ([Bader, 1994](#)). Subarachnoid block is felt by some authorities to be contraindicated, but others support its use ([Littleford and colleagues, 1999](#)). Antimicrobial prophylaxis is indicated if the peritoneal cavity is entered for cesarean delivery or tubal sterilization.

BRAIN DEATH

A few instances of maternal brain death during pregnancy have been described in which life support systems and parenteral alimentation were used for extended periods of time while the fetus achieved maturity ([Dillon and associates, 1982](#); [Field and colleagues, 1988](#)). In the case described by [Bernstein and co-workers \(1989\)](#), life support was begun at 15 weeks for a brain-dead woman and continued until 32 weeks. [Catanzarite and colleagues \(1997\)](#) described a case of brain death at 25 weeks in which aggressive tocolysis and antibiotic therapy were required to continue the pregnancy another 25 days. Such therapy is not always successful ([Vives and collaborators, 1996](#)). The ethical, financial, and legal implications, both civil and criminal, that may arise from attempting or not attempting such care are profound.

BENIGN INTRACRANIAL HYPERTENSION (PSEUDOTUMOR CEREBRI)

This condition is characterized by headache, stiff neck, visual disturbances, and papilledema from increased intracranial pressure in an otherwise healthy individual. Its cause is thought to be overproduction or underabsorption of cerebrospinal fluid. It is commonly found in young women, especially those who are obese or who recently have gained weight. It is probably not more prevalent during pregnancy, as once believed ([Ireland and associates, 1990](#)). Criteria for diagnosis include elevated cerebrospinal fluid pressure, normal cerebrospinal fluid composition, and normal cranial computed tomography or magnetic resonance imaging. In some patients, spinal fluid protein concentration may be low. Interestingly, [Bates and associates \(1982\)](#) reported that men and nonpregnant women with this condition had significantly increased cerebrospinal fluid prolactin concentrations.

Pseudotumor is usually self-limited; however, permanent visual impairment may develop in a significant number of patients, and optic atrophy can cause blindness. Treatment is aimed at prevention of visual defects by lowering the elevated pressure. Repetitive lumbar punctures to remove cerebrospinal fluid will lower pressure, and can be performed safely without brainstem herniation if there is no ventriculomegaly. Drugs that can be given safely during pregnancy to lower pressure include acetazolamide, furosemide, or dexamethasone. In rare cases, lumboperitoneal shunting of spinal fluid is necessary.

EFFECTS OF PREGNANCY. Benign intracranial hypertension is usually detected by midpregnancy, is self-limited, and resolves postpartum. Headache is the presenting symptom in 95 percent of women, and almost 75 percent have blurred vision. It is arguable whether the incidence of pseudotumor is increased in pregnancy. [Katz and colleagues \(1989\)](#) reported it in about 1 in 1000 pregnancies. They described 11 such pregnancies and concluded that pregnancy increased the likelihood of symptoms in women who already had intracranial hypertension. They also reported a 30 percent recurrence rate. In our experiences, the incidence is not nearly so high.

Treatment of benign intracranial hypertension during pregnancy is identical to that for nonpregnancy. Any perceived increased risk of pregnancy complications is probably due to the associated obesity, and not to the pseudotumor. From their review of 54 pregnancies, [Katz and associates \(1989\)](#) did not report increased adverse perinatal outcomes. Labor is permitted, the route of delivery is decided by obstetrical indications, and epidural analgesia is not contraindicated. [Landwehr and colleagues \(1994\)](#) have described four women in whom lumboperitoneal shunting was performed.

CHOREA GRAVIDARUM

Any chorea that develops during pregnancy is known as chorea gravidarum ([Golbe, 1994](#)). Because cases in the past were linked to rheumatic fever, chorea is now rare. It can still occur in association with streptococcus A infection, but more often may be caused by collagen-vascular disease ([Prasher and Barrett, 1993](#)). Up to 2 percent of patients with systemic lupus erythematosus exhibit chorea ([Branch, 1990](#)). Most of these patients have antiphospholipid antibodies ([Chap. 52, p. 1391](#)). [Omdal and Roalso \(1992\)](#) described a woman with chorea gravidarum who had a recurrence while taking steroidal contraceptives 20 years later.

PSYCHIATRIC DISORDERS

Pregnancy and the puerperium are at times sufficiently stressful to provoke mental illness. Such illness may represent recurrence or exacerbation of a preexisting psychiatric disorder, or it may be the onset of a new disorder. The Department of Health and Human Services has reported that 1 of every 8 persons will suffer from a depressive disorder and that the rate is almost doubled for women ([Depression Guideline Panel, 1993](#)). Unfortunately, depression is appropriately treated in fewer than a fourth of affected women ([American College of Obstetricians and Gynecologists, 1993a](#)). The under-recognition of depression frequently occurs in primary care settings where most medical care is obtained. Similarly, women who suffer with postpartum depression are often not properly identified and treated.

PSYCHOLOGICAL ADJUSTMENT TO PREGNANCY. While pregnancy often evokes overwhelming joy, it is also stressful for most women. In some women with ambivalent feelings about the pregnancy, stress may be appreciably increased. Response to stress may be seen in a variety of subtle or not so subtle ways. For

example, many women express concerns about whether their baby is normal. For those whose fetus is at higher risk for a congenital malformation, stress is increased ([Tunis and Golbus, 1991](#)). Throughout pregnancy, and especially toward term, anxiety develops about child care and the lifestyle changes that will ensue after delivery. In a number of women, the fear of childbirth pain is particularly stressful. Pregnancy experiences may be altered by medical and obstetrical complications that may ensue. [Burger and colleagues \(1993\)](#) have shown that women who suffer complicated pregnancies are twice as likely to have fear for their fetus or to become depressed.

For those women with a history of psychiatric illness, pregnancy is often a time of general well-being. Indeed, mood disorders with their initial onset during pregnancy tend to be milder ([O'Hara and colleagues, 1984](#)). However, for women who have serious forms of mental disorders that predate pregnancy—in particular bipolar illness, schizoaffective disorder, or schizophrenia—the illness may not remain quiescent.

By contrast, the puerperium has long been recognized as a time of increased risk for mental illness. According to [Weissman and Olfson \(1995\)](#), 10 to 15 percent of recently delivered women will develop a nonpsychotic postpartum depressive disorder. In some, severe, psychotic depressive or manic illness follows delivery. Although puerperal psychosis is not a separate diagnosis, a woman is at least 30 times more likely to require admission for a psychotic or severe mental illness in the month following delivery than she is in the previous 2 years ([Kendell and colleagues, 1987](#)). Importantly, preexisting mental illness has a high recurrence rate in the puerperium. Despite this predilection, suicide is uncommon during pregnancy and the year following delivery ([Appleby, 1991](#)).

PRENATAL EVALUATION. Issues concerning mental health should be addressed. Screening for mental illness should be performed during the first prenatal examination. This involves obtaining a history of any prior psychiatric disorders, including hospitalizations, outpatient care, and prior or current use of psychoactive medications. Current symptoms that might indicate mental dysfunction should be investigated. According to [Oates \(1989\)](#), 15 to 20 percent of pregnant women will have mental health issues that need to be considered in their management. Certain conditions such as anxiety and depression may be associated with an increased risk of preterm delivery ([Paarlberg and associates, 1996](#)).

Risk factors for mental illness should also be carefully evaluated. A history of sexual abuse increases the risk for depressive illness. [Benedict and co-workers \(1999\)](#), in a study involving 357 high-risk pregnant women, reported that women with a past history of sexual abuse were significantly more likely to report depressive symptomatology, negative life events, and physical and verbal abuse before and during pregnancy. Substance abuse, violence, and depression also appear to be linked. [Horrihan and colleagues \(2000\)](#) found that women who reported a history of substance abuse were highly likely to have severe depression or to be a victim of physical or sexual abuse, or both. They recommended that women who report one of these factors be carefully monitored for evidence of the other two (also [Chap. 9, p. 210](#)). Because eating disorders are exacerbated by pregnancy, evidence of such a disorder should also prompt careful follow-up during pregnancy.

CLASSIFICATION OF MENTAL DISORDERS

The American Psychiatric Association last revised its Diagnostic and Statistical Manual (DSM-IV) in 1993. Its purpose is to classify mental disorders and specify criteria required for their diagnosis.

MAJOR MOOD DISORDERS. These disorders include major depression, considered a unipolar disorder, and bipolar disorder or manic-depressive illness, which includes manic and depressive episodes. Primary mood disorders occur de novo, while both depressive and manic disorders are significantly influenced by genetic factors. First-degree relatives of individuals with manic depression are at 15 percent risk of being similarly affected ([McInnis and DePaulo, 1996](#)). A number of provocative conditions can also lead to mood disorders. For depression, these include grief reactions, substance abuse, use of certain medications, and other medical disorders ([Depression Guideline Panel, 1993](#)). Potential causes of mania or manic symptoms include substance abuse such as cocaine, hyperthyroidism, and central nervous system tumors. The importance of detecting major mood disorders is underscored when one considers that they are a predisposing factor in up to two thirds of suicides in the United States.

SCHIZOPHRENIA. This is a common major form of mental illness, with a 6-month prevalence rate of about 1 percent ([Myers and colleagues, 1984](#)). Its morbidity is higher than for any other psychiatric disorder. Its hallmarks include delusions, hallucinations, incoherence, and inappropriate affect. Four major subtypes of schizophrenia are recognized: catatonic, disorganized, paranoid, and undifferentiated. Schizophrenia has a major genetic component, with 50 percent concordance with monozygotic twins. If one parent is schizophrenic, the empirical risk to offspring is 5 to 10 percent. The onset of illness is around age 20 and commonly, work and psychosocial functioning deteriorate over time. Women have a slightly later onset than men, and may occasionally marry and become pregnant before they fall ill. With appropriate treatment, patients may experience a decrease or cessation of symptoms such that the 5-year social recovery is 60 percent. For all patients at 5 years, half are employed, 30 percent are mentally handicapped, and 10 percent require continued hospitalization.

Patients with a schizoaffective disorder have a chronic deteriorating psychotic disorder similar to schizophrenia, but combined with prominent mood symptoms. Although the psychosis rarely abates, the mood symptoms often improve with therapy, giving this condition a better prognosis than schizophrenia.

ANXIETY DISORDERS. These disorders involve paroxysmal and persistent psychological feelings of dread, irritability, and ruminations that are accompanied by physiological changes such as sweating, dyspnea, insomnia, and trembling. Anxiety disorders are commonly encountered in everyday medical practices, and they are more easily recognized when subdivided into panic disorder, obsessive-compulsive disorder, post-traumatic stress disorder, and phobic disorder.

PERSONALITY DISORDERS. These disorders are characterized by the chronic use of certain coping mechanisms in an inappropriate, stereotyped, and maladaptive manner. The Diagnostic and Statistical Manual recognizes three clusters of personality disorders:

1. Paranoid, schizoid, and schizotypal personality disorders, which are characterized by oddness or eccentricity.
2. Histrionic, narcissistic, antisocial, and borderline disorders, which are all characterized by dramatic presentations along with self-centeredness and erratic behavior.
3. Avoidant, dependent, compulsive, and passive/aggressive personalities, which are characterized by underlying fear and anxiety.

Genetic and environmental factors are important in the genesis of these disorders, whose prevalence may be as high as 20 percent. Management is through psychotherapy; however, only about 20 percent of affected individuals recognize their problems and seek psychiatric help.

EFFECTS OF PREGNANCY ON MENTAL ILLNESS

It is difficult to differentiate biochemical factors from life stressors as a primary cause of mental illness in pregnancy. Hormones are known to affect mood, as evidenced by premenstrual syndrome and menopausal depression. The absolute level of hormone appears to be important. Estrogen modulates serotonergic function, has been used therapeutically to treat depression, and may be a factor in the mood elevation experienced by many women during pregnancy ([Joffe and Cohen, 1998](#)). Conversely, corticotropin-releasing hormone, which is usually elevated in pregnancy, is present at lower levels in women with pregnancy-related depression ([Schmeelk and colleagues, 1999](#)). The rate of change of hormone levels also appears to be influential. Women who experience postpartum depression often have higher predelivery estrogen and progesterone levels, and experience a greater drop to lower levels postpartum ([Ahokas and co-workers, 1999](#); [Harris and associates, 1994](#)).

It is also true, however, that pregnancy is a major life stressor that can unmask or exacerbate depressive tendencies. According to [Weissman and Olfson \(1995\)](#), almost 10 percent of pregnant women meet diagnostic criteria for major depression. It is more likely with marital problems, unwanted pregnancy, and a personal or family history of depression. [Seguin and co-workers \(1995\)](#) further showed that women of low socioeconomic status are more depression prone. [Bergant and colleagues \(1999\)](#) correlated pregnancy-related depression to low socioeconomic status as well as increased burden from children, diminished life satisfaction, and increased anxiety. [Bryan and co-workers \(1999\)](#), in a study that included the population of Olmstead County Minnesota, found that pregnancy-related depression was associated with young maternal age, single marital status, tobacco or illegal drug use during pregnancy, hyperemesis gravidarum, high utilization of emergency services, and previous affective disorder.

POSTPARTUM DISORDERS

MATERNITY BLUES. Also called *postpartum blues*, this is a mood disturbance experienced by approximately 50 percent of women within 3 to 6 days after parturition ([Kendell and colleagues, 1987](#)). There is evidence that blues are precipitated by progesterone withdrawal ([Harris and co-workers, 1994](#)).

Although a variety of symptoms have been assessed, core features include insomnia, weepiness, depression, anxiety, poor concentration, irritability, and affective

lability. Obviously, these are common symptoms present in minor or even major depressive episodes. Affective lability describes the changeable mood experienced by many of these women. They may be transiently tearful for several hours and then recover completely, only to be tearful again the next day. Importantly, symptoms are mild and usually only last between a few hours to a few days. Supportive treatment is indicated, and mothers can be reassured that the dysphoria is transient and most likely due to the biochemical changes. They should be monitored for development of more severe psychiatric disturbances including postpartum depression or psychosis.

POSTPARTUM DEPRESSION. In nearly all respects, postpartum depression is similar to other major and minor depressions that develop at any time. Typically, depression is considered postpartum if it begins within 3 to 6 months after childbirth. Criteria for diagnosis of major depression are given in [Table 53-5](#).

Depressive disorders with an onset within 2 to 3 months of delivery develop in approximately 8 to 15 percent of postpartum women. This incidence is only slightly higher than the usual 6-month prevalence for depression among women in the general population. Certain groups of women have a much higher likelihood of developing depression during the puerperium. Adolescents and women with a history of a depressive illness each have a risk of postpartum depression of about 30 percent ([Weissman and Olfson, 1995](#)). Up to 70 percent of women with previous postpartum depression will have a subsequent episode. Finally, if a woman has both a previous puerperal depression and current episode of blues, her chances of developing a major depression increase to 85 percent ([Hannah and associates, 1992](#)).

COURSE AND TREATMENT. The natural course is one of gradual improvement over the 6 months after delivery ([Fleming and colleagues, 1992](#)). The prospects for full recovery are generally good. [Pfuhlmann and colleagues \(1999\)](#) reexamined 39 women 6 to 26 years after they suffered from a postpartum psychiatric illness. They reported that although half of the women relapsed in a subsequent delivery, only 10 percent never recovered completely. Almost 15 percent had a monophasic course with full recovery, and half had a multiphasic course with an average of 2.5 depressive episodes per patient with eventual full recovery.

Because in some cases the woman may remain symptomatic for months to years, maternal depressive illness may affect the quality of her relationship with her child. Depressed mothers have shown less social interaction and play facilitation with their children ([Stein and associates, 1991](#)).

Supportive treatment alone is not sufficient for major postpartum depression. Pharmacological intervention is needed in most instances, and affected women should be managed in conjunction with a psychiatrist. Treatment options include antidepressants, anxiolytic agents, and electroconvulsive therapy. As discussed in [Chapter 38 \(p. 1026\)](#), some psychotropic medications pass into breast milk and can cause neonatal sedation, and lithium toxicity has been reported ([Chaudron and Jefferson, 2000](#); [Ito, 2000](#)). Bottle feeding should therefore be considered.

Treatment also includes monitoring for thoughts of suicide or infanticide, emergence of psychosis, and response to treatment. Psychotherapy focuses on the woman's fears and concerns regarding her new responsibilities and roles. For some women, the course of illness is severe enough to warrant hospitalization.

POSTPARTUM PSYCHOSIS. This is the most worrisome and severe puerperal mental disorder. It is estimated to occur in 1 to 4 of 1000 births ([Weissman and Olfson, 1995](#)). In our experiences, it is not nearly so common. Women with postpartum psychosis lose touch with reality. They have stretches of lucidity alternating with psychosis. Also frequently noted are symptoms of confusion and disorientation that are often seen in toxic states or delirium.

Two types of women seem to be susceptible: women with an underlying depressive, manic, schizophrenic, or schizoaffective disorder, and women who have had a history of depression or a severe life event in the preceding year ([Kumar and associates, 1993](#)). Women with preexisting psychotic illness are at highest risk, with bipolar disorder and schizoaffective disorder being the most strongly associated. A brief interval between the earlier psychiatric episode and parturition increases the likelihood of relapse. Other risk factors are biologically related and include younger age, primiparity, and family history of psychiatric illness. [Marks and co-workers \(1991\)](#) studied 88 high-risk women after childbirth. Of these, 45 women had no previous psychiatric disorder and 43 had a history of psychosis. A fourth developed postpartum psychosis, and all these cases occurred in women with a history of bipolar or schizoaffective disorder. Another fourth had a nonpsychotic postpartum depression, and all these cases were in women with a history of a severe life event.

Approximately a quarter of women who have had one episode of postpartum psychosis will have a recurrence in the next pregnancy. This statistic emphasizes the need to identify women with a prior history and to monitor them closely. The peak onset of psychotic symptoms is 10 to 14 days after parturition, but the risk remains high for months after delivery ([Brockington and colleagues, 1981](#)). Even though rare, the risk of a psychotic episode during the postpartum period is still 10 to 15 times greater than at other times during a woman's life. In most instances, women with this disorder will go on to develop a relapsing psychotic illness that recurs during times unrelated to pregnancy or parturition.

COURSE AND TREATMENT. The course is variable and depends upon the type of underlying illness. For those with manic-depressive and schizoaffective psychoses, the time to recovery is about 6 months ([Sneddon, 1992](#)). The clinical course of bipolar illness or schizoaffective disorder in puerperal women is comparable to that of nonpuerperal women. The most impaired level of functioning at follow-up is among those suffering from schizophrenia. These women should be referred for psychiatric care. The severity of postpartum psychosis mandates pharmacological treatment and, in most cases, hospitalization. The woman who is psychotic usually will have difficulty in caring for her infant, and may have delusions leading to thoughts of self-harm or harm of the infant. Fortunately, reports from mother-baby psychiatric units claim few incidents of infant harm.

TREATMENT OF MENTAL DISORDERS

A large number of psychotropic medications are now available for management of mental disorders ([Kuller and colleagues, 1996](#)). The fetal risks are discussed in [Chapter 38 \(p. 1026\)](#). Most pregnant women requiring pharmacotherapy have preexisting severe psychiatric illnesses such as bipolar disorder, schizoaffective disorder, schizophrenia, or recurrent major depression. Other women requiring treatment are those who have an emotional disorder that evolves during pregnancy.

ANTIDEPRESSANTS. Ethical considerations for managing depressed pregnant women have been reviewed by [Coverdale and colleagues \(1996\)](#). Severe depression requires treatment and, in most cases, the benefits of therapies outweigh the risks. Tricyclic antidepressants such as amitriptyline, doxepin, imipramine, and nortriptyline are commonly used for depressive disorders. Maternal side effects include orthostatic hypotension, and constipation. Sedation is also common, making these medications particularly helpful with depression-associated sleep problems. Monoamine oxidase inhibitors (MAOIs) are very effective antidepressants that are used less frequently because they cause orthostatic hypotension. Also, simultaneous administration of meperidine and some anesthetic agents can stimulate a life-threatening hyperthermic crisis ([Mortola, 1989](#)). Experience with selective serotonin reuptake inhibitors (SSRIs), including fluoxetine and sertraline, has made them the primary treatment for most depressive illnesses. They do not cause orthostatic hypotension, constipation, or sedation, which makes them preferable to other antidepressants.

ANTIPSYCHOTICS. Women with severe psychiatric syndromes such as schizophrenia, schizoaffective disorder, or bipolar disorder have a high likelihood of requiring antipsychotic treatment during pregnancy. Typical antipsychotics are dopamine antagonists. Clozapine is the only available atypical antipsychotic, and it has a different but unknown action. Antipsychotics differ by potency and side-effect profile. The lower-potency agents, chlorpromazine and thioridazine, have greater anticholinergic properties and are sedating.

LITHIUM. The safety of lithium during pregnancy is controversial ([Chap. 38, p. 1027](#)). In addition to concerns about teratogenicity, there are considerations of its narrow therapeutic index. Lithium toxicity in the breast-feeding newborn has been reported.

BENZODIAZEPINES. These may be required during pregnancy for women who have severe and debilitating anxiety disorders or for assaultive or agitated psychotic patients. Diazepam may be associated with prolonged neonatal neurological depression when given close to delivery.

ELECTROCONVULSIVE THERAPY. Treatment of depression with electroshock during pregnancy is occasionally necessary for the woman with a major mood disorder unresponsive to pharmacological therapy. [Griffiths and colleagues \(1989\)](#) reported results obtained in a woman who underwent 11 such treatments from 23 to 31 weeks. They used thiethylal and succinylcholine, intubation, and assisted ventilation during each treatment. They found that plasma levels of epinephrine, norepinephrine, and dopamine were elevated two- to threefold within minutes of electroshock. Despite this, the fetal heart rate tracing and maternal heart rate, blood pressure, and oxygen saturation remained normal. [Varan and co-workers \(1985\)](#) described a variable fetal heart rate deceleration characteristic of cord compression during electroconvulsive therapy. [Sherer and associates \(1991\)](#) described a woman who underwent seven weekly antepartum electroconvulsive treatments beginning at 30 weeks. Each treatment was followed by hypertension, uterine hypertonicity, and uterine bleeding ([Fig. 53-3](#)). Subsequently, placental abruption was shown to be the cause. [Miller \(1994\)](#) reviewed 300 published case reports of electroconvulsive therapy during pregnancy, and found that complications occurred in about 10 percent. These included transient benign fetal arrhythmias, mild vaginal bleeding, abdominal pain, and self-limited uterine contractions. Women who were not adequately prepared also had an increased risk for aspiration, aortocaval compression, and respiratory alkalosis. Important preparatory steps include cervical assessment, discontinuation of nonessential anticholinergic medication, uterine and fetal heart rate monitoring, intravenous hydration, administration of a

nonparticulate antacid, and positioning in left lateral tilt. During the procedure, excessive hyperventilation should be avoided and the airway should be protected.

TABLE 53-3. Treatment with Antiepileptic Drugs, According to Type of Seizure and Epileptic Syndrome

Type of Seizure and Epileptic Syndrome	First-Line Drug	Second-Line Drug
Primary generalized		
Absence seizures ^a	Ethosuximide, valproic acid ^b	Lamotrigine
Myoclonic seizures ^a	Valproic acid ^b	Acetazolamide, clonazepam, lamotrigine, primidone
Tonic-clonic seizures	Valproic acid, ^b carbamazepine, phenytoin	Lamotrigine, phenobarbital, primidone
Absence epilepsy with onset in childhood ^a	Ethosuximide	Valproic acid, ^b lamotrigine
Absence epilepsy with onset in adolescence ^a	Valproic acid ^b	Ethosuximide, lamotrigine
Juvenile myoclonic epilepsy ^a	Valproic acid ^b	Acetazolamide, clonazepam, primidone, lamotrigine
Infantile spasms (West syndrome)	Corticotropin ^c	Clonazepam, valproic acid ^b
Lennox-Gastaut syndrome	Valproic acid, ^b lamotrigine	Carbamazepine ^d
Partial		
Simple partial seizures, complex partial seizures, secondarily generalized tonic-clonic seizures, and partial epileptic syndromes	Carbamazepine, phenytoin	Gabapentin, lamotrigine, phenobarbital, primidone, tiagabine, topiramate, valproic acid ^{b, e}

^a Carbamazepine and phenytoin are contraindicated.

^b Divalproex sodium may be better tolerated than valproic acid.

^c Vigabatrin, which is not marketed in the United States, may be an alternative first-line drug where available.

^d Clonazepam, felbamate, phenobarbital, primidone, or vigabatrin may be used alternatively.

^e Methsuximide may be used alternatively for any of the partial seizures or partial epilepsy syndromes.

TABLE 53-5. Criteria for Major Depressive Episode

At least five^a of the following symptoms for a 2-week period; one symptom must be either depressed mood or loss of interest or pleasure nearly every day:

1. Depressed mood most of the day
2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day
3. Significant weight loss or weight gain when not dieting, or decrease or increase in appetite
4. Insomnia or hypersomnia
5. Psychomotor agitation or retardation
6. Fatigue or loss of energy
7. Feelings of worthlessness or excessive or inappropriate guilt
8. Diminished ability to think or concentrate
9. Recurrent thoughts of death, recurrent suicidal ideation without a specific plan or a suicide attempt

The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Symptoms are not due to the direct effects of a substance or general medical condition.

Symptoms are not within 2 months of the loss of a loved one.

In severe cases, may be accompanied by psychosis (bizarre or paranoid thought).

^a Minor depression requires 2 weeks of depressed mood and fewer than five symptoms. Adapted from American Psychiatric Association (1993).

54. Dermatological Disorders

Most skin diseases are encountered with similar frequency in pregnant and nonpregnant women. There are, however, a number of skin changes induced by the hormonal influences of pregnancy. For example, episodes of pruritus are common during pregnancy, and in many instances, itching is not accompanied by a skin eruption. A common etiology is intrahepatic cholestasis and bile salt retention, commonly known as *pruritus gravidarum* ([Chap. 48, p. 1283](#)). There also are a number of pregnancy-specific dermatoses that usually are symptomatic and thus may be alarming. Importantly, some of these may be associated with adverse pregnancy outcomes.

PHYSIOLOGICAL SKIN CHANGES IN PREGNANCY

Hormonal changes induced by normal pregnancy may have rather remarkable influences on the skin. As discussed in [Chapters 6 and 8](#), fetoplacental hormone production, stimulation, or alteration of clearance may increase the plasma availability of estrogens, progesterone, and a variety of androgens. Similarly, there are profound changes in the availability or concentrations of some adrenal steroids, including cortisol, aldosterone, and deoxycorticosterone. Presumably related to enlargement of the intermediate lobe of the pituitary gland, plasma levels of melanocyte-stimulating hormone (MSH) become remarkably elevated by 8 weeks' gestation. Production of pro-opiomelanocortin has been demonstrated in placental extracts, and this ultimately is a source of α - and β -melanocyte-stimulating hormone. In their review, [Paus and Cotsarelis \(1999\)](#) describe hair-growth modulation by estrogens, androgens, thyroid hormones, glucocorticoids, and prolactin.

HYPERPIGMENTATION

According to [Vaughan Jones and Black \(1999\)](#), some degree of skin darkening is observed in 90 percent of all pregnant women. Its exact cause is not known, but it is doubtful that elevated serum levels of melanocyte-stimulating hormone are responsible. Estrogens play a role in melanogenesis in mammals and may be the inciting factor. Hyperpigmentation is evident beginning early in pregnancy, and this is more marked in dark-skinned women. These effects are more pronounced in naturally hyperpigmented areas such as the areolae, perineum, and umbilicus. Areas prone to friction, including the axillae and inner thighs, also may become darkened. When the *linea alba* becomes pigmented, it is renamed the *linea nigra*.

Pigmentation of the face, referred to as the mask of pregnancy, is also called *chloasma* or *melasma*. This is seen in at least half of pregnant women. Melasma is aggravated by sunlight or other ultraviolet light exposure; its severity may be altered by avoiding excessive exposure and using sunscreens. It is caused by melanin deposition into epidermal or dermal macrophages, and although the former usually regresses postpartum, dermal melanosis may persist up to 10 years in a third of women. Oral contraceptives may aggravate melasma and should be avoided in susceptible women. If particularly disfiguring, topical application of 2 to 5 percent hydroxyquinone or 0.1 percent tretinoin ointment or cream may provide some improvement ([Griffiths and colleagues, 1993](#); [Kimbrough-Green and co-workers, 1994](#)). Sunscreen use should be continued.

NEVI

All persons have some form of benign or melanocytic nevi. It has been taught that these pigmented cutaneous tumors commonly enlarge and darken during pregnancy, and they may be confused with malignant melanomas. Recently, however, [Pennoyer and colleagues \(1997\)](#) carefully observed these benign lesions and found that only 6 percent of 129 nevi changed in diameter over pregnancy. Four of these increased by 1 mm, and four decreased by 1 mm. They concluded that the more striking changes were in nonmelanocytic lesions. Thus, although nevi are shown histologically to have enlarged melanocytes and increased melanin deposition, there is no evidence that they undergo malignant transformation during pregnancy. According to the study by the World Health Organization Melanoma Program, the average malignant tumor is slightly but significantly thicker when discovered during pregnancy ([Mackie and colleagues, 1991](#)). These authors concluded that this represents either a delay in identification or pregnancy-induced melanoma stimulation. Malignant melanoma is discussed in detail in [Chapter 55 \(p. 1447\)](#).

CHANGES IN HAIR GROWTH

During pregnancy, there is an increased proportion of *anagen*—growing hairs, to that of *telogen*—resting hairs ([Lynfield, 1960](#); [Randall, 1994](#)). Estrogens prolong the anagen state and androgens enlarge hair follicles in dependent areas such as the beard ([Paus and Cotsarelis \(1999\)](#)). Postpartum, these effects are lost and shedding of hair becomes prominent. *Telogen effluvium* describes the rather abrupt hair loss that is seen beginning approximately 1 to 4 months postpartum. This process is sometimes characterized by alarming amounts of hair shedding, usually associated with brushing or washing. Fortunately, the process is self limited, and the woman may be reassured that normal hair growth is usually restored by 6 to 12 months ([Headington, 1993](#); [Kois and Phelan, 1994](#)).

Mild hirsutism is common during pregnancy, and this may be most noticeable on the face. Women who are predisposed genetically to coarse hair growth are affected most profoundly. More severe degrees of hirsutism are unusual, and if accompanied by other evidence for masculinization, this should prompt consideration for another androgen source. We have cared for several pregnant women at Parkland Hospital who had virilization caused by adrenal tumors or pregnancy luteomas ([Chap. 8, p. 171](#)).

VASCULAR CHANGES

Augmented cutaneous blood flow in pregnancy is associated with marked decreases in peripheral vascular resistance ([Spetz, 1964](#)). This is thought to serve to dissipate excess heat generated by increased metabolism. There are a number of presumably estrogen-induced changes in the small vessels that are encountered with some frequency. Spider angiomas are found in two thirds of white women and about 10 percent of African Americans during pregnancy ([Wong and Ellis, 1984](#)). Most of these vascular lesions regress postpartum. Palmar erythema is likewise more commonly noticed in whites—two thirds, than in blacks—one third. Capillary hemangiomas, especially of the head and neck, are seen in about 5 percent of women during pregnancy.

One vascular condition that may be distressing is *pregnancy gingivitis*, which is caused by growth of the gum capillaries. This so-called *epulis of pregnancy* may become more severe as gestation progresses, but it may be controlled by proper dental hygiene and avoidance of trauma. Epulis should not be confused with *pyogenic granuloma of pregnancy*, which is also called *granuloma gravidarum*. These lesions are typical pyogenic granulomas, which are found in the oral cavity and often arise from the gingival papillae. [Powell and colleagues \(1994\)](#) described laser excision of a large granuloma in a 37-week pregnant woman.

DERMATOSES OF PREGNANCY

A number of dermatological conditions have been identified as unique to pregnancy, or if not unique, they are encountered with a greater frequency during gestation. Terminology has been confusing. [Shornick \(1998\)](#) concluded that only three conditions are universally accepted as unique to pregnancy: cholestasis, pruritic urticarial papules and plaques of pregnancy, and herpes gestationis ([Table 54-1](#)). Pruritus during pregnancy is common, but the incidence is obviously subject to subjective reporting. In nearly 3200 pregnant women who were carefully studied over one year, [Roger and colleagues \(1994\)](#) found that 1.6 percent had significant pruritus by their protocol.

CHOLESTASIS OF PREGNANCY

This syndrome includes *pruritus gravidarum* and *cholestatic jaundice of pregnancy*. In the study of 3200 pregnant women by [Roger and associates \(1994\)](#), 51 (1.6 percent) women had pruritus, and 22 women (0.6 percent of the total) had pruritus gravidarum. The disorder is considered to be a mild variant of intrahepatic cholestasis of pregnancy ([Chap. 48, 1283](#)). Bile salts deposited in the dermis cause pruritus, and skin lesions develop with scratching and excoriation. The gross appearances and clinical presentation of these dermatoses may be confusing ([Table 54-1](#)).

PRURITIC URTICARIAL PAPULES AND PLAQUES OF PREGNANCY

Pruritic urticarial papules and plaques of pregnancy (PUPPP), referred to as *polymorphic eruption of pregnancy* in the United Kingdom, is the most common pruritic dermatosis of pregnancy. In the study by [Roger and co-workers \(1994\)](#) cited previously, 25 of nearly 3200 women (0.8 percent) had this dermatosis during pregnancy. It is characterized by an intensely pruritic cutaneous eruption that usually appears late during pregnancy ([Table 54-1](#)). Shown in [Figure 54-1](#) are the erythematous urticarial papules and plaques that first develop on the abdomen, usually around striae. The lesions then are likely to spread to the buttocks, thighs and extremities ([Alcalay and associates, 1987](#); [Aronson and colleagues, 1998](#)).

Pruritus may be severe with these lesions. In about 40 percent of women, the urticarial component predominates; in 45 percent, the erythematous pattern is prominent; and in 15 percent, a combination is seen ([Aronson and associates, 1998](#)). The erythematous patches are widespread. The face is usually spared, and seldom is there excoriation. The disease is more common in nulliparas and seldom recurs in subsequent pregnancies. It may resemble herpes gestationis, but there are no vesicles or bullae.

PATHOPHYSIOLOGY. The pathogenetic mechanism is unknown. Because of diverse clinical findings, classification can be confusing. On biopsy, there is a mild nonspecific lymphohistiocytic perivascularitis with an eosinophilic component. Importantly, there is no immunoglobulin or complement deposition seen using immunofluorescent staining of dermis ([Aronson and colleagues, 1998](#)). The absence of a linear band of C₃ in the basement membrane differentiates this dermatosis from herpes gestationis. [Aractingi and associates \(1998\)](#) have reported provocative evidence that this disorder may be stimulated by fetal cells that have invaded maternal skin.

TREATMENT. Some women obtain relief from oral antihistamines and skin emollients, but most require topical corticosteroid creams or ointments for relief. Oral corticosteroids are given if these fail to relieve severe itching. The rash disappears quickly either before or within several days following delivery. In 15 to 20 percent of women, symptoms persist for 2 to 4 weeks postpartum ([Vaughan Jones and co-workers, 1999](#)). There is no evidence that perinatal morbidity is increased ([Aronson and colleagues, 1998](#)).

PRURIGO OF PREGNANCY

These lesions have been described by a multitude of names. According to [Shornick \(1998\)](#), the disorder includes *prurigo gestationis* and *papular dermatitis*, which likely are variants of the same disease and are not specific to pregnancy. The mild and more common variant, prurigo gestationis, is characterized by small, pruritic, rapidly excoriated lesions on the forearms and trunk. Lesions typically have their onset at 25 to 30 weeks, and vesicles or bullae do not develop. Papular dermatitis, described by [Spangler and colleagues in 1962](#), is a rare dermatitis of late pregnancy. It is characterized by generalized pruritic eruptions. These lesions appear as soft, red to violet to red-brown papules, some of which have a centrally hemorrhagic crust.

Pruritus is usually controlled with antihistamines and topical corticosteroid creams. Perinatal outcome does not appear to be adversely affected with these syndromes ([Vaughan Jones and Black, 1999](#)).

HERPES GESTATIONIS

This pruritic blistering skin eruption usually presents in multiparous women in late pregnancy, but it may begin early in pregnancy or up to a week postpartum. It occasionally may accompany gestational trophoblastic disease. Also called *pemphigoid gestationis*, herpes gestationis is similar to bullous pemphigoid seen in elderly patients ([Fine, 1995](#)). Immunologically, it is indistinguishable from bullous pemphigoid ([Nousari and Anhalt, 1999](#); [Triffet and colleagues, 1999](#)). Thus, it is an autoimmune organ-specific blistering skin disease ([Engineer and associates, 2000](#)).

Severe herpes gestationis can be serious, but fortunately it is rare. The previously reported incidence of about 1 in 50,000 pregnancies may have been an underestimate. [Roger and colleagues \(1994\)](#) reported an incidence of 1 in 1700 pregnancies, and [Zurn and associates \(1992\)](#) reported an incidence of 1 in 7000.

Herpes gestationis is characterized by an extremely pruritic widespread eruption with lesions that vary from erythematous and edematous papules to large, tense vesicles and bullae ([Figs. 54-2 and 54-3](#)). Common sites of involvement are the abdomen and the extremities. Exacerbations and remissions throughout pregnancy are common, and up to 75 percent of women suffer intrapartum exacerbations ([Shornick, 1998](#)). In subsequent pregnancies, the disease invariably recurs, and it usually does so earlier and is more severe. [Baxi and colleagues \(1991\)](#) reported a woman in whom recurrence was documented in five pregnancies; however, in each pregnancy, the disease was less severe. Although morphological changes may develop in the small intestinal mucosa similar to those of adult celiac disease, they do not appear to cause significant malabsorption.

ETIOPATHOGENESIS. This autoimmune disease is caused by development of an antibody to the basement membrane zone (anti-BMZ) in the epidermis. There is an inherited predisposition with a markedly increased incidence of HLA-DR3 and HLA-DR4 antigens in affected women ([Baker, 1997](#)). Although over half of women with herpes gestationis have these antigens, they are found in only 3 percent of unaffected women. These antigens are also associated with Graves disease and Hashimoto thyroiditis. For example, [Shornick and Black \(1992\)](#) reported that 10 percent of 75 women with herpes gestationis also had Graves disease.

Autoantibodies are common in women with herpes gestationis, and [Shornick and associates \(1993\)](#) demonstrated anti-HLA antibodies in all 39 women with biopsy-proven disease. The incidence of these antibodies in normal nulliparas is only 20 percent. This antibody is a thermostable immunoglobulin G that reacts with bullous pemphigoid antigen 2 (BPAG2) in the epidermis. BPAG2¹ is a 180-kD protein that is integral to adhesion structures that anchor basal cells to their basement membrane ([Nousari and Anhalt, 1999](#)). It is also called *herpes gestationis serum factor*, and it reacts with amniotic tissue. Finally, this antibody is passively transferred to the fetus.

Histologically, the classical finding in herpes gestationis is subepidermal edema with infiltrates of lymphocytes, histocytes, and eosinophils. Direct immunofluorescent techniques applied to a skin biopsy are of value for confirming the diagnosis, and C₃ complement and sometimes IgG are deposited along the basement membrane zone.

TREATMENT. Pruritus may be quite severe. Only a few women obtain relief from topical corticosteroids and antihistamines. Orally administered prednisone, 1 mg/kg daily, usually brings relief promptly and inhibits formation of new lesions. The healed sites usually are not scarred but frequently are hyperpigmented. Dapsone and cyclosporine have been used to treat women who cannot tolerate corticosteroid therapy ([Fine, 1995](#); [Paternoster and colleagues, 1997](#)). [Castle and associates \(1996\)](#) used cyclophosphamide successfully to treat a woman whose herpes gestationis persisted postpartum despite high-dose corticosteroid therapy.

EFFECT ON PREGNANCY. It is unclear if herpes gestationis causes adverse fetal outcomes. [Shornick and Black \(1992\)](#) reviewed 74 pregnancies and reported an increased incidence of preterm delivery and growth-restricted infants. Perinatal mortality, however, was not increased.

Lesions similar to those of the mother develop in up to 10 percent of neonates ([Chen and colleagues, 1999](#)). These usually clear spontaneously within a few weeks. C₃ complement deposited at the basement membrane of the newborn's skin and herpes gestationis factor in cord serum were described by [Katz and associates \(1976\)](#).

IMPETIGO HERPETIFORMIS

This is a rare pustular eruption that may be seen in late pregnancy. Some authors consider it to be a form of pustular psoriasis that occurs coincidental to pregnancy, while others consider it to be a distinct pregnancy dermatosis ([Aronson and Halaska, 1995](#)). [Oumeish and associates \(1982\)](#) described a woman in whom this dermatosis recurred in nine successive pregnancies. In three pregnancies, there was fetal hydrocephaly. There also were two unexplained perinatal deaths. This woman also developed characteristic skin lesions when taking estrogen-progesterone oral contraceptives.

The hallmark lesions of impetigo herpetiformis are sterile pustules that form around the margin of erythematous patches ([Fig. 54-4](#)). The erythematous lesions characteristically begin at flexures and extend peripherally. Mucous membranes are usually involved. The characteristic histological lesion is a microabscess. The spongeliike epidermal cavity, which is filled with neutrophils, has been termed the *spongiform pustule of Kogoj*.

Pruritus is not severe, but constitutional symptoms are common. In addition to nausea, vomiting, diarrhea, and chills and fever, hypoalbuminemia and hypocalcemia are common. Although the pustules are initially sterile, they may become secondarily infected after rupture, and sepsis is a serious concern.

Treatment is given with systemic corticosteroids along with antimicrobials to treat secondary infection and sepsis. The disease may persist for several weeks to months after delivery. Fetal morbidity and mortality are related to the severity of maternal infection, but may be seen even with controlled disease ([Vaughan Jones and Black, 1999](#); [Wolf and colleagues, 1995](#)).

PREEXISTING SKIN DISEASE

A number of chronic dermatological disorders may complicate pregnancy. These may antedate pregnancy or manifest for the first time during pregnancy. Many of these diseases are like other chronic disorders, which usually have no predictable course during pregnancy.

ACNE

An oral cogener of retinoic acid, *isotretinoin* (Accutane), is commonly prescribed for severe cystic acne, but it has proven to be highly teratogenic ([Chap. 38, p. 1015](#)). [Lammer and colleagues \(1985\)](#) reported a 26-fold risk for craniofacial, cardiac, and central nervous system malformations in fetuses exposed to isotretinoin. Likewise, *etretinate*, a similar compound utilized for the treatment of psoriasis, has been classified as category X because of associated major anomalies. Oral *tretinoin* is an antineoplastic drug that also is teratogenic.

Retinoic acid derivatives have prolonged biological activity, and [Nulman and colleagues \(1998\)](#) found the elimination half-life of isotretinoin to be nearly 40 hours. [Wiegand and Chou \(1998\)](#) demonstrated complete clearance by 2 weeks. Etretinate may be detected in the serum of women for as long as 2 years after cessation of therapy ([DiGiovanna and associates, 1989](#)). Fortunately, the Pregnancy Prevention Program implemented in 1988 has been successful in avoiding most pregnancies in women taking isotretinoin ([Mitchell and colleagues, 1995](#)). The program calls for serum pregnancy testing 2 weeks before therapy is begun. According to [Chan and associates \(1995\)](#), this program was not as effective in Australia because of lack of compliance with use of effective contraception.

For the pregnant woman with severe acne, topically applied benzoyl peroxide appears to be safe, and along with either clindamycin or erythromycin gel, may suffice to control the disease. **Topical tretinoin** is thought to pose no significant teratogenic risk; however, it is class C_m ([Briggs and colleagues, 1998](#)).

HIDRADENITIS SUPPURATIVA

A chronic, progressive inflammatory and suppurative disorder of skin and supporting structures, hidradenitis suppurativa is characterized by apocrine gland plugging that leads to anhidrosis and bacterial infection. Subcutaneous extension causes scarring and sinus formation. In most cases, skin involvement is in multiple apocrine gland sites, but it may be seen only in the axillae, groin, perineum, perirectal area, or under the breasts.

The disease is hormonally responsive and thus not seen until puberty. It has been said to be improved by pregnancy, but postpartum exacerbations may occur. In our experiences, it is not appreciably changed by pregnancy. Treatment is control of acute infections with either systemic antimicrobials or clindamycin ointment. Low-dose isotretinoin for 4 to 6 months has been used with good long-term results in a retrospective study by [Boer and van Gemert \(1999\)](#). **Isotretinoin is a category X drug contraindicated during pregnancy.** Definitive treatment is wide surgical excision, but this most often should be postponed until after pregnancy.

OTHER CONDITIONS

[Boyd and colleagues \(1996\)](#) noted that 65 percent of women reported improvement of *psoriasis* with pregnancy. Almost 90 percent, however, reported a postpartum flare. If *pemphigus* appears during pregnancy for the first time, it may be confused with herpes gestationis ([Vaughan Jones and Black, 1999](#)). Even with corticosteroid therapy, mortality is 10 percent secondary to sepsis caused by infection of denuded skin. [Daniel and colleagues \(1995\)](#) reviewed 17 immunopathologically confirmed cases and reported four stillborn infants. Lesions of *neurofibromatosis* may increase in size and number as a result of pregnancy. As discussed in [Chapter 56 \(p. 1475\)](#), *Hansen disease* likely worsens during pregnancy ([Aronson and Halaska, 1995](#)).

TABLE 54-1. Dermatological Disorders Unique to Pregnancy

Disorder	Frequency	Clinical Characteristics	Histopathology	Perinatal Outcome	Treatment
Cholestasis of pregnancy	Common (1-2%)	Onset third trimester; intense pruritus; generalized; excoriations common	Noncharacteristic; excoriations common	Perinatal morbidity increased	Antipruritics, cholestyramine
Pruritic urticarial papules and plaques of pregnancy (PUPPP)	Common (0.25-1%)	Onset second or third trimester; intense pruritus; patchy or generalized; abdomen, thighs, arms, buttocks; erythematous papules, urticarial papules and plaques	Lymphocytic perivascular infiltrate; negative immunofluorescence	No adverse effects	Antipruritics, emollients, topical corticosteroids, oral corticosteroids if severe
Prurigo of pregnancy (prurigo gestationis and papular dermatitis)	Uncommon (1:300-1:2400)	Onset second or third trimester; localized or generalized; 1-5 mm pruritic papules; excoriations common	Lymphocytic perivascular infiltrate; parakeratosis; acanthosis; negative immunofluorescence	Probably unaffected	Antipruritics, topical corticosteroids, oral corticosteroids if severe
Herpes gestationis (pemphigoid gestationis)	Rare (1:10,000)	Onset second or third trimester, sometimes 1-2 weeks postpartum; severe pruritus; abdomen, extremities, or generalized; urticarial papules and plaques, erythema, vesicles, and bullae	Edema; infiltrate of lymphocytes, histiocytes, and eosinophils; C ₃ and IgG deposition at basement membrane	Possibly increased preterm birth; transient neonatal lesions (5-10%)	Antipruritics, topical corticosteroids, oral corticosteroids if severe
Impetigo herpetiformis	Rare	Onset third trimester; local, then generalized; erythema with marginal sterile pustules; mucous membranes involved; systemic symptoms	Microabscesses; spongiform pustules of Kogoj; neutrophils	Maternal sepsis common from secondary infection	Antibiotics, oral corticosteroids

55. Neoplastic Diseases

Cancer during pregnancy is uncommon but not rare. In a survey of 2.7 million births in Sweden, [Lambe and Ekblom \(1995\)](#) found an incidence of 1 in 6000 pregnancies. According to [Martin and associates \(1999\)](#) from the National Center for Health Statistics, malignancies are the second leading cause of death in women 25 to 44 years of age, and the most common are those of the hemopoietic and lymphatic systems, thyroid, breast, cervix, ovary, and colon, and melanoma. [Sachs and colleagues \(1990\)](#) reviewed 886 maternal deaths in Massachusetts from 1954 to 1985, and reported that 5 percent were cancer related. The most common malignancies associated with pregnancy are those of the genital tract and breast, and malignant melanoma ([Buekers and Lallas, 1998](#); [Kaiser and associates, 2000](#); [Nevin and colleagues, 1995](#)).

Although the approach to the pregnant woman with cancer may need to be modified compared with that of a nonpregnant patient, *the woman should not be penalized for being pregnant*. Specific questions to be asked include:

1. Does pregnancy adversely affect maternal cancer?
2. What risk does cancer or its treatment pose to the fetus?
3. Should the pregnancy be terminated because it represents a significant obstacle for effective cancer therapy?
4. Should the pregnancy be allowed to continue under a very carefully defined regimen?
5. If the neoplasm exists before conception, how should the woman be counseled regarding birth control and advisability of pregnancy?
6. Is pregnancy advisable following cancer treatment?
7. How should the woman be counseled preconceptionally regarding risk of chemotherapy to future offspring?

PRINCIPLES OF CANCER THERAPY DURING PREGNANCY

SURGERY

Surgical intervention for suspected or proven malignancies may be indicated for diagnostic, staging, or therapeutic purposes. Extra-abdominal procedures are usually well tolerated by both mother and fetus, as are most intraperitoneal operations that do not interfere with the reproductive tract. If indicated, however, the ovaries may be removed safely after about 8 weeks' gestation because placental progesterone production is adequate ([Chap. 6, p. 123](#)). Ovariectomy before this time may cause abortion, which often can be prevented by progesterone administration.

Although diagnostic and staging operations have classically been deferred until the second trimester so as to minimize abortion risks, this probably is not necessary. Documenting fetal life by ultrasound between 9 and 11 weeks indicates that 95 percent of fetuses will reach viability. Therapeutic surgery should be performed regardless of gestational age if maternal well-being is imperiled.

RADIATION THERAPY

Unlike diagnostic x-ray procedures, therapeutic radiation may result in significant fetal exposure to ionizing radiation. The amount of radiation exposure will depend on the dose, tissue being treated, and field size. The potential adverse effects of diagnostic radiation include cell deaths, carcinogenesis, and genetic effects on future generations ([Brent, 1989, 1999](#); [Hall, 1991](#)). As discussed in [Chapter 42 \(p. 1149\)](#), the characteristic adverse fetal effects of high-dose radiation are microcephaly and mental retardation. For example, children born to pregnant women exposed to atomic bomb explosions had a 2.4 percent incidence of mental retardation with 10 to 50 rad exposure, and this was increased to nearly 18 percent if exposure was 50 to 100 rad ([Otake and Schull, 1984](#)). The most critical time appeared to be between 8 and 15 weeks' gestation.

The National Council on Radiation Protection and Measurements ([Brent, 1987](#)) concluded that exposure of the embryo to less than 5 rad is associated with negligible risk for major malformations. It was further suggested that the threshold for radiation effects may be 15 to 20 rad. Although the most susceptible period appears to be during organogenesis, there is no gestational age that is considered safe for therapeutic radiation exposure, because late exposure can cause fetal growth restriction and brain damage. Diagnostic x-ray procedures have very low exposure and should not be delayed if the information gained will directly affect therapy ([Chap 42, p. 1150](#)).

The necessity for therapeutic radiation raises issues such as abortion, teratogenesis, and fetal sequelae. Therapeutic radiation to the abdomen is contraindicated because of a high risk of fetal death or damage, unless of course abortion induction is one of its purposes. In some cases, such as the head and neck, radiation therapy to supradiaphragmatic areas can be given relatively safely with abdominal shielding; however, in others, such as the breasts, significant scatter doses can accrue to the fetus. [Lippman and colleagues \(1988\)](#) calculated fetal doses of up to 100 rad during radiotherapy for breast cancer if the uterus reached the xiphoid.

CHEMOTHERAPY

EFFECT ON PREGNANCY OUTCOME. Chemotherapy is now recommended for a variety of malignancies such as those of the hemopoietic and lymphatic systems, ovarian cancer, and breast cancer—not only as palliative therapy but also as potentially curative therapy. Chemotherapeutic agents are often recommended as adjunctive therapy along with surgery or radiation in an attempt to provide optimal therapy in women of reproductive age. Although such therapy with these agents may be associated with either increased rates of cure or at least remission, there is a general reluctance to use chemotherapy in the pregnant woman because of the concern for potential malformations, growth retardation, and the risk of malignancy in future offspring. The risk of adverse fetal effects is dependent primarily on the gestational age at the time of chemotherapy. Most antineoplastic drugs should be considered potentially harmful to the fetus, especially if given between 5 and 10 weeks' gestation, and thus during organogenesis—the period of maximal susceptibility. Most antineoplastic drugs given after the first trimester are without obvious adverse sequelae, although long-term effects have not been evaluated thoroughly. In a review of the reproductive toxicology of alkylating agents, [Glantz \(1994\)](#) concluded that these agents could be employed after the first trimester as necessary. As expected, most of the antineoplastic drugs shown in [Table 55-1](#) are classified as category D.

[Zemlickis and associates \(1992b\)](#) reported four spontaneous abortions and two of five fetuses with major malformations when chemotherapy was given to nine women during the first trimester. Eight women treated later in pregnancy had lower-birthweight infants than controls, but no malformations. [Doll and collaborators \(1988\)](#) reviewed chemotherapy-induced teratogenesis, and their findings are shown in [Table 55-2](#). These investigators noted six instances (25 percent) of fetal malformations during 24 first-trimester exposures to combination chemotherapy compared with 24 of 139 (17 percent) exposed to single-agent therapy. Many of these women had been given folate antagonists and some were given concomitant radiation. If these women were excluded, the incidence of malformations with single-agent therapy was only 6 percent. In contrast, during the second and third trimesters there was no evidence for increased risk of teratogenesis, and of 131 cases there were only two fetal malformations. From their review, [Koren and colleagues \(1990\)](#) estimate the major malformation rate at 10 percent for first-trimester exposure.

Because the magnitude of secretion of chemotherapeutic agents in breast milk has not been established, breast feeding is not recommended. There is also concern for exposure of health-care workers to chemotherapeutic agents. [Selevan and colleagues \(1985\)](#) reported a twofold increased risk of fetal loss in nurses exposed during the first trimester, and they recommended caution during mixing and administration of antineoplastic drugs. Currently, guidelines from the Occupational Safety and Health Administration are that all antineoplastic drugs be mixed in biological safety cabinets with laminar flow hoods.

Late effects on offspring of women treated for cancer during pregnancy have also been analyzed. [Li and associates \(1979\)](#) found only two childhood malignancies in offspring of 146 women treated during 286 pregnancies. Similarly, [Aviles and colleagues \(1991\)](#) found no adverse sequelae in 43 children exposed to antineoplastic drugs in utero, and who were evaluated 3 to 19 years later.

OVARIAN FUNCTION AND FERTILITY AFTER CANCER THERAPY. Treatment of advanced Hodgkin lymphoma with multiple-drug regimens may result in azoospermia ([Waxman, 1985](#)). In women there is depressed follicular maturation as well as ovarian fibrosis. Ovarian susceptibility depends on the woman's age and

the drug dose given. Interestingly, the prepubertal ovary is more resistant to effects of chemotherapy.

If fertility is not lost, there does not appear to be an increased incidence of abortion, fetal chromosomal damage, or fetal anomalies ([Rustin and colleagues, 1984](#)). [Gershenson \(1988\)](#) reviewed subsequent outcomes in women successfully treated with chemotherapy for germ cell ovarian tumors, and although 68 percent had regular menses, the remainder had total or partial ablation of ovarian function. Affected women were significantly older at diagnosis.

Following bone marrow transplantation, either for aplastic anemia or malignant disease, long-term mortality is excessive even for patients free of disease at 2 years ([Socie and co-workers, 1999](#)). This was found to be due to late-recurring leukemia or graft-versus-host disease.

BREAST CARCINOMA

Breast cancer is the most common malignancy of women of all age groups. Almost 1 of every 10 American women will eventually be afflicted. Thus, it is not surprising that breast cancer is one of the three most common malignancies encountered during pregnancy ([Berry and colleagues, 1999](#); [Sorosky and Scott-Conner, 1998](#)). Its incidence has been estimated to be 10 to 30 women per 100,000 pregnancies ([Isaacs, 1995](#)). Nulliparity is a risk factor for breast cancer.

A number of obstetrical outcomes may influence the risk for breast cancer. Term pregnancy increases the short-term risk, and this amplifies the effects of carriers of BRCA1 and BRCA2 mutations ([Jernstrom and co-workers, 1999](#)). Conversely, preterm delivery, preeclampsia, and induced abortion have no effect ([Ekblom, 1997](#); [Hsieh, 1999](#); [Melbye, 1997](#), and all of their colleagues). Women with breast cancer and their controls are equally likely to report induced abortions ([Tang and associates, 2000](#)). Breast feeding also seems to have no association with breast cancer occurrence ([Michels and colleagues, 1996](#)).

EFFECTS OF PREGNANCY ON BREAST CANCER

Pregnancy does not have dramatic influences on the course of mammary cancer. [Melbye and colleagues \(2000\)](#) have presented intriguing evidence that higher serum levels of alpha-fetoprotein are associated with a lower incidence of breast cancer. It is, however, undisputed that regional nodes are more likely involved with microscopic metastases. [Hochman and Schreiber \(1953\)](#), and others since then, contend that the 5-year survival rate in breast cancer coexisting with pregnancy is primarily dependent on the stage of the disease at the time of diagnosis, and that interruption of pregnancy has no influence on the course. Thus, survival in pregnant women is comparable with the rates expected with similar disease stages in nonpregnant women ([King and colleagues, 1985](#); [Nugent and O'Connell, 1985](#); [Zemlickis and associates, 1992a](#)).

Past pregnancy may adversely affect the survival of young women with breast cancer. For example, in a review of 407 women aged 20 to 29 years, [Guinee and colleagues \(1994\)](#) reported that the risk of dying from breast malignancy was significantly greater in women whose cancer was first diagnosed during pregnancy compared with those who had never been pregnant. [Korzeniowski and Dyba \(1994\)](#), in a review of the survival of 1885 women with operable breast cancer, reported that the survival rates decreased with the number of pregnancies, and the prognosis was best in women who had never been pregnant. Thus, almost paradoxically, the reproductive factors reported to decrease the risk of breast cancer may actually have an adverse effect on the prognosis.

Although survival is stage-dependent, there may be serious delays in clinical assessment, diagnostic procedures, and treatment of pregnant women with breast tumors ([Berry and colleagues, 1999](#)). Delays in diagnosis may be greater than 1 year in some women ([Marchant, 1994](#)). Although most women undergo examination during pregnancy, hormonally induced physiological breast changes tend to obscure breast masses. This is particularly evident during lactation when there is lobular hyperplasia and galactostasis. This observation at least partially explains the more advanced stages of cancer at diagnosis, which consequently have a worse prognosis ([Sorosky and Scott-Conner, 1998](#)). According to [Jacob and Stringer \(1990\)](#), about 30 percent of pregnant women with breast cancer have stage I disease; 30 percent, stage II; and 40 percent, stages III and IV. [Souadka and colleagues \(1994\)](#) reported that a fourth of 43 pregnant women with breast cancer had metastatic disease apparent at the outset. [Bonnier and associates \(1997\)](#) found an inordinately and significantly higher incidence of inflammatory cancer in 154 pregnant women compared with 308 age-matched nonpregnant controls (26 versus 9 percent). As shown in [Table 55-3](#), about two thirds of pregnant women have concomitant axillary node involvement. This is substantively higher than the 40 to 50 percent reported for nonpregnant women ([Hoover, 1990](#)).

[King and colleagues \(1985\)](#) described experiences with 63 pregnant women treated for breast carcinoma at the Mayo Clinic. They reported that 63 percent of these women had axillary nodal metastases compared with only 38 percent of similar-age nonpregnant women described by others. [Zemlickis and associates \(1992a\)](#) reported that pregnant women with breast cancer had a 2.5-fold risk of metastatic disease compared with nonpregnant control women. Utilizing a mathematical model, [Nettleton and colleagues \(1996\)](#) have estimated that a delay in diagnosis of 6 months increases the chance of nodal metastasis by more than 10 percent.

PLACENTAL METASTASES. Occasionally, malignant breast cells are found upon placental microscopic examination ([Dunn and co-workers, 1999](#)). These have been confined to the intervillous space, and fetal disease has not been reported ([Chap. 32, p. 849](#)).

DIAGNOSIS AND TREATMENT

The diagnostic approach in the pregnant woman with a breast tumor should not differ significantly from that for a nonpregnant woman. **Any suspicious breast mass found during pregnancy should prompt an aggressive plan to determine its cause, whether by fine-needle aspiration or by open biopsy.** Fine-needle aspiration is often the preferred procedure for the initial evaluation of a breast mass detected in pregnancy or during lactation, and breast biopsy is usually reserved for masses in which fine-needle aspiration is not diagnostic ([Sorosky and Scott-Conner, 1998](#)). The risk of mammography is negligible for the fetus if appropriate shielding is used, and the amount of radiation exposure is less than 100 mrad. ([Chap. 42, p. 1150](#)). The dense breast tissue of pregnancy makes this test less reliable. In the review by [Lieberman and colleagues \(1994\)](#), of 23 cases of pregnancy-associated invasive breast carcinoma, there were mammographic findings in only 18 (78 percent). Using fine-needle aspiration, it is possible to differentiate a cyst or galactocele from solid tumors. Excisional biopsy should be done if cytological results are not diagnostic. According to [Barnavon and Wallack \(1990\)](#), aspiration is 66 percent sensitive and 95 percent specific. [Collins and co-workers \(1995\)](#) biopsied masses in 17 pregnant women and found only one cancer. Thirteen of these had a lactating adenoma.

Once the breast malignancy is diagnosed, chest x-ray and limited metastatic search is performed. Whereas computerized tomography bone and liver scans are both sensitive and specific, they are probably contraindicated during pregnancy because of the ionizing radiation ([Pelsang, 1998](#)). Magnetic resonance imaging and ultrasonography are reasonable alternatives to assess for liver involvement. Magnetic resonance imaging is not only sensitive but has the added advantage of multiplanar images and excellent contrast resolution. Ultrasound has been reported to be more sensitive than magnetic imaging for detection of liver metastases ([Pelsang, 1998](#)). [Clarke and colleagues \(1989\)](#) have reported that the sensitivity of ultrasound in detecting liver metastasis is 76 percent.

Surgical treatment should not be delayed because of pregnancy. In the absence of metastatic disease, wide excision, modified radical mastectomy, or total mastectomy with axillary node staging can be performed ([Isaacs, 1995](#)). [Berry and colleagues \(1999\)](#) performed modified radical mastectomy followed by chemotherapy in 18 of 22 pregnant women. Risks from these procedures are minimal, and the incidence of abortion is negligible. Because breast-conserving surgery usually requires adjunctive radiotherapy, this technique is usually not recommended for pregnant women unless the malignancy is diagnosed in the late third trimester ([Sorosky and Scott-Conner, 1998](#)).

Radiotherapy is not recommended during pregnancy because abdominal scatter is considerable even with shielding. The fetus receives at least 100 to 150 rad when the maternal radiation dose to the breast is 5000 rad ([Sorosky and Scott-Conner, 1998](#)).

Data indicate that nonpregnant women with node-positive cancer should be given adjuvant **chemotherapy** without delay. It therefore seems advisable to give chemotherapy for node-positive disease if delivery is not anticipated soon. Chemotherapy with cyclophosphamide, doxorubicin, and 5-fluorouracil is currently recommended by most ([Berry and colleagues, 1999](#)). After the first trimester, methotrexate can be substituted for doxorubicin ([Sorosky and Scott-Conner, 1998](#)). Surgical ablation of the ovaries would appear to have no place in the management of pregnant women with breast cancer ([Isaacs, 1995](#)).

[Berry and colleagues \(1999\)](#) have recently described their experience with 24 pregnant women with primary or recurrent carcinoma of the breast. Of the 22 women with primary cancer of the breast, 18 had modified radical mastectomies—14 during pregnancy and four during the postpartum period. Each woman had a central venous catheter placed, and all of the women were given combination chemotherapy with cyclophosphamide, doxorubicin, and fluorouracil every 3 to 4 weeks during the second and third trimester of pregnancy. The median gestational age at delivery was 38 weeks with a range of 33 to 40 weeks. Only one newborn had a birthweight less than the 10th percentile for gestational age, and none of the 24 infants had congenital malformations.

PREGNANCY FOLLOWING BREAST CANCER

About 10 percent of women treated for breast cancer subsequently become pregnant, and 70 percent of these do so within the first 5 years ([Harvey and colleagues, 1981](#); [Hornstein and colleagues, 1982](#)). There is little evidence to suggest that pregnancy after mastectomy for breast cancer adversely affects survival ([Averette and colleagues, 1999](#)). [Dow and colleagues \(1994\)](#) found no differences in recurrences or distant metastasis with or without subsequent pregnancies. More recent investigations by [Kroman \(1997\)](#) and [Velentgas \(1999\)](#) and their colleagues confirmed these findings. Similarly, there are no data to suggest that lactation adversely affects the course of breast cancer. Moreover, successful lactation and breast feeding is possible after conservative surgery and radiation for breast cancer, even from the side of the treated breast ([Higgins and Haffty, 1994](#)). Recommendations for future pregnancies in women successfully treated for breast malignancy are based on several factors, including consideration for recurrence. It seems reasonable to advise a delay of 2 to 3 years, which is the most critical observation period.

LYMPHOMAS AND LEUKEMIAS

LYMPHOMAS

HODGKIN DISEASE. The lymphatic tumor of Hodgkin disease constitutes approximately 40 percent of malignant lymphomas. Hodgkin disease is the most common lymphoma encountered in childbearing-age women. It has a bimodal peak incidence in ages 18 to 30 and again after 50. Its concurrence with pregnancy has been estimated to be about 1 in 6000 ([DiSaia and Creasman, 1993](#)), although our experience indicates that it is much less common. The most common finding is peripheral adenopathy, and neck and supraclavicular nodes are commonly involved. Patients may be asymptomatic or they may present with fever, night sweats, malaise, weight loss, and pruritus ([Peleg and Ben-Ami, 1998](#)). Diagnosis is established by histological examination of involved nodes. In more than 70 percent of cases of Hodgkin disease, patients present with painless enlargement of lymph nodes above the diaphragm—axillary, cervical, or submaxillary ([Peleg and Ben-Ami, 1998](#)).

The pregnant woman with Hodgkin disease presents special management considerations. A tenet of treatment is that careful staging is essential, and either local radiotherapy or systemic chemotherapy is indicated. The *Ann Arbor staging system*, shown in [Table 55-4](#), was designed for Hodgkin lymphomas but is also used for other lymphomas. Some use its revision, termed the *Cotswold classification* ([Urba and Longo, 1992](#)). Pregnancy limits the widespread application of some radiographic studies of the chest, abdomen, pelvis, and lower extremities. Spiral chest computed tomography can be used with the "pitch" set so that radiation dosage approaches that of conventional chest scanning. Magnetic resonance imaging is a reasonable alternative to computed tomographic scanning for evaluating thoracic and abdominal para-aortic lymph nodes. Radionuclide gallium scanning is used more frequently and has about 750 to 1000 mrad (see [Table 42-9](#), p. 1153). Routine staging laparotomy is controversial but is considered essential for those patients in whom radiotherapy alone is chosen, and thus documentation of unsuspected abdominal disease would significantly alter treatment. Although this may be done in early pregnancy, it does not seem advisable in later pregnancy.

Treatment is individualized depending upon the suspected disease stage and pregnancy duration. Whereas radiotherapy is preferable for isolated neck adenopathy, it is not recommended if the fields to be used will deliver significant radiation scatter to the fetus. [Wong and Strassner \(1990\)](#) estimated fetal exposure from maternal therapy with 4400 rad delivered to the midline of the central supradiaphragmatic axis. Fetal dosage was calculated to be 63, 88, and 220 rad in early, mid-, and late pregnancy, respectively. Because of this, [Ward and Weiss \(1989\)](#) recommend dose and field modification. [Nisce and colleagues \(1986\)](#) temporarily modified their radiotherapeutic regimen to deliver only 1500 to 2000 rad to supradiaphragmatic sites in seven women with a second- or third-trimester pregnancy. Despite this reduction to what were considered subcurative doses, fetal radiation exposure ranged from 2 to 50 rad and averaged about 20 rad. When evaluated at 6 to 11 years of age, all seven children were normal, but two mothers had died.

Because of data shown in [Table 55-2](#), chemotherapy is probably best avoided during the first trimester, but it is a relatively safe option later. With obvious widespread disease, chemotherapy is given at diagnosis. Postponement of therapy until fetal maturity is achieved is considered reasonable by some if the diagnosis is made late in pregnancy and the mother is asymptomatic.

There are no convincing data that pregnancy itself adversely affects Hodgkin lymphoma, and the disease does not cause increased pregnancy wastage. Because aggressive radiation and chemotherapy are often necessary to affect cure, pregnancy termination may be a reasonable option when the diagnosis of Hodgkin disease is made in the first half of pregnancy. [Holmes and Holmes \(1978\)](#) analyzed 93 pregnancy outcomes when either the pregnant woman or the father had Hodgkin disease, and the great majority were satisfactory. [Jacobs and associates \(1981\)](#) reported their experiences from Stanford University and found that neither chemotherapy during the second and third trimesters, nor irradiation to the mediastinum and neck, appeared to adversely affect the fetus or neonate. **Pregnant women with Hodgkin disease are inordinately susceptible to infections and sepsis, and both radiotherapy and chemotherapy increase this susceptibility.**

FERTILITY AFTER TREATMENT. [Horning and co-workers \(1981\)](#) evaluated the reproductive potential of women after treatment for Hodgkin disease. They reported that 55 percent of women resumed normal menses after chemotherapy. No birth defects or developmental abnormalities were evident in 24 infants subsequently born to these women. The risk of second cancers, especially leukemia, is substantively increased in patients with Hodgkin disease. [Tucker and colleagues \(1988\)](#) reported this to be almost 20 percent within 15 years. When compared with radiotherapy given alone, [Kaldor and associates \(1990\)](#) reported that the risk for leukemia was increased almost ninefold following chemotherapy.

Other complications of therapy for Hodgkin disease include myocardial damage and infarction, pulmonary fibrosis, hypothyroidism, and marrow suppression ([Peleg and Ben-Ami, 1998](#)).

NON-HODGKIN LYMPHOMAS. Non-Hodgkin lymphomas have recently become the most common neoplasms among persons aged 20 to 40. Their incidence has risen sharply because of their relationship to the acquired immunodeficiency syndrome. Indeed, 5 to 10 percent of persons infected with human immunodeficiency virus (HIV) will develop a lymphoma. [Pollack and colleagues \(1993\)](#) described a case of non-Hodgkin lymphoma of B-cell origin, with metastasis to the placenta, in a woman with HIV¹ infection. Burkitt lymphoma is an aggressive tumor usually of B-cell origin. [Barnes and associates \(1998\)](#) reviewed 19 pregnancies complicated by this lymphoma; 17 women did not survive one year.

The concurrence of non-Hodgkin lymphoma with pregnancy has been rare, although its incidence is expected to increase because of the rising incidence of HIV¹ infection. In a 50-year literature review, [Ward and Weiss \(1989\)](#) described only 75 cases associated with pregnancy. [Aviles and colleagues \(1990\)](#) reported their experiences with 16 pregnant women with these malignancies. Although half of the cases of lymphoma were discovered in the first trimester, these investigators began cytotoxic drug therapy and observed no fetal malformations. All but one offspring were healthy at 3 to 11 years. Eight of the 16 mothers who had remissions were alive 4 to 9 years later. [Catlin and co-workers \(1999\)](#) described a fascinating case in which a maternal natural-killer-cell lymphoma metastasized transplacentally and engrafted the fetus. Both mother and infant succumbed from the malignancy.

Extensive staging is required for non-Hodgkin lymphomas, and the Ann Arbor system shown in [Table 55-4](#) is used. Radiotherapy typically is used for stage I disease, whereas chemotherapy is recommended for most stage II and all stage III and IV tumors. Unfortunately, the disease is often widespread when the peripheral nodes are involved and staging laparotomy is of little or no benefit ([Peleg and Ben-Ami, 1998](#)).

LEUKEMIAS

Except for acute lymphocytic leukemia, which is a childhood disorder, leukemias are more prevalent after age 40. Despite this, acute leukemias are among the most common malignant neoplasms of young women, but paradoxically, their incidence complicating pregnancy is cited to be about 1 case per 100,000 ([Harrison and colleagues, 1994](#)). This has also been our experience at Parkland Hospital, and we have encountered about 10 women with leukemia in nearly 300,000 pregnancies. [Caligiuri and Mayer \(1989\)](#) reviewed 350 reports of pregnancy complicated by leukemia. Of 72 newly diagnosed cases during pregnancy and reported since 1975, 44 had acute myelogenous leukemia, 20 acute lymphocytic leukemia, and eight had one of the chronic leukemias.

EFFECT ON PREGNANCY. Most pregnant women with acute leukemia will have pancytopenia. The survival of untreated acute leukemia may be extremely short, with the median survival of acute myelogenous leukemia being 3 months or less ([Peleg and Ben-Ami, 1998](#)). In more recent times, there is an improved survival rate with these malignancies, and in three fourths of women who develop **acute leukemia** during pregnancy, remission can usually be induced with chemotherapy. Thus, maternal and fetal outcomes have improved substantively in recent years ([Reynoso and colleagues, 1987](#)). For example, [McLain \(1974\)](#) reported that the maternal mortality rate was 100 percent and perinatal mortality was 34 percent in 256 women with acute leukemia treated before 1970. According to [Lewis and Laros \(1986\)](#), maternal death from acute leukemia has become negligible since 1970, although many of these unfortunate women die months to years following pregnancy. Survival has also improved for women with **chronic myelogenous** and **lymphocytic leukemias**. The rare chronic **hairy-cell leukemia** has been reported in only six pregnancies ([Stiles and colleagues, 1998](#)).

Despite being improved, perinatal outcomes are generally poor for leukemic women. [Reynoso and colleagues \(1987\)](#) analyzed 58 reported cases of acute leukemia during pregnancy in a 10-year period. Nearly 75 percent of these were diagnosed during the second and third trimesters. Half of the women had acute myelogenous leukemia, and most cases were treated with chemotherapy, with a reported remission rate of 75 percent. Only 40 percent of pregnancies in these women resulted in

live-born infants. Similarly, [Caligiuri and Mayer \(1989\)](#) reported preterm delivery in about 50 percent of women diagnosed during pregnancy. The stillbirth rate was also increased.

Several cases of **congenital leukemia** in infants of nonleukemic mothers have been recorded, although no case of transmission of maternal leukemia to the fetus has been authenticated. Conversely, a third of tumors metastatic to the placenta are leukemias and lymphomas ([Chap. 32, p. 849](#)).

MANAGEMENT. In general, multiagent chemotherapy is given as soon as the diagnosis of leukemia is established, even if in the first trimester. Rare cases of spontaneous remission of acute leukemia after pregnancy have been reported ([Antunez-de-Mayolo and colleagues, 1989](#)). These observations perhaps implicate a hormonal influence, but hormone receptors were not studied. Because there is no evidence that pregnancy has a deleterious effect on leukemia, termination is not recommended to improve the prognosis, but it is a consideration in early pregnancy to avoid potential teratogenesis from chemotherapy. [Morishita and colleagues \(1994\)](#) described the use of umbilical blood sampling to monitor the fetus of a woman receiving combination chemotherapy for acute myelogenous leukemia. Fetal hemopoiesis was not adversely affected, and there were no apparent developmental abnormalities.

The use of all-trans-retinoic acid (tretinoin) has been described for treatment of acute promyelocytic leukemia, a subset of acute myelogenous leukemia ([Celo and colleagues, 1994](#)). [Harrison and associates \(1994\)](#) reported successful treatment of this leukemia with tretinoin in the second trimester without adverse fetal effects. Currently, it would seem prudent to avoid this vitamin A derivative during pregnancy. As discussed in [Chapter 38 \(p. 1015\)](#), the teratogenic effects of vitamin A and two of its derivatives, isotretinoin and etretinate, have been well described ([American College of Obstetricians and Gynecologists, 1995](#)). [Claahsen and colleagues \(1998\)](#) have recently reported a woman with acute myeloid leukemia who was treated with idarubicin and cytosine-arabioside during the second and third trimesters of pregnancy. The newborn had growth restriction and was preterm, but had no structural abnormalities.

Significant complications in pregnancy that include infection and hemorrhage should be anticipated at the time of delivery in women with active disease. Manifestations include anemia, neutropenia, and thrombocytopenia. Vaginal delivery is preferable, and cesarean section is reserved for obstetrical indications.

MALIGNANT MELANOMA

Melanomas are relatively common in women of childbearing age, and a significant proportion of women may have the diagnosis made during pregnancy ([MacKie, 1999](#)). The incidence of melanoma in general has been increasing over the last several decades ([Dennis, 1999](#); [Squarrito and Harlow, 1998](#)). Its incidence in pregnancy is not known exactly, but has been estimated to range from 0.14 to 2.8 per 1000 live births ([Derek and Strassner, 1990](#)). As emphasized by [Salopek and colleagues \(1995\)](#), melanomas are underreported because many are treated on an outpatient basis and are not entered into a tumor registry. Melanomas are most common in light-skinned Caucasians, and over 90 percent originate in the skin from pigment-producing melanocytes, usually arising from a preexisting nevus. Any suspicious behavior in a pigmented cutaneous lesion such as changes in contour, surface elevation, discoloration, itching, bleeding, or ulceration warrants a biopsy.

Melanomas are clinically staged: stage I has no palpable lymph nodes, stage II has palpable nodes, and in stage III there are distant metastases. Approximately 85 percent of cases are stage I disease ([Squarrito and Harlow, 1998](#)). Tumor thickness is the single most important predictor of survival in stage I patients. The Clark classification is most widely used and includes five levels of involvement by depth into the epidermis, dermis, and subcutaneous fat.

EFFECT OF PREGNANCY

Earlier reports that pregnancy stimulates growth of malignant melanoma have not been substantiated. Pregnancy is associated with increased melanocyte-stimulating hormones, and some melanomas contain sex steroid hormone receptors. [Ellis \(1991\)](#) has shown that pregnancy and estrogen-containing oral contraceptives probably increase dysplastic nevus changes, a forerunner to melanoma development. More recent data would suggest that oral contraceptives are not etiological in the development of melanoma ([Gefeller and colleagues, 1998](#); [Pfahlberg, 1997](#)). In his review of 11 studies, however, [Holly \(1986\)](#) concluded that there was no adverse effect on survival if melanoma was first diagnosed during pregnancy, or if pregnancy developed in a woman with previously recognized melanoma. Findings from the World Health Organization (WHO) Melanoma Programme ([MacKie and colleagues, 1991](#)) indicate that women in whom melanoma was diagnosed during pregnancy had significantly greater tumor thickness when compared with women diagnosed before or after pregnancy.

Primary surgical treatment for melanoma is determined by the stage of the disease and includes wide local resection sometimes with extensive regional lymph node dissection. In a study from the WHO Melanoma Programme, [Cascinelli and co-workers \(1998\)](#) reported that routine regional node dissection improved survival in nonpregnant patients with microscopic node metastases. Prophylactic chemotherapy or immunotherapy is usually avoided during pregnancy; however, chemotherapy for active disease is given if indicated by tumor stage, maternal prognosis, and gestational age. In most cases of metastatic melanoma, treatment is at best palliative. Therapeutic abortion does not appear to improve survival in women with melanoma ([Dipaola and colleagues, 1997](#)).

Prognosis is determined by the stage of the lesion, and patients with deep cutaneous invasion or regional node involvement have a much poorer prognosis. As discussed earlier, women who are pregnant when melanoma is diagnosed have thicker skin tumors. As shown in [Figure 55-1](#), these women have a higher mortality rate when compared with women whose melanoma was diagnosed before or after pregnancy. Survival is equivalent, however, stage-for-stage, when pregnancy is compared with nonpregnancy. [Kjems and Krag \(1993\)](#) summarized the survival rate from five studies of 338 pregnant and 1360 nonpregnant women with stage I melanoma. They found no significant differences in 5-year survival rates between the two groups. Because most recurrences manifest by 2 (60 percent) to 5 (90 percent) years, most authorities recommend that future pregnancies be avoided for 3 to 5 years after treatment.

PLACENTAL METASTASES. According to their review, [Dildy and colleagues \(1989\)](#) found that a third of reported cases of malignancies metastatic to the fetus or placenta have been malignant melanoma ([Chap. 32, p. 848](#)). [Ferreria and co-workers \(1998\)](#) described a case of melanoma metastatic to the placenta that reacted with melanoma-specific anti-S-100 protein and HMB-45 antibodies. Although in some cases, the tumor undergoes regression in the neonate, many infants have succumbed to disease ([Anderson and colleagues, 1989](#)).

GENITAL CANCER

Genital tract cancer is the most common form of cancer encountered during pregnancy. The distribution of various malignancies is summarized in [Table 55-5](#).

CERVICAL NEOPLASIA

Pregnancy provides an opportune time for screening for cervical neoplasia and premalignant disease, especially for women who do not seek or have access to routine health care. Incidence data for cervical neoplasia complicating pregnancy varies widely. Cervical dysplasia is quite common; [Jolles \(1989\)](#) cited an incidence in reproductive-age women of 26 per 1000. The incidence of carcinoma-in-situ was about 5 per 1000 women. According to [Hacker and associates \(1982\)](#), the average incidence of carcinoma-in-situ during pregnancy is about 1.3 per 1000, and for invasive carcinoma it is about 1 per 2200 pregnancies. [Nevin and colleagues \(1995\)](#) reported that approximately 1 in 2000 pregnancies is associated with cervical carcinoma and approximately 3 percent of women with cervical cancer were pregnant. [Method and Brost \(1999\)](#) cite the incidence to range from 0.1 to 1.3 per 1000 pregnancies. In our experiences, invasive cervical cancer is not nearly so common as these higher figures. Certain types of human papillomavirus are associated with both high-grade intraepithelial lesions as well as invasive cancer. Routine human papillomavirus testing is not recommended except for research studies ([Kaufman and Adam, 1999](#)).

INTRAEPITHELIAL NEOPLASIA

The effects of pregnancy and delivery on premalignant and malignant epithelial cervical lesions are not understood completely. In the study by [Kiguchi and co-workers \(1981\)](#), progression from dysplasia to invasive carcinoma after delivery (0.4 percent) was almost half that for nonpregnant women (1 percent). Moreover, the regression rates of moderate and marked dysplasia within 6 months after delivery were higher than those for the general population. [Fife and colleagues \(1996\)](#) found an increased incidence of high-cancer risk viruses—human papillomavirus types 16, 18, 31, 35, 45, 51, 52, and 56—when they compared pregnant with nonpregnant women.

According to [Talebian and co-workers \(1976\)](#), the incidence of abnormal cytology during pregnancy is about 3 percent, which is similar to that reported for nonpregnant women. Evaluation of the Papanicolaou smear can, however, be more difficult during pregnancy ([Connor, 1998](#)). Evaluation of an abnormal cytological smear is the same as for nonpregnant women with minor modifications ([Economos and associates, 1993](#)). During pregnancy, colposcopic evaluation is easier to perform because the transformation zone is better exposed due to physiological eversion. Colposcopically directed biopsies are used liberally to assess any suspicious lesions ([Palle and co-workers, 2000](#)). Biopsy sites may actively bleed because of hyperemia, and this can usually be stopped easily with Monsel solution, silver nitrate, vaginal packing, or occasionally a suture. Multiple biopsies need not all be taken on one occasion but rather may be obtained over a period of time. The

diagnostic accuracy of colposcopy is 99 percent, and complications arise in fewer than 1 percent of uses ([Economos and associates, 1993](#); [Hacker and co-workers, 1982](#)).

During pregnancy, endocervical curettage is omitted to avoid risks of hemorrhage and membrane rupture. Cone biopsy usually is reserved to exclude invasive cancer. If possible, conization is avoided because of an increased incidence of hemorrhage, abortion, and preterm labor ([Table 55-6](#)). Indeed, conization during pregnancy is less than satisfactory for at least three reasons:

1. The epithelium and underlying stroma within the cervical canal cannot be excised extensively because of the risk of membrane rupture. Of 376 conizations during pregnancy reviewed by [Hacker and colleagues \(1982\)](#), residual neoplasia was found in 43 percent of subsequent specimens.
2. Blood loss is common during and after conization and [Averette and colleagues \(1970\)](#) reported that nearly 10 percent of 180 pregnant women required transfusion.
3. There is increased relative risk of 1.6-fold for preterm delivery ([El-Bastawissi and colleagues, 1999](#)). Of interest, laser vaporization of the cervix for intraepithelial neoplasia before pregnancy does not appear to be associated with preterm delivery ([van Rooijen and Persson, 1999](#)).

If cytological changes of mild cervical intraepithelial neoplasia are identified and subsequently confirmed, further follow-up during pregnancy may consist of colposcopic evaluation. In the absence of lesions detected by a satisfactory colposcopy, simply repeating the cervical smears later in pregnancy is usually adequate. Cytological changes that are suggestive of moderate or severe dysplasia or invasive disease require colposcopically directed biopsies to identify the responsible lesion. Women with histologically confirmed intra-epithelial neoplasia may be followed with cytology and colposcopically directed biopsies, allowed to deliver vaginally, and given definitive treatment after delivery. In a recent study by [Yost and colleagues \(1999\)](#), there was regression postpartum in 68 percent of women with grade II and 70 percent of those with grade III neoplasia. Although 7 percent of women with grade II lesions progressed to grade III lesions, none of the lesions progressed to invasive carcinoma.

INVASIVE CARCINOMA OF THE CERVIX. Pregnancy coexisting with invasive cervical carcinoma complicates both staging and treatment. Accurate identification of the extent of cancer is more difficult during pregnancy because induration of the base of the broad ligaments—which in nonpregnant women characterizes tumor spread beyond the cervix—may be less prominent during pregnancy. Thus, the extent of the tumor is more likely to be underestimated in the pregnant woman. Limited computed tomography of the pelvis is acceptable, but to avoid ionizing radiation, magnetic resonance imaging is a useful adjunct to ascertain extent of disease, including urinary tract involvement ([Gilstrap and colleagues, 2001](#); [Hannigan, 1990](#)). Cystoscopy and sigmoidoscopy can be performed as necessary to rule out mucosal involvement.

Because cervical carcinoma is relatively uncommon during pregnancy, only a few institutions have had extensive experience with its management. Some generalizations, however, can be made. The survival rate for invasive carcinoma has not been profoundly different for pregnant and nonpregnant women within a given stage of disease, although these descriptive studies have been small. [Van Der Vange and colleagues \(1995\)](#), in a review of 44 women with cervical cancer associated with pregnancy who were matched with 44 controls, reported an overall 5-year survival rate of 80 percent among pregnant subjects and 82 percent among controls. The mode of delivery has not been shown to affect maternal survival significantly, although experiences are limited because most women were delivered by hysterotomy or cesarean section ([Hacker and colleagues, 1982](#)). In general, when frankly invasive carcinoma is identified, most clinicians favor abdominal delivery, if for no other reason than that the cervix would not lacerate during dilatation.

MANAGEMENT. Treatment of cervical cancer varies according to its stage and pregnancy duration. Treatment for microinvasive disease diagnosed by cone biopsy to exclude frankly invasive disease follows guidelines similar to those for intraepithelial disease. Thus, continuation of pregnancy and vaginal delivery are considered safe, with therapy given postpartum.

Invasive cancer demands relatively prompt therapy. In general, during the first half of pregnancy, immediate treatment is advised, whereas during the latter half a reasonable option is to await not only fetal viability, but fetal maturity ([Greer and colleagues, 1989](#)). In a report of 12 pregnant women with invasive cervical carcinoma along with a review of the literature, [van Vliet and colleagues \(1998\)](#) concluded that delayed treatment to allow greater fetal maturity was reasonable in women with nonbulky lesions, lesions less than stage IIB, and gestation past 20 weeks. Preferred treatment for selected patients with stage I and early stage IIA small-diameter (less than 3 cm) invasive carcinoma is **radical hysterectomy plus pelvic lymphadenectomy**. Surgical treatment allows ovarian conservation and vaginal function, and minimizes exposure at an early age to the adverse effects of radiation on the intestinal and urinary tracts. [Nisker and Shubat \(1983\)](#) described 49 cases of stage IB cervical cancer complicating pregnancy, and reported a 30 percent severe complication rate from radiation therapy compared with only 7 percent in those treated by radical surgery. Surgical dissection during pregnancy actually may be facilitated by softening of uterine supportive structures. Before 20 weeks, hysterectomy is usually performed with the fetus in situ. In later pregnancy, however, hysterotomy may first be necessary.

Radiotherapy is given for more extensive cancer. Early in pregnancy, external irradiation is given and if spontaneous abortion does not ensue, then curettage is performed. During the second trimester, spontaneous abortion may be delayed, and hysterotomy may be necessary in up to a fourth of cases. About a week following abortion, external radiation is begun, followed by intracavitary radium application. After 24 weeks, the risk of delay to allow fetal maturity is unknown, but allowing pulmonary maturity seems reasonable, especially for early lesions (i.e., stage I disease).

PROGNOSIS. The overall prognosis for all stages of cervical cancer during pregnancy is probably similar to that for nonpregnant women ([Sood and Sorosky, 1998](#)). The results from several published reports are shown in [Table 55-7](#). These aggregate results suggest no difference in survival when pregnant women are compared with nonpregnant women. Included are 49 cases of stage IB cancer and reported by [Nisker and Shubat \(1983\)](#). These investigators found a 5-year survival of only 70 percent compared with 87 percent in nonpregnant women with similar stages. This difference might be due to understaging of the disease during pregnancy.

It is unknown if vaginal delivery through a cancerous cervix worsens the prognosis; however, most oncologists favor abdominal delivery based on theoretical considerations. Moreover, recurrence in the episiotomy scar after vaginal delivery has been reported ([Cliby and colleagues, 1994](#)). Direct implantation of tumor cells is likely the mechanism of recurrence in these cases.

ENDOMETRIAL CARCINOMA

Because endometrial carcinoma characteristically develops in women past the reproductive age, it is seen only rarely in association with pregnancy. [Schammel and colleagues \(1998\)](#) reviewed 14 cases reported in the literature and described an additional five cases. The majority of cases reported thus far have been well-differentiated adenocarcinomas. Although treatment consists primarily of abdominal hysterectomy and bilateral salpingo-oophorectomy, [Schammel and colleagues \(1998\)](#) reported conservative therapy consisting of curettage with or without progestational therapy in four women. Interestingly, there have been at least four viable infants reported out of these 19 cases. [Kowalczyk and co-workers \(1999\)](#) described a 28-year-old woman with well-differentiated carcinoma who conceived after successful treatment with megestrol for 6 months.

OVARIAN CARCINOMA

Malignant ovarian neoplasms are the fourth most common cause of death from cancer and the leading cause of death from genital tract cancers in North American women. Their incidence during pregnancy is not accurately known, but it has been reported to average about 1 per 25,000 deliveries ([Jacob and Stringer, 1990](#); [Jolles, 1989](#)). According to the [American College of Obstetricians and Gynecologists \(1990\)](#), about 1 of every 1000 pregnant women will undergo surgical exploration for an adnexal mass. Most adnexal masses encountered during pregnancy will be either mature teratomas or cystadenomas ([Boulay and Podczaski, 1998](#); [Whitecar and colleagues, 1999](#)). According to several reviews, only about 5 percent of adnexal neoplasms diagnosed during pregnancy are malignant, compared with 15 to 20 percent in nonpregnant women ([Jacob and Stringer, 1990](#); [Whitecar and associates, 1999](#)). This is likely due to the younger age of pregnant women, and because of the disparate number of corpus luteum cysts.

Pregnancy apparently does not alter the prognosis of most ovarian malignancies, but complications such as torsion and rupture may develop. Most pregnant women who have ovarian cancer are asymptomatic. Prior to widespread use of ultrasonic evaluation of pregnancy, most pelvic masses were detected by routine prenatal examination during early pregnancy. Diagnosis afterward is more difficult because an adnexal tumor is usually obscured by the enlarging uterus. In many centers, universal sonography is performed during pregnancy, and the detection of adnexal masses has increased concomitantly. Certainly, sonography is indicated for women in whom there is a palpable adnexal mass, and it is helpful to differentiate functional cystic masses from solid or multiseptated masses. With the former, expectant management is acceptable, but the latter require surgery for diagnosis. Evaluation of pelvic masses is discussed in detail in [Chapter 35 \(p. 930\)](#).

MANAGEMENT. If ovarian cancer is discovered at laparotomy, treatment is similar to that for the nonpregnant woman, and this depends on gestational age as well as

the stage, histological type, and grade of the tumor. After frozen section verifies malignancy, complete surgical staging with careful inspection of all peritoneal and visceral surfaces is performed. **Malignant ovarian tumors apparently confined to one ovary require complete surgical staging, and this is recommended also in tumors of low malignant potential** (Yazigi and associates, 1988). Procedures include peritoneal washings for cytological examination, multiple biopsies of the diaphragmatic undersurface and pelvic and parietal peritoneum, wedge resection of the opposite ovary, partial omentectomy, and excisional biopsies of pelvic and aortic lymph nodes. Whereas in most advanced stages hysterectomy and bilateral adnexectomy are indicated, in certain circumstances it can be justified to remove the tumor and await fetal maturity. In some cases, chemotherapy is given while awaiting pulmonary maturation. Maternal CA-125 serum levels are too variable during pregnancy to monitor for response to therapy (Aslam and associates, 2000; Spitzer and colleagues, 1998).

PROGNOSIS. According to Jolles (1989), two thirds of ovarian cancers found during pregnancy are of the common epithelial types. The remainder are germ-cell tumors, and occasionally a stromal-cell tumor. There does not appear to be an adverse influence of pregnancy on these malignancies. About 70 cases of invasive **epithelial cell tumors** coexistent with pregnancy have been reported (Dgani and colleagues, 1989; Van Dessel and co-workers, 1988). Foersterling and Blythe (1999) have recently described a woman with both an ovarian serous cystadenocarcinoma (stage IC) and a stage IA endometrial adenocarcinoma. Epithelial tumors are the most frequent ovarian malignancies in nonpregnant as well as pregnant women. Because of the relatively young age of the pregnant population, there is a higher proportion of less-advanced tumors. Thus, tumors with low-malignant potential and stage IA are seen more often compared with nonpregnant women. In some cases, borderline tumors will have been diagnosed before pregnancy and treated conservatively (Gotlieb and colleagues, 1998).

Karlen and associates (1979) reviewed 27 cases of **dysgerminomas** during pregnancy. They found significant obstetrical complications in nearly half of the women and reported a 30 percent recurrence in apparent stage IA cases. Buller and colleagues (1992) described conservative surgical management to allow pregnancy progression in three women with dysgerminomas. They recommended follow-up with magnetic resonance imaging and tumor markers to monitor for recurrences. Young and associates (1984) reviewed 36 cases of **gonadal stromal tumors** that accounted for 4 percent of reported ovarian malignancies complicating pregnancy. All of these tumors were stage I and they had an excellent prognosis. An **endodermal sinus tumor** has been diagnosed because of persistently elevated maternal serum alpha-fetoprotein levels (van der Zee and colleagues, 1991). This tumor has an overall bad prognosis (Farahmand and associates, 1991; Malhotra and Sood, 2000). Elit and colleagues (1999) reported on the use of bleomycin, cisplatin, and etoposide in a woman with this malignancy at 24 weeks. The newborn had ventriculomegaly and cerebral atrophy, the etiology of which was unclear. Maymon and co-workers (1998) described a woman with primary ovarian **hepatoid carcinoma** who also had elevated alpha-fetoprotein levels. Kalir and Friedman (1998) have described a **gynandroblastoma**—sex cord and stromal cells of both ovarian and testicular types—in a 32-year-old pregnant woman.

VULVAR CANCER

Invasive **squamous cell carcinoma** of the vulva is primarily a disease of postmenopausal women, and thus is only rarely associated with pregnancy. Regan and Rosenzweig (1993) found 17 cases in their review. Heller and associates (2000) more recently found 23 cases to review and described a 28-year-old with a 4-cm vulvar lesion noted near term. They concluded that radical surgery for stage I disease was feasible during pregnancy even in the last trimester. **Vulvar intraepithelial neoplasia** is seen more often in young women, and it is associated with human papillomavirus in most. Its potential for progression to invasive disease is unclear. Interestingly, the association with invasive disease and papillomavirus infection is not as closely linked as it is with cervical carcinoma (American College of Obstetricians and Gynecologists, 1994). Despite this, Messing and Gallup (1995) reported a trend toward younger women with vulvar carcinoma, which more frequently has a papillomavirus association. Kuller and colleagues (1990) reviewed five cases of **vulvar sarcoma** discovered during pregnancy. In four of these, cure was obtained by a variety of therapies.

Any suspicious vulvar lesion should be biopsied. Treatment of invasive disease is individualized according to the clinical stage and depth of invasion. Vaginal delivery is not contraindicated if the vulvar incisions are well healed.

UTERINE LEIOMYOMAS

Benign uterine leiomyomas are common in older pregnant women, and especially in black women. Because they are seldom malignant, leiomyomas complicating pregnancy are considered in [Chapter 35 \(p. 926\)](#).

LEIOMYOMATOSIS PERITONEALIS DISSEMINATA

Rarely at cesarean section or puerperal tubal ligation, numerous subperitoneal smooth muscle tumors are found that at first appear to be disseminated carcinomatosis. Leiomyomatosis peritonealis disseminata results from stimulation, probably by estrogen, of multicentric subcoelomic mesenchymal cells to become smooth muscle cells. According to the review by Lashgari and colleagues (1994), about half of the 45 reported cases were discovered during pregnancy. Although surgical excision has been recommended, there is evidence that these tumors regress after pregnancy. Marom and associates (1998) as well as Ling and colleagues (2000) have described women who had tumors extending up the vena cava into the heart. Bekkers and colleagues (1999) have reported a rare malignant leiomyoblastoma during pregnancy.

GASTROINTESTINAL TRACT CANCER

COLORECTAL CARCINOMA

Cancer of the colon and rectum are the second most frequent malignancies in women of all age groups in the United States. These tumors seldom complicate pregnancy because they are uncommon before age 40 (Cappell, 1998). The majority—80 percent or more—of colorectal carcinomas in pregnant women arise from the rectum (Skilling, 1998). Fewer than 250 cases of colon cancer have been reported in pregnant women (Walsh and Fazio, 1998).

The most common symptoms of colorectal cancer are abdominal pain, distention, nausea and vomiting, constipation, and rectal bleeding. The diagnosis may be delayed because these symptoms may be ascribed to the pregnancy. Gonsoulin and colleagues (1990) described a woman with colon carcinoma and hepatic metastases in whom maternal serum alpha-fetoprotein levels were elevated persistently after first being measured at 16 weeks. Certainly, if symptoms suggestive of colon disease persist, digital rectal examination, tests for occult blood, and flexible sigmoidoscopy followed by colonoscopy are done if indicated. Seidman and colleagues (1992) described a woman in whom an intussuscepted colon cancer was diagnosed using magnetic resonance imaging.

From limited information available, it appears that the segmental distribution of colon cancer lesions is the same as in nonpregnant women. Importantly, 60 to 70 percent of lesions are palpable by rectal examination. Tumors above the peritoneal reflection are uncommon, and Chan and associates (1999a) described only 41 cases in their review of the English-language literature. Van Voorhis and Cruikshank (1989) reported two additional women with colon cancer who had persistent microcytic, hypochromic anemia from occult bleeding.

MANAGEMENT. Treatment of colorectal cancer follows the same general guidelines as for nonpregnant patients, and when there is no evidence for metastatic disease, surgery is performed. During the first half of the pregnancy, hysterectomy is not necessary in order to perform colon or rectal resection, and thus therapeutic abortion is not mandated. During later pregnancy, as well as in the presence of metastatic disease, delaying therapy to allow fetal maturation is considered. Vaginal delivery is usually permitted if obstetrical conditions are favorable, but rectal lesions below the pelvic brim may cause dystocia. Hemorrhage, obstruction, or perforation may force surgical intervention (Donegan, 1983).

There is no evidence that pregnancy influences the usual course of colorectal cancer. Thus, prognosis is similar to that for identical stages in nonpregnant patients. Unfortunately, pregnant women usually present with advanced disease (Walsh and Fazio, 1998). Carcinoembryonic antigen (CEA), a useful tumor marker for colon cancer, may be elevated during pregnancy and therefore is of little value.

OTHER GASTROINTESTINAL NEOPLASMS

Gastric cancer is rarely associated with pregnancy, and most reported cases are from Japan. Hirabayashi and collaborators (1987) reviewed outcomes in 60 pregnant women with this malignancy seen over a 70-year period from 1916 to 1985. Delay in diagnosis during pregnancy was unfortunately common, and the prognosis was consistently poor—88 percent of women were dead within one year of diagnosis. As discussed in [Chapter 48 \(p. 1274\)](#), persistent upper gastrointestinal symptoms should be evaluated by endoscopy. Davis and Chen (1991) and Chan and colleagues (1999b) each described a woman with gastric cancer who attributed her continued epigastric pain during pregnancy to preexisting peptic ulcer disease.

Stewart and colleagues (1997) reviewed their experiences with seven pregnancies in five women with **Zollinger-Ellison syndrome**. They advise surgical resection of

the tumor before pregnancy is undertaken, but in women with metastatic disease or in those with previously undiagnosed tumors, antacid and antisecretory treatment usually suffices.

At least 21 cases of **carcinoid tumors** complicating pregnancy have been reported. In his review, [Durkin \(1983\)](#) found that most cases were of gastrointestinal origin, and some were incidentally diagnosed at cesarean section. **Pancreatic cancer** is very rare during pregnancy ([Gamberdella, 1984](#)). [Bondeson and colleagues \(1990\)](#) described an endocrine pancreatic malignancy in which the diagnosis was confused because of chorionic gonadotropin produced by an early pregnancy. Primary **hepatic cancer** during pregnancy also is rare ([Gisi and Floyd, 1999](#); [Purtilo and associates, 1975](#)). [Balderston and co-workers \(1998\)](#) described a 23-year-old woman at 26 weeks who had a massive intrahepatic cholangiocarcinoma masquerading as the HELLP syndrome (syndrome of hemolysis, elevated liver enzymes, and low platelet count). She died 3 weeks postpartum.

RENAL TUMORS

[Walker and Knight \(1986\)](#) reviewed 71 cases of primary renal neoplasms associated with pregnancy. Half were **renal cell carcinoma**, and a palpable abdominal mass was the presenting finding in almost 90 percent of these women. Pain was the second most common presenting symptom (50 percent), and hematuria was found in half the cases. Only a fourth of these women had the classical triad of hematuria, pain, and a palpable mass. Diagnosis has been improved by contemporaneous imaging studies ([Fig. 55-2](#)). [Smith and co-workers \(1994\)](#) added nine new cases since 1986 in their updated review. They suggest that earlier diagnosis is common now because of ultrasonography. We have encountered only six pregnant women with this malignancy during the past 30 years at Parkland Hospital. They either presented because of painless hematuria, or the tumor was found by abdominal palpation done routinely in conjunction with cesarean deliveries. If suspected antepartum, the diagnosis can be confirmed by intravenous pyelography, ultrasonic-directed needle biopsy, magnetic resonance imaging, or limited computed tomographic scanning as shown in [Figure 55-2](#). [Fazeli-Matin and co-workers \(1998\)](#) described partial nephrectomy in a woman with renal carcinoma at 14 weeks.

OTHER TUMORS

Thyroid cancers are the most common endocrine malignancies, and it has been estimated that approximately 10 percent of those cases occurring during the reproductive years are diagnosed during pregnancy or within the first year after birth ([Morris, 1998](#)). [Tewari and associates \(1998\)](#) described a woman with Graves thyrotoxicosis and thyroid storm who was subsequently found to also have papillary adenocarcinoma involving the cervical nodes. [Rossing and colleagues \(2000\)](#) have presented intriguing findings that suggest that thyroid stimulation during pregnancy and lactation may result in a transient increase in papillary thyroid cancer. Diagnosis is usually by fine-needle aspiration. Treatment consists primarily of surgery performed during the second trimester or after delivery ([Chap. 50, p. 1346](#)). Most thyroid cancers are well-differentiated and follow an indolent course.

Brain tumors are uncommon. [Isla and colleagues \(1997\)](#) described seven cases in over 126,000 deliveries from Hospital La Paz in Madrid. Two women died, one from intrapartum hemorrhage into a meningioma. [Tewari and co-workers \(2000\)](#) described eight women with malignant brain tumors associated with pregnancy. Another two women had postpartum gestational choriocarcinoma metastatic to the brain. These cases were from a 20-year survey of five California hospitals with about 312,000 deliveries during the 20-year study period. Maternal outcomes were horrific—five women died, two who lived had significant neurological defects, and only three are in remission.

56. Infections

The pregnant woman and her fetus are susceptible to many infections and infectious diseases. Some of these may be quite serious and life-threatening for the mother, whereas others may have a profound impact on neonatal outcome by virtue of a high likelihood of fetal infection.

IMMUNOLOGICAL CHANGES OF PREGNANCY

There is much speculation concerning possible effects of decreased immune surveillance during pregnancy. These effects are engendered by maternal tolerance for the foreign-tissue antigens of the semiallogeneic fetal "graft" ([Chap. 2, p. 21](#)). Although there are subtle changes in circulating immunoglobulin levels in pregnancy, these appear to be of no consequence. Polymorphonuclear leukocyte chemotaxis and adherence may be depressed beginning in midpregnancy. Assessment of cell-mediated immunity is difficult, but available evidence suggests that maternal lymphocytes are as fully competent as paternal and unrelated cells in producing a cytotoxic response ([Stirrat, 1991](#)).

FETAL AND NEWBORN IMMUNOLOGY. The active immunological capacity of the fetus and neonate is compromised compared with that of older children and adults. According to [Stirrat \(1991\)](#), fetal cell-mediated and humoral immunity begin to develop by 9 to 15 weeks. Despite the ability to synthesize immunoglobulin G (IgG), the primary fetal response to infection is immunoglobulin M (IgM) production. Conversely, passive immunity is provided by IgG¹ transferred actively across the placenta. By 16 weeks, transfer begins to increase rapidly, and by 26 weeks fetal concentrations are equivalent to those of the mother. After birth, breastfeeding is protective against some infections. But this begins to decline at 2 months of age (WHO Collaborative Study Team, 2000).

Neonatal infection, especially in its early stages, may be difficult to diagnose because of failure to respond in a classical fashion. If the fetus was infected in utero, there may be depression and acidosis at birth for no apparent reason. The infant may suck poorly, vomit, or develop abdominal distention. Respiratory insufficiency may develop, which is similar in many ways to idiopathic respiratory distress syndrome. The neonate may be lethargic or jittery. The response to sepsis may be hypothermia rather than hyperthermia, and the total leukocyte count and neutrophil counts may be depressed or not influenced by sepsis.

Bacteria, viruses, or parasites may gain access transplacentally during the viremic, bacteremic, or parasitemic stage of maternal infection ([Newton, 1999](#)). They may also cross the intact membranes ([Table 56-1](#)). Fetal infections may develop early in pregnancy to produce obvious stigmata at birth. Conversely, organisms may colonize and infect the fetus during labor and delivery. Thus, preterm rupture of membranes, prolonged labor, and manipulations may increase the risk of neonatal infection ([Yancey and colleagues, 1996](#)). Infections occurring at less than 72 hours of age usually are caused by bacteria acquired in utero or during delivery, whereas infections after that time most likely have been acquired after birth.

A major mechanism for postnatal infection is from those caring for the infant. Indwelling venous and arterial umbilical catheters may cause infection. Ventilatory systems can be the source of life-threatening infection. **The very-low-birthweight infant who survives the first few days is at considerable risk of dying later from infection acquired in the intensive-care nursery.**

Bacteria most often responsible for sepsis in the newborn have varied during the past several decades. For example, in the 1930s and 1940s, group A β -hemolytic streptococci were involved principally. With the widespread use of penicillin, these infections decreased, to be replaced by staphylococcus in the 1950s, and coliforms and group B streptococcus beginning in the 1970s and predominating today.

VIRAL INFECTIONS

VARICELLA-ZOSTER

This is a DNA herpesvirus that remains latent in the dorsal root ganglia after primary infection. It may be reactivated years later to cause herpes zoster or shingles ([Gilden and co-workers, 2000](#)). Most adults have had chickenpox acquired during childhood and 95 percent have serological evidence of immunity ([Glantz and Mushlin, 1998](#)). Varicella infection in adults tends to be much more severe than in children. Approximately half of all varicella deaths occur in the 5 percent of adult population that are susceptible, a mortality 23 times greater than that from childhood varicella ([Preblud, 1986](#)).

Although disputed, there is evidence that varicella infection is especially severe during pregnancy. [Paryani and Arvin \(1986\)](#) reported that 4 of 43 of infected pregnant women, or about 10 percent, developed pneumonitis. Two of these women required ventilatory support, and one died. Despite this, successful pregnancy outcomes can follow complicated varicella pneumonia ([Chandra and colleagues, 1998](#)). Treatment is described in [Chapter 46 \(p. 1228\)](#) and usually consists of oxygenation, assisted ventilation when necessary, and treatment with acyclovir given intravenously ([Cox and colleagues, 1990](#)).

Maternal herpes zoster infection is more common in older or immunocompromised patients. There is no evidence that zoster is more frequent or more severe in pregnant women. [Eyal and associates \(1983\)](#), in a review of 15 cases of zoster during pregnancy, concluded that there was little evidence that zoster caused congenital malformations.

PREVENTION. Administration of **varicella-zoster immunoglobulin (VZIG)** will either prevent or attenuate varicella infection in exposed susceptible individuals if given within 96 hours. The dose is 125 U per 10 kg given intramuscularly with a maximum dose of 625 units or five vials. Immunoglobulin is recommended by the [Centers for Disease Control and Prevention \(1996b\)](#) for immunocompromised susceptible adults who are exposed, but it is not recommended routinely for pregnant women. Because of the severity of varicella during pregnancy, some authors do recommend immunoglobulin administration for exposed but otherwise healthy pregnant women ([McGregor and colleagues, 1987](#); [Paryani and Arvin, 1986](#)). Up to 80 to 90 percent of adults are immune from prior symptomatic or asymptomatic infection, and thus antibody testing with enzyme-linked immunosorbent assay (ELISA) or fluorescent antibody to membrane antigen (FAMA) is done, if possible, prior to immune globulin therapy. [Rouse and colleagues \(1996\)](#) performed decision analysis and found such an approach to be cost effective.

An attenuated live-virus vaccine (Varivax) was approved for use in 1995 ([American College of Obstetricians and Gynecologists, 2000](#)). One dose is recommended routinely for all children between 1 and 12 years old. This successfully results in 97 percent seroconversion. Two doses, 4 to 8 weeks apart, are recommended for adolescents and adults with no history of varicella. **The vaccine is not recommended for pregnant women.** Using a decision analytic model, [Glantz and Mushlin \(1998\)](#) concluded that routine antenatal screening of all pregnant women with negative or indeterminate varicella histories was not cost effective. [Smith and colleagues \(1998\)](#), utilizing an analytic cost-effectiveness model, concluded that selective serotesting of all pregnant women with a negative or uncertain history of varicella, followed by postpartum vaccination, would prevent almost 50 percent of cases of chickenpox and was cost effective.

FETAL EFFECTS. Maternal chickenpox during the first half of pregnancy may cause congenital malformations by transplacental infection. Some of these include chorioretinitis, cerebral cortical atrophy, hydronephrosis, and cutaneous and bony leg defects ([Fig. 56-1](#)). [Pastuszak and co-workers \(1994\)](#) described 106 women with varicella infection before 20 weeks and computed the absolute risk of embryopathy to be about 2 percent. In a prospective study by [Enders and colleagues \(1994\)](#), a total of 1373 women had varicella infection during pregnancy. There was no clinical evidence of congenital varicella infection after 20 weeks. Only 2 of 472 pregnancies (0.4 percent) in which there was maternal infection before 13 weeks had infants with congenital varicella. The highest risk was between 13 and 20 weeks, during which time 7 of 351 exposed fetuses (2 percent) had evidence of congenital varicella. [Jones and associates \(1994\)](#) likewise observed a 1.4 percent incidence of fetal varicella syndrome in 146 live-born infants exposed before 20 weeks.

Fetal exposure later in pregnancy is associated with congenital varicella lesions, and zoster occasionally develops at several months of age ([Chiang and colleagues, 1995](#)). Fetal exposure to the virus just before or during delivery, and therefore before maternal antibody has been formed, poses a serious threat to the newborn. [Friedman and associates \(1994\)](#) described an epidemic outbreak in a neonatal intensive care unit. The incubation period for varicella infection is short and usually less than 2 weeks. In some instances, the infant will develop disseminated visceral and central nervous system disease, which is commonly fatal. Varicella-zoster or zoster immunoglobulin (ZIG) is administered to the neonate whenever the onset of maternal disease is within about 5 days before or after delivery. Perinatal mortality at other times is minimal because passive maternal antibody is protective. Despite passive immunoglobulin therapy, however, [Miller and colleagues \(1989\)](#) reported that 15 percent of infants developed severe infection.

INFLUENZA

These infections are caused by members of the **Orthomyxoviridae** family. Influenza A and B form one genus of these RNA viruses and are identified by nucleoprotein antigenic reactions. These are subclassified further by hemagglutinin (H) and neuraminidase (N) antigenic makeup. The viral strain then is

characterized by its origin and the year isolated. For example, one component in the 1995-1996 trivalent vaccine was A/Johannesburg/33/94-like (H₃N₂), the 33rd influenza A virus isolated from a patient in Johannesburg, South Africa, in 1994 and having antigens of the H₃ hemagglutinin and N₂ neuraminidase subtypes.

Influenza A is more serious than influenza B and usually develops during winter epidemics. Infection usually is not life-threatening for otherwise healthy adults. If pneumonia develops, the prognosis becomes serious. In a statistical study based on 1350 cases, [Harris \(1919\)](#) found a gross maternal mortality rate of 27 percent, which increased to 50 percent when pneumonia developed. In August and September 1957, 50 percent of childbearing-age women who died of influenza in Minnesota were pregnant ([Freeman and Barno, 1959](#)).

PREVENTION. Vaccination against influenza is recommended by the [Centers for Disease Control and Prevention \(1998b\)](#) for all pregnant women after the first trimester. Regardless of gestational age, women who have chronic underlying medical disorders such as diabetes or heart disease are vaccinated. There is no evidence of teratogenicity ([Chap. 10, p. 240](#)).

Amantadine is an antiviral agent with specific activity against influenza A viruses. Given prophylactically during epidemics, it is 70 to 90 percent effective in preventing influenza ([Centers for Disease Control and Prevention, 1994a](#)). If therapy is begun within 48 hours of onset of symptoms, amantadine reduces the duration of fever and systemic symptoms. It is reserved for nonimmunized women at high risk for influenza complications ([Chap. 46, p. 1227](#)).

A new class of antiviral drugs—**neuraminidase inhibitors**—is highly effective to treat early influenza in adults ([Centers for Disease Control and Prevention, 1999a](#); [Gubareva and colleagues, 2000](#)). There are now two approved agents for nonpregnant individuals. **Oseltamivir** is taken orally and **zanamivir** is inhaled. They are discussed further in [Chapter 46 \(p. 1227\)](#).

FETAL EFFECTS. There is no firm evidence that influenza A virus causes congenital malformations ([Korones, 1988](#)). [Saxen and associates \(1990\)](#) identified no association with increased first-trimester influenza in 248 mothers of anencephalic children. Conversely, [Lynberg and associates \(1994\)](#) reported increased neural-tube defects in children born to women with influenza early in pregnancy. This may be related to associated hyperthermia ([Kashyap and Gruslin, 2000](#)). [McGregor and colleagues \(1984\)](#) have convincingly demonstrated that the virus can infect the fetus, at least late in pregnancy. There is controversial evidence that fetal exposure to influenza A may predispose to schizophrenia in later life ([Kunuqi and associates, 1995](#); [McGrath and Castle, 1995](#)).

MUMPS

Mumps is an uncommon adult infectious disease caused by an RNA paramyxovirus. Up to 80 to 90 percent of adults are seropositive. The virus primarily infects the salivary glands, but may involve the gonads, meninges, pancreas, and other organs. Treatment is symptomatic. Mumps during pregnancy is no more severe than in nonpregnant adults and there is no evidence for its teratogenicity ([Ouhilal, 2000](#)).

The live attenuated Jeryl-Lynn vaccine strain is contraindicated in pregnant women. Likewise, **MMR vaccine**—measles, mumps, and rubella—is composed of live-attenuated viruses and contraindicated in pregnancy ([Association of Professors of Gynecology and Obstetrics, 1999](#)).

FETAL EFFECTS. Infection has been confirmed in a 10-week fetus ([Kurtz and colleagues, 1982](#)). Attenuated Jeryl-Lynn virus has been recovered from placental tissue of women given the vaccine 7 to 10 days before elective abortion ([Yamauchi and co-workers, 1974](#)). Despite this, there is no firm evidence that mumps infection causes increased fetal wastage. We agree with [Miller and Hager \(2000\)](#) that mumps infection is not an indication for termination of pregnancy. [Manson and associates \(1960\)](#) described 501 cases complicating pregnancy and reported that major fetal anomalies were not increased. [Siegel \(1973\)](#) confirmed this in a cohort study. Congenital mumps is very rare.

RUBEOLA (MEASLES)

Most adults are immune to measles. Unfortunately, when measles becomes epidemic, as it did from 1989 to 1991, unvaccinated women may develop measles pneumonia with adverse maternal and perinatal outcomes ([Eberhart-Phillips and colleagues, 1993](#); [Stein and Greenspoon, 1991](#)). About 3 percent of nonpregnant adults with measles develop clinical pneumonia.

The virus does not appear to be teratogenic, but there is an increased frequency of abortion and low-birthweight infants with maternal measles ([Siegel, 1973](#); [Siegel and Fuerst, 1966](#)). [Moroi and colleagues \(1991\)](#) reported that placental infection caused death in a 25-week uninfected fetus. If the woman develops measles shortly before birth, there is considerable risk of serious infection developing in the neonate, especially in preterm infants. Passive immunization can be achieved by administering immune serum globulin, 5 mL given intramuscularly within 3 days of exposure. Active vaccination is not done during pregnancy, but susceptible women are vaccinated routinely postpartum ([Association of Professors of Gynecology and Obstetrics, 1999](#)). Periodic "catch-up" vaccination campaigns that target children age 9 months to 14 years have been successful in control of measles ([de Quadros and colleagues, 1996](#)).

RESPIRATORY VIRUSES

Approximately three fourths of acute viral respiratory infections are caused by more than 200 antigenetically distinct viruses. Respiratory viruses cause the common cold, pharyngitis, laryngotracheobronchitis, bronchitis, and pneumonia. Rhinovirus, coronavirus, and adenovirus are major causes of the common cold. The first two are RNA viruses and usually produce a trivial, self-limited illness characterized by rhinorrhea, sneezing, and congestion. There are 100 distinct serotypes. The DNA-containing adenovirus is more likely to produce cough and lower respiratory tract involvement, including pneumonia. Pneumonia complicating pregnancy is often preceded by an acute upper respiratory viral infection.

Mothers suffering from common cold had a four- to fivefold increased risk of fetal anencephaly when a 393-woman cohort of the Finnish Register of Congenital Malformations was analyzed ([Kurppa and associates, 1991](#)). These investigators further found that fever—a commonly quoted possible cause of anencephaly—was not found to be a factor. Adenoviral infection is a common cause of childhood myocarditis, and [Towbin and colleagues \(1994\)](#) used polymerase chain reaction to document fetal myocarditis at 29 weeks.

HANTAVIRUS. An outbreak in western states caused by the virulent respiratory hantavirus had an overall 60 percent case-fatality rate ([Centers for Disease Control and Prevention, 1993](#)). Pneumonitis that progresses to adult respiratory distress syndrome is characteristic. [Gilson and colleagues \(1994\)](#) described two pregnant women with the *Four Corners* strain who survived.

ENTEROVIRUS INFECTIONS

These viruses are a major subgroup of RNA picornaviruses that include poliovirus, coxsackievirus, and echovirus. Even though they are trophic for intestinal epithelium, they can cause widespread infections that may include the central nervous system, skin, heart, and lungs. Most infections are subclinical. Occasionally, fulminant newborn disease is caused by enteroviral infections. Hepatitis A is an enterovirus 72 that is discussed in [Chapter 48 \(p. 1289\)](#). These viruses may cause fetal infection. [Dahlquist and colleagues \(1995\)](#) found that maternal enteroviral infection is a risk factor for childhood-onset diabetes.

COXSACKIEVIRUS. Most of these infections are clinically inapparent, but the virus may cause aseptic meningitis, a polio-like illness, rashes, respiratory disease, or pleuritis, pericarditis, and myocarditis. The virus can be fatal to the fetus-infant, although causing only minor symptoms in the mother.

[Brown and Karunas \(1972\)](#) reported that congenital malformations were increased slightly in pregnant women who had serological evidence of coxsackievirus, but not echovirus infections. Viremia may cause hepatitis, myocarditis, and encephalomyelitis, which can cause fetal death. [Garcia and associates \(1991\)](#) reported that histological placentitis was common following maternal enteroviral infection. [Strong and Young \(1995\)](#) described clinical chorioamnionitis associated with maternal coxsackie viremia. The virus was grown from amniotic fluid as well as from neonatal spinal fluid in both twins. [Dommergues and colleagues \(1994\)](#) described fetal ventriculomegaly and cardiomyopathy in a stillborn infant whose amniotic fluid contained enterovirus.

POLIOVIRUS. Most of these infections are subclinical or mild. The virus is trophic for the central nervous system and symptomatic infections can cause paralytic disease—poliomyelitis. [Siegel and Goldberg \(1955\)](#), in a carefully controlled study in New York City, demonstrated that pregnant women not only were more susceptible to polio but also had a higher death rate. With the widespread use of vaccination during childhood, polio has become rare in the United States. Inactivated subcutaneous polio vaccine is recommended for susceptible pregnant women who must travel to endemic areas or in other high-risk situations. Live oral polio vaccine has been used for mass vaccination during pregnancy without harmful fetal effects ([Harjulehto and associates, 1989](#)).

PARVOVIRUS

Human B19 parvovirus causes **erythema infectiosum**, or **fifth disease**. This is a trivial maternal infection but occasionally causes fetal death. B19 is a small, single-stranded DNA virus that replicates in rapidly proliferating cells, such as erythroblast precursors. It is the only known human parvovirus ([Rodis, 1999](#)). Viremia occurs during the prodrome, which is followed by clinical features, including a bright red macular rash and erythroderma that affects the face giving a *slapped cheek* appearance. The rash, with accompanying arthralgias, may be due to immune-complex disease. In most women, the disease is asymptomatic. Confirmation of infection is by IgM^2 -specific antibody. There is no evidence that the mild infection is altered by pregnancy ([Valeur-Jensen and colleagues, 1999](#)).

The attack rate of susceptible adults in school outbreaks is 20 to 30 percent ([Young, 1995](#)). In a study of 30,946 pregnant women, [Valeur-Jensen and colleagues \(1999\)](#) reported that having children aged 6 to 7 years was associated with a fourfold rate of seroconversion. [Harger and colleagues \(1998\)](#) as well as [Jensen and associates \(2000\)](#) reported that B19 infection in pregnancy was significantly higher if the woman was exposed to her own children. Interestingly, being a schoolteacher was not the highest risk factor in either of these two studies.

B19 parvovirus is trophic for erythroid cells and only those persons with the erythrocyte membrane P antigen are susceptible ([Brown and colleagues, 1994](#)). In women with hemolytic anemia—for example, sickle-cell disease—parvovirus infection may cause an aplastic crisis. [Ville and associates \(1995\)](#) described a **mirror syndrome** or **maternal hydrops syndrome**—preeclampsia-like disease related to placentomegaly—in a 25-week pregnancy with fetal hydrops caused by anemia from parvo-virus infection.

FETAL EFFECTS. Maternal infection may be associated with abortion and fetal death. [Rogers and co-workers \(1993\)](#) found B19 parvovirus in two of 80 spontaneous abortuses, but there were no associated pathological changes. [Tiessen and associates \(1994\)](#) described a fetus with congenital anomalies possibly caused by first-trimester parvovirus infection. [Shilieto and colleagues \(1996\)](#) found evidence for fetal myocardial damage by measuring creatine kinase levels obtained by cordocentesis. During an outbreak in Connecticut, the fetal loss rate was 5 percent in 39 infected women ([Rodis and colleagues, 1990](#)). In London, the [Public Health Laboratory Service Working Party on Fifth Disease \(1990\)](#) prospectively followed 190 women infected during pregnancy. The transplacental infection rate was 33 percent. The overall risk of fetal death was 9 percent, and midpregnancy infection was associated with 12 percent fetal loss. Early fetal death is not usually associated with hydropic changes but is common in fetuses dying after midpregnancy ([Wright and colleagues, 1996](#)). [Pustilnik and Cohen \(1994\)](#) described discordant infection at 20 weeks in diamniotic-dichorionic twins.

Diagnosis is confirmed by parvovirus-specific IgM^2 antibodies. Viral DNA may be detectable in serum during the prodrome but not after the rash develops. Use of polymerase chain reaction to detect viral DNA has been described ([Rogers and colleagues, 1993](#); [Yamakawa and associates, 1995](#)). For women with positive serology, ultrasonic examination is indicated. If there is hydrops, then fetal transfusion is recommended by some authors ([Peters and Nicolaidis, 1990](#); [Sahakian and associates, 1991](#); [Thorp and colleagues, 1994](#)). The technique is described in [Chapter 37 \(p. 993\)](#). Conversely, [Morey \(1991\)](#) and [Fairley \(1995\)](#) and their co-workers have described spontaneous resolution. [Rodis and colleagues \(1998a\)](#) did a survey and reported that approximately a third of fetuses with hydrops had spontaneous resolution and almost 85 percent of hydropic fetuses who received intrauterine transfusions survived. In another report, [Rodis and colleagues \(1998b\)](#) described the long-term outcome of children following maternal B19 parvovirus infection. They concluded that developmental delay was not apparently increased from fetal exposure.

RUBELLA

Also called **German measles**, rubella virus typically causes infections of minor import in the absence of pregnancy. During pregnancy, however, it has been directly responsible for inestimable wastage, and even more importantly, for severe congenital malformations. This relationship was first recognized by [Gregg \(1942\)](#), an Australian ophthalmologist.

PREVENTION. Although large epidemics of rubella have virtually disappeared in the United States because of immunization, the disease, with its horrific teratogenic potential, persists. From 1992 to 1997, 65 percent of reported cases were in persons older than 20 ([Association of Professors of Gynecology and Obstetrics, 1999](#)). From 6 to 25 percent of women are susceptible, and the [Centers for Disease Control and Prevention \(1994b\)](#) reported that outbreaks in 1993 and 1994 involved colleges, work settings, and prisons. In a review of 350 women from a cohort of high-risk pregnant women, 53 (15 percent) were found to be nonimmune ([McElhaney and colleagues, 1999](#)).

To eradicate the disease completely, the following approach is recommended for immunizing the adult population, particularly women of childbearing age:

1. Education of health-care providers and the general public on the dangers of rubella infection.
2. Vaccination of susceptible women as part of routine medical and gynecological care, including college health services.
- BR>3. Vaccination of susceptible women visiting family planning clinics.
4. Identification and vaccination of unimmunized women immediately after childbirth or abortion.
5. Vaccination of nonpregnant susceptible women identified by premarital serology.
6. Vaccination of all susceptible hospital personnel who might be exposed to patients with rubella or who might have contact with pregnant women.

Rubella vaccination should be avoided shortly before or during pregnancy because the vaccine contains attenuated live virus ([Association of Professors of Gynecology and Obstetrics, 1999](#)). The [Centers for Disease Control \(1990\)](#) has maintained a registry since 1971 to monitor the fetal effects of vaccination. Through 1989, 321 susceptible women who were immunized within 3 months of conception had been followed to term. Fortunately, there is no evidence that the vaccine induces malformations.

DIAGNOSIS. Confirmation of rubella infection is often difficult. Not only are the clinical features of other illnesses quite similar, but about a fourth of rubella infections are subclinical despite viremia that may infect the embryo and fetus. Absence of rubella antibody indicates susceptibility. Antibody signifies an immune response to viremia. If maternal antibody is demonstrated at the time of exposure to rubella or before, it is exceedingly unlikely that the fetus will be affected. Despite native or vaccine-induced immunity, subclinical rubella infections may develop during outbreaks. Although asymptomatic **reinfection** in early pregnancy has been described without fetal effects ([Morgan-Capner and colleagues, 1985](#)), fetal infection has been documented in five seropositive mothers ([Best and associates, 1989](#)). In two, therapeutic abortion was performed, and the other three term infants had aspects of congenital rubella syndrome.

Viremia precedes clinically evident disease by about 1 week. The nonimmune person who acquires rubella viremia demonstrates peak antibody titers 1 to 2 weeks after the onset of the rash, or 2 to 3 weeks after the onset of viremia. The promptness of the antibody response, therefore, may complicate serodiagnosis unless serum is collected initially within a few days after the onset of the rash. If, for example, the first specimen was obtained 10 days after the rash, detection of antibodies would fail to differentiate between very recent disease or preexisting immunity to rubella. Specific IgM^2 antibody by radioimmunoassay can be detected from early after onset of clinical disease. It peaks at 7 to 10 days, and persists for 4 weeks after appearance of the rash ([American College of Obstetricians and Gynecologists, 1992](#)). Using very sensitive radioimmunoassays, it may persist for up to a year. Importantly, rubella reinfection can give rise to transient low levels of IgM . The use of immunoglobulin is not recommended for exposure.

CONGENITAL RUBELLA SYNDROME. Rubella is one of the most teratogenic agents known ([Chap 38, p. 1006](#)). **With rubella, as with any fetal infection, the concept of an infected versus an affected infant must be understood.** Only about half of women with affected infants give a history of a rash during pregnancy. [Miller and colleagues \(1982\)](#) have shown that 80 percent of women with rubella infection and a rash during the first 12 weeks have a fetus with congenital infection ([Fig. 56-2](#)). At 13 to 14 weeks this incidence was 54 percent, and it was 25 percent by the end of the second trimester. As the duration of pregnancy increases, fetal infections are less likely to cause congenital malformations. For example, rubella defects were seen in all infants with evidence of intrauterine infections before 11 weeks, but only in 35 percent of those infected at 13 to 16 weeks. Although no defects were found in 63 children infected after 16 weeks, they were followed only 2 years. [Hwa and associates \(1994\)](#) reported a much lower incidence of infection in 103 fetuses whose mothers had serologically confirmed rubella infection prior to 29 weeks.

Thus, clinical manifestations of congenital rubella correlate with the timing of maternal infection and fetal organ development. Congenital rubella syndrome includes one or more of the following:

- Eye lesions, including cataracts, glaucoma, microphthalmia, and other abnormalities
- Heart disease, including patent ductus arteriosus, septal defects, and pulmonary artery stenosis
- Sensorineural deafness
- Central nervous system defects, including meningoencephalitis
- Fetal growth restriction
- Thrombocytopenia and anemia
- Hepatitis, hepatosplenomegaly, and jaundice
- Chronic diffuse interstitial pneumonitis
- Osseous changes
- Chromosomal abnormalities

Infants born with congenital rubella may shed the virus for many months and thus be a threat to other infants, as well as to susceptible adults who come in contact with them.

The **extended rubella syndrome**, with progressive panencephalitis and type I diabetes, may not develop clinically until the second or third decade of life. Perhaps as many as a third of infants who are asymptomatic at birth may manifest such developmental injury (American College of Obstetricians and Gynecologists, 1993). [Webster \(1998\)](#) recently reviewed the teratogenic effects of the rubella virus.

CYTOMEGALOVIRUS

This is a ubiquitous DNA herpesvirus that eventually infects most humans. It is the most common cause of perinatal infection, and evidence for fetal infection is found in from 0.5 to 2 percent of all neonates. The virus is transmitted horizontally by droplet infection and contact with saliva and urine, vertically from mother to fetus-infant, and as a sexually transmitted disease. Day-care centers are a common source of infection. Usually by 2 to 3 years of age, children acquire the infection from one another and then transmit it to their parents ([Demmler, 1991](#); [Pass, 1991](#)).

Following primary infection, the virus becomes latent, and like other herpesvirus infections, there is periodic reactivation with viral shedding despite the presence of serum antibody. Humoral antibody is produced, but cell-mediated immunity appears to be the primary mechanism for recovery. Immunosuppressed states, whether naturally acquired or drug-induced, increase the propensity for serious cytomegalovirus infection. Presumably, decreased cell-mediated immune surveillance places the fetus-infant at high risk for sequelae of these infections.

The public health importance concerning morbidity of perinatal cytomegalovirus infection was first emphasized in 1971. According to [Yow and Demmler \(1992\)](#), in the ensuing 20 years, over 800,000 fetuses were infected and 50,000 were born with symptomatic disease. Many have died, and most of the survivors have severe handicaps, including mental retardation, blindness, and deafness. Collectively, the annual cost for their care is nearly \$2 billion ([American College of Obstetricians and Gynecologists, 2000](#)). Another 120,000 infected children who were asymptomatic at birth have neurological impairments.

MATERNAL INFECTION. There is no evidence that pregnancy increases the risk or clinical severity of maternal cytomegalovirus infection. Most infections are asymptomatic, but about 15 percent of adults have a mononucleosis-like syndrome characterized by fever, pharyngitis, lymphadenopathy, and polyarthritis. As shown in [Figure 56-3](#), the risk of seroconversion among susceptible women during pregnancy is from 1 to 4 percent. Immunity from previous infection can be demonstrated in up to 85 percent of pregnant women from lower socioeconomic backgrounds, whereas only half of women in higher income groups are seropositive. Primary infection, which is transmitted to the fetus in approximately 40 percent of cases, more often is associated with severe morbidity ([Fowler and co-workers, 1992](#); [Liesnard and associates, 2000](#)). Although transplacental infection is not universal, an infected fetus is more likely with maternal infection during the first half of pregnancy.

As with other herpesviruses, maternal immunity to cytomegalovirus does not prevent recurrence (reactivation), nor unfortunately does it prevent congenital infection. In fact, because most infections during pregnancy are recurrent, the majority of congenitally infected neonates are born to these women. Fortunately, congenital infections that result from recurrent infection are less often associated with clinically apparent sequelae than are those from primary infections.

CONGENITAL INFECTION. This causes **cytomegalic inclusion disease**, a syndrome that includes low birthweight, microcephaly, intracranial calcifications, chorioretinitis, mental and motor retardation, sensorineural deficits, hepatosplenomegaly, jaundice, hemolytic anemia, and thrombocytopenic purpura. Many of these features are also common with rubella. [Perlman and Argyle \(1992\)](#) emphasized the need to consider cytomegaloviral infection in preterm infants with neurological findings, and suggest that such an encephalopathic process is progressive. Fortunately, of the estimated 40,000 infants born infected in the United States each year, only approximately 10 percent demonstrate this syndrome, which is more prevalent in neonates born to women with primary infection during the first half of pregnancy.

[Fowler and colleagues \(1992\)](#) reported long-term results from 197 newborns with congenital cytomegalovirus viremia followed at the University of Alabama at Birmingham. About 20 percent of infants in the primary-infection group had symptomatic infection at birth; none in the recurrent-infection group were symptomatic at birth. After a mean of 4.7 years, morbidity was identified in 25 percent of the primary-infection group and 8 percent of the recurrent-infection group. Overall, 13 percent of primarily infected mothers had children whose intelligence quotients (IQs) were less than 70, whereas none of the other children had mental impairment. Sensorineural hearing loss was found in 15 versus 5 percent of primary- and recurrent-infection groups, respectively.

MANAGEMENT. Currently, there is no effective therapy. Serological screening is not recommended by the [American College of Obstetricians and Gynecologists \(2000\)](#):

1. There is no accurate predictability of the sequelae of primary infection.
2. There is no vaccine.
3. 1 to 2 percent of all infants excrete cytomegalovirus, and attempts to identify and isolate them are expensive and impractical ([Demmler, 1991](#); [Hagay and colleagues, 1996](#)).

The predictive value of a positive maternal genitourinary culture or cervical cytology in assessing fetal risk for infection is likewise minimal. Asymptomatic cytomegalovirus excretion can be shown in up to 10 percent of pregnant women, and the majority have recurrent infections that are low-risk for their fetuses.

Primary infection is diagnosed by fourfold-increased IgG^1 titers in paired acute and convalescent sera measured simultaneously, or preferentially by detecting maternal IgM^2 cytomegalovirus antibody. Recurrent infection usually is not accompanied by IgM antibody production. Unfortunately, neither of these methods is totally accurate.

Counseling regarding fetal outcome depends on the stage of gestation during which primary infection is documented. Even with a high infection rate with primary infection in the first half of pregnancy, the majority of infants develop normally.

PRENATAL DIAGNOSIS. In some cases, effects of fetal infection are detected by sonography, computed tomography, or magnetic resonance imaging. Microcephaly, ventriculomegaly, or cerebral calcifications may be seen ([Fig. 56-4](#)). Hyperechoic bowel has also been described as a sequela ([Forouzan, 1992](#); [Muller and colleagues, 1995](#); [Peters and associates, 1995](#)). Nearly 30 years ago, fetal cytomegalovirus infection was confirmed by amniotic fluid culture. As risks became better known for fetal involvement, a number of investigators reported the efficacy of confirming suspected primary infections by amniocentesis for viral culture or by cordocentesis to detect IgM^2 . More recently, polymerase chain reaction has been used to detect viral DNA in amniotic fluid and fetal blood.

[Lynch and colleagues \(1991\)](#) reported that viral isolation from amniotic fluid and elevated cord-blood total IgM² were helpful to confirm infection. [Hohlfeld and co-workers \(1991\)](#) confirmed fetal infection using the **shell vial assay** for viral antigen in amniotic fluid and fetal blood. [Donner and co-workers \(1993\)](#) measured cord blood IgM antibodies, viral culture, and polymerase chain reaction to diagnose fetal infections. In all of these studies, amniocentesis provided diagnostic results, but fetal blood analysis provided further information concerning fetal condition—anemia, thrombocytopenia, elevated hepatic enzymes, and total IgM.

[Lamy and colleagues \(1992\)](#) prospectively evaluated fetal cytomegalovirus transmission in nearly 1800 Belgian women. At their initial prenatal visit, about half (861) were seronegative. They were tested at each prenatal visit and 20 (2.3 percent) seroconverted before 22 weeks. Only seven allowed evaluation and two were uninfected. In the other five, amniotic fluid cultures were positive for cytomegalovirus; abortions were performed and histopathological evaluation disclosed brain involvement in all five.

[Bodeus and colleagues \(1999\)](#) described 98 pregnancies with congenital infection and emphasize that a negative culture or polymerase chain reaction of amniotic fluid does not always exclude fetal infection. [Antsaklis and associates \(2000\)](#) also observed this.

In another study from Belgium, [Liesnard and co-workers \(2000\)](#) described 210 fetuses born to women with suspected primary cytomegaloviral infection. Of these, at least 60 percent were proven to have primary infection while the other 40 percent had IgG¹ and IgM² antibodies when first studied. All women underwent amniocentesis and in most cases fetal cord blood was also obtained. These samples were tested with polymerase chain reaction, viral culture, and anticytomegalovirus IgM as well as nonspecific tests. The results of these are shown in [Table 56-2](#). The overall fetal transmission rate was about 25 percent. Combined culture and polymerase chain reaction results allowed diagnosis in 44 of 55 infected fetuses (80 percent). Polymerase chain reaction of amniotic fluid was 78 percent sensitive and superior to culture techniques. Importantly, the false-negative rate in samples taken before 21 weeks was 70 percent. The authors concluded that sampling had been done too close to maternal infection (seroconversion) and recommend amniocentesis after this time. [Antsaklis and colleagues \(2000\)](#) also concluded that polymerase chain reaction to amplify amniotic fluid viral DNA was the most accurate test.

BACTERIAL INFECTIONS

GROUP A STREPTOCOCCUS

Infection caused by **Streptococcus pyogenes** is rarely encountered today. These infections are particularly virulent, and the organism produces a number of toxins and enzymes. More recently, sporadic puerperal infections from group A streptococci have been observed. Postoperative or postpartum infection outbreaks may be nosocomial from asymptomatic carriage in health-care workers ([Centers for Disease Control and Prevention, 1999b](#); [Kolmos and colleagues, 1997](#)). The organism produces a **toxic shock-like syndrome** that is highly fatal. We encountered three cases at Parkland Hospital in 1992, and two caused maternal deaths ([Nathan and colleagues, 1993](#)). Prompt penicillin treatment, sometimes combined with surgical debridement, may be lifesaving ([Chap. 26, p. 678](#)). A less virulent exotoxin causes **scarlet fever**, and treatment is also given with penicillin. **Erysipelas** is an acute streptococcal skin infection, and bacteremia is common.

GROUP B STREPTOCOCCUS

Asymptomatic carriage of group B streptococcus—*S. agalactiae*—is common, especially in the vagina and rectum. The Vaginal Infections and Prematurity Study Group ([Regan and co-workers, 1991](#)) reported that 15 to 20 percent of over 8000 pregnant women from five clinical centers were culture positive for group B streptococci between 23 and 26 weeks. The organism has been implicated in several adverse pregnancy outcomes, including preterm labor, prematurely ruptured membranes, covert and overt chorioamnionitis, and puerperal sepsis, as well as in fetal and neonatal infections. There also have been case reports of postpartum maternal osteomyelitis and mastitis caused by group B infection ([Berkowitz and McCaffrey, 1990](#); [Rench and Baker, 1989](#)).

EPIDEMIOLOGY. Half of newborns of carrier women become colonized almost immediately at birth. Serious neonatal infections with group B streptococci are at least as prevalent as those from coliform organisms. During the 1970s, neonatal group B infections increased remarkably in frequency. For example, in Victoria, Australia, group B infection caused one third of perinatal deaths due to infection ([Fliegner and Garland, 1990](#)).

It is clear that intrapartum fetal transmission from the colonized mother may lead to severe neonatal sepsis soon after birth. The overall attack rate of early-onset sepsis is about 1 to 2 per 1000 of all births. In a multicenter case-control study of over 50,000 births, early-onset sepsis from all organisms was 3.5 per 1000 live births ([Schuchat and colleagues, 2000](#)). Group B streptococcus caused 1.4 per 1000 and *Escherichia coli* 0.6 per 1000. Although preterm or low-birthweight infants are at highest risk, more than half of the cases of neonatal sepsis are in term neonates. In the study by [Schuchat and associates \(2000\)](#), group B streptococcal sepsis was found less often in preterm neonates than sepsis from other organisms such as *E. coli*.

NEONATAL SEPSIS. Infection in infants before 7 days is defined as **early-onset disease** ([Schrag and colleagues, 2000](#)). In some cases, the infant is born acidemic and depressed. We have even encountered a number of "unheralded" intrapartum stillbirths. In many neonates, septicemia includes signs of serious illness that usually develop within 6 to 12 hours of birth. These include respiratory distress, apnea, and shock. At the outset, therefore, the illness must be differentiated from idiopathic respiratory distress syndrome. The mortality rate with early-onset disease is about 25 percent, and preterm infants fare less well. Unfortunately, it is not uncommon for surviving infants to exhibit neurological sequelae apparently sustained during hypotension from the sepsis syndrome.

Late-onset disease usually manifests as meningitis a week or more (7 days to 3 months) after birth. These cases are most often caused by serotype III organisms. The mortality rate, although appreciable, is less for late-onset meningitis than for early-onset sepsis. Here again, neurological sequelae are common in survivors.

EVOLUTION OF PREVENTION STRATEGIES. [Steigman and associates \(1978\)](#) reported an absence of early-onset group B streptococcal sepsis in 130,000 newborn infants given 50,000 units of aqueous penicillin G intramuscularly at birth as prophylaxis against gonococcal ophthalmia neonatorum. A prospective study of nearly 19,000 infants was then carried out by [Siegel and co-workers \(1980\)](#) at Parkland Hospital. About half of these infants were randomized to receive aqueous procaine penicillin G intramuscularly within 1 hour of birth as prophylaxis against ophthalmia neonatorum and also to evaluate its impact on group B infections. The incidence of streptococcal disease was significantly lowered in those given penicillin. It was worrisome, however, that the incidence of infection and mortality caused by penicillin-resistant nonstreptococcal organisms increased. In another study of almost 11,000 neonates, [Patel and colleagues \(1999\)](#) gave postnatal penicillin prophylaxis and reported a reduction in the incidence of neonatal group B infection from 9 per 1000 to 4 per 1000. Death from sepsis was also decreased from 3 per 1000 to 1 per 1000.

Earlier, [Pyati and co-workers \(1983\)](#) reported that penicillin prophylaxis at birth was of little benefit in preventing early-onset group B disease in low-birthweight neonates. Many infants who did poorly were subsequently found to have positive cord blood cultures when single-dose penicillin was given for ophthalmic prophylaxis. Thus, in these already covertly infected fetuses, single-dose penicillin was inadequate to treat established neonatal infection.

Emphasis was next placed on intrapartum treatment of mothers found to be colonized near the time of delivery. [Boyer and Gotoff \(1986\)](#) randomized intrapartum and neonatal ampicillin treatment of colonized mothers. They observed decreased neonatal colonization (9 versus 51 percent) and early-onset sepsis (none versus 6 percent) in infants born to treated women. [Garland and Fliegner \(1991\)](#) screened over 30,000 Australian clinic patients at 32 weeks and treated asymptomatic carriers intrapartum with intravenous penicillin. Nearly 27,000 private patients admitted to their hospital were not screened. Although there were no group B infections in neonates of clinic patients, by contrast, there were 27 infections and eight deaths in the unscreened private control group. [Tuppurainen and Hallman \(1989\)](#) reported similar results with almost 9000 women screened for heavy colonization using a rapid test on arrival to the delivery unit.

[Gibbs and colleagues \(1994\)](#) and [Pylipow and associates \(1994\)](#) performed screening cultures at around 28 weeks. They treated culture-positive women in labor only if they developed risk factors. Using this approach, they prevented half to two thirds of cases of neonatal sepsis. Choice of antimicrobials may prove to be important. In the earlier study from Parkland, [Siegel and associates \(1980\)](#) documented penicillin-resistant neonatal infections. [McDuffie and colleagues \(1993\)](#) reported ampicillin-resistant enterobacterial infection in four neonates whose mothers were given intrapartum ampicillin. For these reasons, [Amstey and Gibbs \(1994\)](#) recommended consideration for penicillin G intrapartum prophylaxis. [Bloom and colleagues \(1996\)](#) found that bactericidal concentrations of ampicillin were achieved in amniotic fluid and cord blood within 5 minutes of administration.

RECOMMENDED PREVENTION STRATEGIES. Although there is not a consensus regarding the most efficacious prevention strategy, there are now guidelines. These consensus opinions were published by the [American College of Obstetricians and Gynecologists \(1996\)](#), the [Centers for Disease Control and Prevention \(1996a\)](#), and the [American Academy of Pediatrics and American College of Obstetricians and Gynecologists \(1997\)](#). Either a risk-based or a screening-based approach should be utilized to identify women to be given intrapartum prophylaxis.

With the risk-based approach, intrapartum antibiotic prophylaxis is given to women with preterm labor (less than 37 weeks), preterm premature rupture of the

membranes, rupture of membranes 18 hours or longer, previous sibling with group B streptococcal disease, or with intrapartum fever (38°C or greater). Prior identification of group B bacteriuria is also considered a risk factor.

With the culture-based approach, all women are screened for group B streptococcal colonization at 35 to 37 weeks and intrapartum antibiotics given to carriers. Because of the concern of ampicillin-resistant organisms, especially *E coli*, penicillin G is recommended by many authorities for intrapartum prophylaxis ([Schuchat and colleagues, 2000](#)). Ampicillin is an acceptable alternative, and continues to be widely used during penicillin G shortages that occurred in 1999 ([Osmon, 2000](#)). Either clindamycin or erythromycin may be utilized in the penicillin-allergic woman.

In 1997, the Centers for Disease Control and Prevention ([Factor and associates, 2000](#)) surveyed 165 hospitals in its Active Bacterial Core Surveillance system and found that 58 percent had group B prevention policies. This is up from 35 percent in 1994. Importantly, hospitals that adopted a policy showed a significantly decreased neonatal infection rate. In another surveillance study involving eight states, [Schrag and colleagues \(2000\)](#) reported a significant decrease in group B streptococcal disease with incorporation of strategies for intrapartum antibiotic prophylaxis—from 1.7 per 1000 births to 0.6 per 1000 in 1998.

In a study of over 5000 consecutive deliveries, [Towers and colleagues \(1999a\)](#) reported that if the risk-based strategy was utilized, 20 percent of women would be candidates for intrapartum prophylaxis. In another study, [Towers and colleagues \(1999b\)](#) identified 49 cases of early-onset group B streptococcal sepsis in 47,000 deliveries. Of these 49 babies, 40 were delivered at term and only 12 (30 percent) were delivered with an intrapartum risk factor.

The screening-based Centers for Disease Control protocol was implemented at McGee Women's Hospital in 1995 and [Brozanski and associates \(2000\)](#) studied its effect on neonatal group B sepsis. Nearly 29,000 deliveries occurred during the 4-year period from 1995 to 1999 when screening was codified. The prevalence of early-onset group B sepsis was 0.14 per 1000 compared with 1.16 per 1000 in 31,000 women delivered from 1992 through 1995 when there was no policy in place.

In early 1995 at Parkland Hospital we adopted the [American College of Obstetricians and Gynecologists \(1996\)](#) risk-based approach for intrapartum antimicrobial treatment for high-risk pregnancies. In addition, all neonates whose mothers were not given intrapartum antibiotic prophylaxis are treated in the delivery room with aqueous procaine penicillin G, 50,000 units intramuscularly. This approach was chosen because surveillance studies from 1972 through 1994 showed the lowest infection rates from 1981 through 1986 when universal neonatal penicillin prophylaxis was utilized ([Siegel and Cushion, 1996](#)). As shown in [Figure 56-5](#), in the first year, early-onset group B infection was decreased from 1.6 per 1000 to 0.4 per 1000 ([Wendel and associates, 2000](#)).

Thus, implementation of either the screening-based or risk-based protocol is associated with diminished group B neonatal sepsis. There are still major concerns about antimicrobial resistance, and we are continuing to monitor this approach to determine its effect on neonatal sepsis, maternal morbidity, and resistant infections in the nursery. [Bergeron and colleagues \(2000\)](#) have provided preliminary data that a rapid-detection polymerase chain reaction method is accurate and reliable to identify women in labor with group B colonization. [Schuchat \(2000\)](#) cautioned that this labor-intensive test, even if proven in clinical trials, is not a panacea for the overall problem.

VACCINATION. Because some protection against serious neonatal infection is conferred by maternal antibody, it is logical that vaccination with capsular polysaccharide antigen may prove efficacious. [Baker and colleagues \(1988\)](#) reported that maternal immunization to type III antigen produces antibody in about 60 percent of women. [Coleman and co-workers \(1992\)](#) as well as the [Institute of Medicine \(1985\)](#) have cited vaccine development as attainable and as a priority.

LISTERIOSIS

Listeria monocytogenes is an uncommon but probably underdiagnosed cause of neonatal sepsis. The [Centers for Disease Control and Prevention \(2001\)](#) estimates that nearly 2500 individuals in the United States annually are ill with listeriosis and over 500 will die. In a recent multistate outbreak, 50 cases were caused by a rare strain that resulted in six deaths in adults and spontaneous abortion in two pregnant women ([Centers for Disease Control and Prevention, 1999d](#)). This Gram-positive aerobic motile bacillus can be isolated from soil, water, and sewage. From 1 to 5 percent of adults carry listeria in their feces. Food-borne transmission is important, and outbreaks of listeriosis have been reported from manure-contaminated cabbage, pasteurized milk, and fresh Mexican-style cheese.

Listerial infections are more common in very old or young, pregnant, or immunocompromised patients. Because cell-mediated immunity is important in defense, some authors have speculated that pregnant women are susceptible. [Tappero and colleagues \(1995\)](#) from the Listeriosis Study Group surveyed culture results from 29 million persons from 1989 through 1992. The incidence of infection had declined by 40 percent compared with the previous 4-year surveillance period. Although perinatal listeriosis infection rates declined by 50 percent, almost a third of reported culture-proven cases were in pregnant women. In the epidemic in Los Angeles County in 1985, which was caused by contaminated Mexican-style cheese, 65 percent of cases were in pregnant women or their fetus-neonates. Interestingly, [Mascola and associates \(1994\)](#) observed that women with multifetal gestation were at a fourfold risk for infection.

Listeriosis during pregnancy may be asymptomatic or cause a febrile illness that is confused for influenza, pyelonephritis, or meningitis ([Silver, 1998](#); [Sirry and colleagues, 1994](#)). The diagnosis usually is not apparent until blood cultures are reported as positive. Occult or clinical infection also may stimulate labor ([Boucher and Yonekura, 1986](#)). Meconium passage is common with fetal infection. Maternal listeremia causes fetal infection that characteristically produces disseminated granulomatous lesions with microabscesses. [Topalovski and colleagues \(1993\)](#) demonstrated macroabscesses in seven infected placentas ([Fig. 56-6](#)).

The neonate is particularly susceptible to infection, and mortality approaches 50 percent. Early-onset neonatal sepsis is a common manifestation, whereas late-onset listeriosis manifests after 3 to 4 weeks of age as meningitis. In this regard, these infections are very similar to those caused by group B streptococci, discussed previously.

TREATMENT. There are no clinical trials concerning efficacy, but a combination of ampicillin and gentamicin is usually recommended because of proven laboratory synergism. The efficacy of trimethoprim-sulfamethoxazole has been documented, and it should be given to penicillin-allergic women. There is evidence that maternal antimicrobial treatment may be effective for fetal infection ([Linnan and colleagues, 1988](#)).

SALMONELLA AND SHIGELLA

SALMONELLOSIS. Infections from *Salmonella* and *Shigella* species continue to be a major cause of food-borne illness. There are from 800,000 to 4 million cases of salmonella infections each year in the United States, which result in 500 deaths ([Centers for Disease Control and Prevention, 1999c](#)). The organisms are ubiquitous in warm-blooded animals and almost all of more than 2200 serovars cause human illness ([Baird-Parker, 1990](#)). Enteritis is contracted through contaminated food, and symptoms include diarrhea, abdominal pain, fever, chills, nausea, and vomiting. [Scialli and Rarick \(1992\)](#) described a woman with enteritis and bacteremia from group C1 salmonella infection. Amniotic fluid cultures also were positive, and infection caused fetal death at 15 weeks. Management is usually by intravenous fluid rehydration. Antimicrobials prolong the carrier state and are not given in uncomplicated infections.

TYPHOID FEVER. Uncommonly seen in the United States, this disease is caused by *Salmonella typhi*, which is spread by oral ingestion of contaminated food, water, or milk. In pregnant women, the disease is more likely to be encountered during epidemics or in those who are infected with human immunodeficiency virus (HIV) ([Duff and Engelsjerd, 1983](#); [Hedriana and colleagues, 1995](#)). From their review, [Dildy and associates \(1990\)](#) reported that antepartum typhoid fever in former years resulted in abortion or preterm labor in up to 80 percent of cases, with a fetal mortality rate of 60 percent and a maternal mortality rate of 25 percent. Subsequent experiences fortunately were much more favorable.

Chloramphenicol remains the most effective treatment, but many clinicians give intravenous trimethoprim-sulfamethoxazole, ampicillin, ciprofloxacin, ofloxacin, or cefotaxime. Antityphoid vaccines appear to exert no harmful effects when administered to pregnant women. Typhoid and cholera vaccine should be given in an epidemic or before travel to endemic areas ([Association of Professors of Obstetrics and Gynecology, 1999](#)).

SHIGELLOSIS. Bacillary dysentery caused from *Shigella* infection is a relatively common cause of inflammatory exudative diarrhea in adults. Bloody stools are common. Shigellosis is more common in children attending day-care centers. It is highly contagious with primary attack rates up to 75 percent, and exposed family members may be infected in over half of cases ([Guerrant and Bobak, 1991](#)). Clinical manifestations range from mild diarrhea to severe dysentery, abdominal cramping, tenesmus, fever, and systemic toxicity. Although shigellosis is self-limited, careful attention to treatment of dehydration is essential in severe cases. We have encountered women in whom secretory diarrhea exceeded 10 L/day! In severely ill women, the treatment of choice is trimethoprim-sulfamethoxazole.

HANSEN DISEASE

This disease, which was in the past termed leprosy, is caused by *Mycobacterium leprae*. From their review, [Lockwood and Sinha \(1999\)](#) reported that type I or

reversal reactions tend to occur postpartum. Type II reactions—erythema nodosum leprosum—occurred throughout pregnancy and during lactation. Dapsone and clofazimine for treatment appear to be safe for use during pregnancy ([Farb and associates, 1982](#)). Rifampin therapy is also effective. [Duncan \(1980\)](#) reported an excessive incidence of low-birthweight infants born to infected women. [Duncan and associates \(1984\)](#) were unable to demonstrate any morphological evidence of placental infection in 82 infected pregnant women. Neonatal infection apparently is acquired from skin-to-skin or droplet transmission.

LYME DISEASE

This disease is caused by the spirochete *Borrelia burgdorferi*. It is the most commonly reported vector-borne illness in the United States. Lyme borreliosis results from the bite of ticks of the genus *Ixodes*. Early local infection causes a distinctive skin lesion, **erythema migrans**, which may be accompanied by a flu-like syndrome and regional adenopathy. If untreated, disseminated infection may develop in days to weeks after inoculation. Multisystem involvement is common, but skin lesions, arthralgia and myalgia, carditis, and meningitis predominate. If still untreated after several weeks to months, late infection manifests in perhaps half of patients. Native immunity is acquired and the disease enters a chronic phase. Whereas some patients remain asymptomatic, others develop a variety of dermatological, rheumatic, or neurological manifestations.

Serological diagnosis has pitfalls and clinical diagnosis is important. Although positive in about half of patients with early disease, most with late untreated Lyme disease have a positive enzyme-linked immunosorbent assay. Optimal treatment has not been established. In early infection, treatment with doxycycline or ampicillin is recommended. Pregnant women are given oral amoxicillin or penicillin V for 3 weeks (American College of Obstetricians and Gynecologists, 1993). Cefuroxime is preferred but erythromycin can be given for penicillin-allergic women. In a study of 58 pregnant Slovenian women with erythema migrans, 14-day treatment with penicillin V, penicillin G, or ceftriaxone were all effective ([Maraspin and colleagues, 1996](#)). For later infection manifested by meningitis or carditis, high-dose intravenous penicillin G is recommended. Chronic arthritis is treated with amoxicillin and probenecid orally for 30 days, or with ceftriaxone or penicillin G intravenously for 14 days ([Smith and co-workers, 1991](#)).

NEONATAL INFECTION. There is concern that infection may have fetal effects because other spirochetes, viz., *Treponema pallidum*, cause congenital infection. [Schlesinger and colleagues \(1985\)](#) documented the persistence of spirochetes in fetal spleen, kidney, and bone marrow at 35 weeks in a woman who had Lyme disease during early pregnancy. [Weber and associates \(1988\)](#) demonstrated the organism in brain and liver of a term infant who died suddenly and unexpectedly at 1 day of age. The mother had responded to oral penicillin for erythema migrans at 8 weeks. [Markowitz and associates \(1986\)](#) reviewed 19 cases complicating pregnancy, and reported that 25 percent had preterm labor, fetal death, or rash-like illness in the newborn. [Strobino and colleagues \(1993\)](#) serologically evaluated 2000 pregnant women in an endemic area of New York state. Although the number of infected women was small, they reported that maternal exposure to Lyme disease was not associated with fetal death, preterm delivery, or malformations. In a review of 105 pregnant women with erythema migrans, 93 had normal pregnancies at term ([Maraspin and colleagues, 1999](#)). Two spontaneously aborted and six were delivered of preterm infants of which two died. Four others had congenital anomalies, and [Strobino and colleagues \(1999\)](#) found no association with Lyme disease and heart malformations when they compared 704 children with cardiac anomalies to 796 controls.

PROTOZOAL INFECTIONS

TOXOPLASMOSIS

Infection with *Toxoplasma gondii* is transmitted through encysted organisms by eating infected raw or undercooked beef or pork and through contact with oocytes in infected cat feces, or the fetus can be infected transplacentally. Maternal immunity appears to protect against fetal infection; thus, for congenital toxoplasmosis to develop, the mother must have acquired the infection during pregnancy. About a third of North American women acquire protective antibodies before pregnancy, and this is higher in those keeping cats as pets ([Freij and Sever, 1996](#)). In Europe, undercooked meat products are the main risk factor ([Cook and associates, 2000](#)). The Centers for Disease Control and Prevention ([Lopez and colleagues, 2000](#)) estimates that there are between 400 and 4000 cases of congenital toxoplasmosis each year in the United States.

Acute toxoplasmosis complicates about 1 to 5 per 1000 pregnancies (American College of Obstetricians and Gynecologists, 1993). Symptoms include fatigue, muscle pains, and sometimes lymphadenopathy, but most often infection is subclinical. Infection in pregnancy may cause abortion or result in a live-born infant with evidence of disease. The risk of fetal infection increases with duration of pregnancy, but overall it approaches 50 percent ([Wong and Remington, 1994](#)). Fetal infection is more virulent the earlier that infection is acquired, but fortunately infection is less common earlier in pregnancy. With third-trimester infection, 60 percent of infants will have evidence of perinatal infection. Conversely, only 10 percent of those infected in the first trimester have congenital toxoplasmosis. Overall, less than a fourth of newborns with congenital toxoplasmosis have evidence for clinical illness at birth. Later, however, most go on to develop some sequela of infection. Clinically affected infants at birth usually have evidence of generalized disease with low birth-weight, hepatosplenomegaly, icterus, and anemia. Some primarily have neurological disease with convulsions, intracranial calcifications (see [Fig. 56-4](#)), mental retardation, and hydrocephaly or microcephaly. Almost all infected infants eventually develop chorioretinitis.

SCREENING. In the past decade, serological screening for toxoplasmosis has become feasible. In some European countries *prenatal screening* is done routinely. Despite this, a multidisciplinary committee of the [Royal College of Obstetricians and Gynaecologists \(1992\)](#) recommended against instituting universal prenatal screening in the United Kingdom. The [American College of Obstetricians and Gynecologists \(2000\)](#) does not recommend routine screening except for pregnant women with HIV³ infection.

If anti-toxoplasma IgG¹ antibody is confirmed before pregnancy, then the woman is not at risk for a congenitally infected fetus. In most cases, however, serological testing is not done until the woman is pregnant. If antibody, usually determined by the Sabin Feldman dye test or indirect fluorescence on enzyme-linked immunosorbent assay, is present in low titers, it probably represents previously acquired immunity. It could also be IgM² from recent infection, although IgM may persist for years ([Freij and Sever, 1996](#); [Wong and Remington, 1994](#)). The Centers for Disease Control and Prevention recommends that all IgM-positive samples be confirmed by a reference laboratory ([Lopez and co-workers, 2000](#)).

The most accurate confirmation of active infection is a rise in IgG¹ titer in two appropriately spaced but simultaneously tested serum samples. Very high titers—that is, greater than 1:512—more likely indicate recent or current illness. [Sever and colleagues \(1988\)](#) reported increased microcephaly, deafness, and mental retardation in children born to women whose titers were 1:256 or higher.

A polymerase chain reaction assay with high specificity and sensitivity has been developed ([Hohlfeld and colleagues, 1994](#)). The technique permits prenatal diagnosis within a day by assay of amniotic fluid. It also can be used to document fetal infection prior to 20 weeks. In a multicenter study of 122 women from six European Toxoplasma Centers, [Foulon and colleagues \(1999a\)](#) reported that amniotic fluid polymerase chain reaction had an 81 percent sensitivity and 96 percent specificity.

MANAGEMENT. For the woman thought to have active disease, [Wong and Remington \(1994\)](#) recommend antimicrobial treatment. There is evidence that **spiramycin**, a macrolide antibiotic used widely in Europe, reduces the incidence of fetal infection, but it may not modify its severity. It is available through the Food and Drug Administration (301-443-4280), or the manufacturer, Rhone-Poulenc Rover in Valley Forge, PA. Treatment may also be given with **pyrimethamine plus sulfadiazine**.

[Daffos and colleagues \(1988\)](#) obtained amniotic fluid and fetal blood samples by cordocentesis in 746 French women with proven infection up to 25 weeks. Maternal infection was diagnosed by toxoplasma-specific IgM² antibody. All women with presumed infection were treated with spiramycin, 3 g daily throughout pregnancy. Of the 42 (6 percent) of their fetuses found to have infection, 39 were already infected before treatment by demonstrating IgM-specific antibody by cordocentesis. For these women, pyrimethamine and either sulfadoxine or sulfadiazine were added to the spiramycin regime.

[Foulon and co-workers \(1990b\)](#) reported a 12 percent incidence of congenital toxoplasmosis in 50 Belgian women infected before midpregnancy. They concluded that serological screening with invasive fetal diagnosis was safe and feasible. [Foulon and associates \(1990a\)](#) described a case in which prenatal diagnosis was confirmed by tissue culture of a chorionic villus biopsy. [Hohlfeld and co-workers \(1994\)](#) showed the risk of fetal infection to be 7.4 percent using the polymerase chain reaction test on amniotic fluid. The negative-predictive value for this test was 99.7 percent. [Berrebi and colleagues \(1994\)](#) studied 163 women with acute toxoplasmosis before 26 weeks. All were treated with spiramycin and some also were given pyrimethamine and sulfadiazine. All 27 of 162 live-born infants with proven congenital infection had normal development at 15 to 71 months of age. [Pratlong and associates \(1996\)](#) reported that antenatal diagnosis of fetal infection was 77 percent effective using ultrasound examination and fetal blood sampling for IgM², IgA, and nonspecific markers.

[Guerina and associates \(1994\)](#) screened 635,000 infants born in Massachusetts and New Hampshire. In 100 of these, cord blood was positive for IgM^2 toxoplasma antibodies. Congenital infection was confirmed in 52, and treatment was given for 1 year. Although not proven, there is some evidence that early treatment may reduce long-term sequelae.

In a review of studies of treatment of toxoplasmosis during pregnancy, [Wallon and colleagues \(1999\)](#) concluded that the efficacy of antenatal treatment in reducing congenital toxoplasmosis was unclear. [Foulon and colleagues \(1999b\)](#), in a study of 144 women from five reference centers, concluded that antenatal antibiotics did not reduce the maternal-fetal transmission rate, but did reduce the sequelae of such infection. Moreover, the earlier the antibiotics were given, the least likely sequelae were to occur.

MALARIA

There are four species of *Plasmodium* that cause human malaria: *vivax*, *ovale*, *malariae*, and *falciparum*. Organisms are transmitted by the bite of a female *Anopheles* mosquito. Nearly 300 to 500 million persons worldwide are infected at any given time and the disease causes from 1 to 3 million deaths annually ([Murray and colleagues, 2000](#)). Almost 40 percent of the world population—2 billion people—are at risk of contracting the disease. Malaria has been effectively eradicated in Europe and most of North America except for parts of Mexico.

The disease is characterized by fever and flu-like symptoms including chills, headaches, myalgia, and malaise, which may occur at intervals. Symptoms are less severe in immune patients. Malaria may be associated with anemia and jaundice, and *falciparum* infections may cause kidney failure, coma, and death.

EFFECTS ON PREGNANCY. Malarial episodes increase significantly by 3- to 4-fold during the latter two trimesters of pregnancy and 2 months postpartum ([Diagne and associates, 2000](#)). Pregnancy enhances the severity of *falciparum* malaria, especially in nonimmune nulliparous women ([Nathwani and colleagues, 1992](#); [Robier and co-workers, 1999](#)). The incidence of abortion and preterm labor is increased with malaria ([Menendez and associates, 2000](#)).

Increased fetal loss may be related to placental and fetal infection. Fifty years ago, [Jones \(1950\)](#) found that parasites have an affinity for decidual vessels and may involve the placenta extensively without affecting the fetus. [Ismail and colleagues \(2000\)](#) studied 1179 placentas from an endemic area in Tanzania. Of these, 35 percent showed parasites, and half of women with infected placentas had negative blood film testing for malaria. Despite heavy placental involvement, neonatal infection is uncommon. [Covell \(1950\)](#) studied this extensively in Africa and cited an incidence of neonatal malaria of only 0.3 percent. In nonimmune women, congenital malaria may develop in up to 7 percent of neonates ([Hulbert, 1992](#)). [Cot and colleagues \(1992\)](#) showed that chloroquine chemoprophylaxis decreased placental infection in asymptomatic infected women to 4 percent compared with 19 percent of untreated controls; however, mean birthweight was not different.

TREATMENT. Commonly used antimalarial drugs are not contraindicated during pregnancy. Some of the newer antimalarial agents have antifolate activity, and may theoretically contribute to the development of megaloblastic anemia. In actual practice, this does not appear to be the case. In at least one study by [Keuter and co-workers \(1990\)](#), nulliparas were more likely to remain parasitemic after therapy for *falciparum* infection. The maternal outcome is worse if *falciparum* malaria is drug resistant ([Alecrim and colleagues, 2000](#)).

Chloroquine is the treatment of choice for all forms of malaria except chloroquine-resistant *P falciparum* and newly emerging strains of resistant *P vivax*. For severe malaria, chloroquine is given intravenously. For the woman with chloroquine-resistant infection, **mefloquine** is given orally. For severe resistant malaria, quinine or quinidine is given parenterally. [Wong and associates \(1992\)](#) report a successful outcome in a 31-week pregnant woman treated with intravenous quinine and exchange transfusion. At high doses, mefloquine is teratogenic and embryotoxic for some laboratory animals. Despite this, sparse data from the [World Health Organization \(1995\)](#) and other reports indicate the drug to be safe and effective in pregnancy ([Briggs and colleagues, 1998](#)).

PROPHYLAXIS. This is recommended for travel to endemic areas. If chloroquine-resistant *falciparum* or *vivax* malaria has not been reported, prophylaxis is initiated 1 to 2 weeks before the endemic area is entered. Chloroquine, 300 mg of base, is given orally once a week, and this is continued until 4 weeks after return to nonendemic areas ([Bradley and Warhurst, 1995](#); [Wyller, 1993](#)). Travel to areas endemic for chloroquine-resistant strains is discouraged during early pregnancy, after which mefloquine prophylaxis is given ([Briggs and associates, 1998](#)). The drug was evaluated for prophylaxis in 339 pregnant women after 20 weeks and found to be 85 percent effective in preventing *falciparum* malaria and 100 percent for *vivax* infections ([Nosten and associates, 1994](#); [Nosten and Price, 1995](#)). In nonpregnant persons, doxycycline is recommended for chemoprophylaxis.

Several vaccines are currently under evaluation. Almost all vaccine trials have focused on two of nearly 6000 estimated *falciparum* proteins. One chimeric protein vaccine, SPF 66, has been field-tested and is perhaps 10 to 30 percent effective ([Olliaro and colleagues, 1996](#)). [Murray and co-authors \(2000\)](#) predict a licensed vaccine in about 5 years.

AMEBIASIS

Most persons infected with *Entamoeba histolytica* are asymptomatic cyst-passers. Amoebic dysentery may take a fulminant course during pregnancy. Prognosis is worse if complicated by a hepatic abscess, which may be quite serious during pregnancy, and rupture has been reported ([Constantine and colleagues, 1987](#)). Therapy is similar to that for the nonpregnant woman, and metronidazole is the drug of choice.

MYCOTIC INFECTIONS

Disseminated infection during pregnancy is uncommon with coccidiomycosis, blastomycosis, cryptococcosis, or histoplasmosis. Their identification and management are considered in [Chapter 46 \(p. 1229\)](#).

57. Sexually Transmitted Diseases

Sexually transmitted diseases are relatively common during pregnancy, especially in indigent, urban populations plagued by drug abuse and prostitution. Screening, identification, education, and treatment are important components of prenatal care for women at increased risk for these infections. Consequently, as a part of routine prenatal care, common sexually transmitted diseases that are often sought include syphilis, gonorrhea, chlamydia, hepatitis B virus, human immunodeficiency virus, and human papillomavirus.

In the following treatment protocols for sexually transmitted diseases, we attempt to adhere to the intensive, but frequently modified, treatment schedules provided periodically by the [Centers for Disease Control and Prevention \(1998b\)](#).

SYPHILIS

Through the 1980s, there was an increase in the incidence of syphilis in the United States that peaked in 1990, but since then, rates have declined 85 percent to 1998 ([Centers for Disease Control and Prevention, 1999d](#)). Shown in [Figure 57-1](#) are the incidences for adult-acquired as well as congenital syphilis. The rate of syphilis in the United States in 1998 was a record low of 2.6 cases per 100,000 persons, which is very near the goal set for the National Health Objective for 2000. The South, with 6.6 cases per 100,000 is the only region not meeting this goal. Likewise, a record low incidence of congenital syphilis, 20.6 cases per 100,000 live births, was recorded in 1998 by the [Centers for Disease Control and Prevention \(1999a\)](#). These declines continued through 1999 ([Vastag, 2001](#)). The results are so promising that the Centers for Disease Control and Prevention have created the National Plan for Syphilis Elimination ([Mitka, 2000](#)).

[Minkoff and colleagues \(1990\)](#) reported associations with maternal syphilis and drug abuse, particularly crack cocaine, and lack of prenatal care. [Klass and colleagues \(1994\)](#), in a study of prenatal syphilis at the Boston City Hospital over four decades, reported a prevalence of syphilis in women either before or during pregnancy of 2.4 percent in 1951 compared with 3.9 percent in 1991. They concluded that the continued prevalence of syphilis at delivery was associated with substance abuse, human immunodeficiency virus infection, lack of prenatal care, treatment failures, and reinfection. Antepartum syphilis can profoundly affect pregnancy outcome by causing preterm labor, fetal death, and neonatal infection by transplacental or perinatal infection ([Gilstrap and Wendel, 1999](#); [Vaules and associates, 2000](#)). Fortunately, of the many congenital infections, syphilis is not only the most readily prevented but also the most susceptible to therapy.

CLINICAL MANIFESTATIONS

Primary syphilis follows an incubation period of 10 to 90 days (average 3 weeks), but usually less than 6 weeks. During pregnancy, the primary genital lesion, or sometimes multiple lesions, may be of such small size or be so located as to go unnoticed. For example, a **cervical chancre** is more common in pregnant women, probably because of inoculation of the friable cervix. The primary chancre is characterized by a painless firm ulcer with raised edges and a granulation base. It persists for 2 to 6 weeks and then heals spontaneously but is often accompanied by nontender, enlarged inguinal lymph nodes.

Approximately 4 to 10 weeks after healing of the chancre, secondary syphilis usually appears in the form of a highly variable skin rash. About 15 percent of women still have a chancre. The lesions of secondary syphilis may be mild and go unnoticed in 25 percent of patients. In some, lesions are limited to the genitalia, where they appear as elevated areas, or **condylomata lata**, which occasionally cause vulvar ulcerations ([Fig. 57-2](#)). Secondary syphilis may also cause alopecia. At times the first and only suggestion of the disease is the delivery of a stillborn infant or a live-born infant severely afflicted with congenital syphilis.

FETAL AND NEONATAL INFECTION

In the past, syphilis accounted for nearly a third of stillbirths. Today syphilis has a smaller but persistent role in fetal death. For example, at Parkland Hospital from 1988 to 1995, congenital syphilis accounted for 6.3 percent of stillbirths ([Cunningham and Hollier, 1997](#)). The number of cases of congenital infection in black women from Baltimore for 1996 was 550 per 100,000 births compared with that for the United States of 30 per 100,000 births ([Centers for Disease Control and Prevention, 1998a](#)). Many of these mothers have inadequate prenatal care, and [Southwick and colleagues \(1999\)](#) reported an outbreak of congenital syphilis associated with inadequate prenatal testing for syphilis. [McFarlin and co-workers \(1994\)](#) reported that the serological titer and unknown duration of infection were major risk factors for congenital syphilis. In a review of 322 cases of congenital syphilis, [Coles and associates \(1995\)](#) reported that only 20 percent of the newborns had a complete laboratory workup, including long-bone radiographs and spinal fluid analysis. Of the 80 women treated for syphilis during pregnancy, only 30 percent were treated appropriately for their stage of infection.

Spirochetes readily cross the placenta and can result in congenital infection. Because of relative immunoincompetence prior to about 18 weeks, the fetus generally does not manifest clinical disease if infected before this time ([Silverstein, 1962](#)). The frequency of congenital syphilis varies with both the stage and duration of maternal infection. The highest incidence is in neonates born to mothers with early syphilis—primary or secondary—and the lowest incidence with late latent disease—greater than 1-year duration ([Centers for Disease Control, 1988](#); [Fiumara and colleagues, 1952](#)). As expected, early latent disease is associated with a higher rate of congenital infection because spirochetemia is greater in proximity to primary infection. **Importantly, any stage of maternal syphilis may result in fetal infection.**

PATHOLOGY

Syphilis is a chronic infection, and the spirochete causes lesions in the internal organs that include interstitial changes in the lungs (*pneumonia alba of Virchow*), liver (*hypertrophic cirrhosis*), spleen, and pancreas. Recently acquired infections are more likely to be associated with fetal morbidity and mortality. Syphilitic infection also causes *osteochondritis* in the long bones, which is most readily recognizable radiographically in the femur, tibia, and radius.

With syphilitic infection, the placenta becomes large and pale. Microscopically, villi appear to have lost their characteristic arborescent appearance and to have become thicker and club shaped. [Rogers and colleagues \(1999\)](#) described large villi in 70 percent of placentas from 34 stillborn infants with congenital syphilis. In 23 live-born infants with congenital syphilis, half had placentas with large villi. There is a marked decrease in the number of blood vessels, which in advanced cases almost entirely disappear as a result of endarteritis and proliferation of stromal cells. Perhaps related to this, [Lucas and colleagues \(1991\)](#) demonstrated increased vascular resistance in uterine and umbilical arteries of infected pregnancies. Spirochetes are sparsely scattered throughout the placenta even when they are present in large numbers in fetal organs. They may be demonstrated by examination under the darkfield microscope of scrapings from the intima of the vessels of the fresh umbilical cord. In a study of 25 untreated women, [Schwartz and associates \(1995\)](#) reported that necrotizing funisitis was the most frequent pathological lesion, occurring in a third of cases. Spirochetes were detected in 89 percent of these cords using silver and immunofluorescent staining.

SEROLOGICAL DIAGNOSIS

A suitable serological screening test such as the *Venereal Disease Research Laboratory (VDRL) slide test* or the *rapid plasma reagin (RPR) test* is performed at the first prenatal visit. Testing is required by law in all 50 states. Fortunately, these serological tests will be positive in the majority of women with primary syphilitic lesion and in all of those with secondary syphilis. They will almost always be positive 4 to 6 weeks after infection. Because such reagin tests lack specificity, a treponemal test such as the *fluorescent treponemal antibody absorption test (FTA-ABS)* or the *microhemagglutination assay for antibodies to *Treponema pallidum* (MHA-TP)* is used to confirm a positive result. A new treponemal specific test that is intended to replace the MHA-TP test is the **Treponema pallidum* passive particle agglutination (TP-PA) test* ([Pope and Fears, 2000](#)).

Cord blood screening is an insensitive test to detect early congenital syphilis. Thus, and especially for women at high risk for syphilis, a second nontreponemal screening test should be done at the time of delivery ([Centers for Disease Control and Prevention, 1998b](#)).

FETAL DIAGNOSIS

[Wendel and colleagues \(1989\)](#) have shown that motile spirochetes can be seen in amniotic fluid obtained transabdominally in women with syphilis and fetal death. They later reported that the polymerase chain reaction was 100 percent specific for detection of *Treponema pallidum* in amniotic fluid and neonatal serum and spinal fluid ([Wendel and colleagues, 1991](#)). Because of myriad pathological changes in the fetus, ultrasound examination may be suggestive or even diagnostic. For example, the infant shown in [Figure 57-3](#) has a large abdomen due to marked hepatosplenomegaly from congenital syphilis. The placenta weighed almost as much as the infant! The fetus may also have edema, ascites, and hydrops. The newborn may be jaundiced with petechiae or purpuric skin lesions, lymphadenopathy, rhinitis ("snuffles"), pneumonia, myocarditis, and nephrosis ([Gilstrap and Wendel, 1999](#)).

TREATMENT

Penicillin remains the treatment of choice; however, treatment of syphilis during pregnancy has not been evaluated rigorously. In a survey, [Rolfs \(1995\)](#) concluded that there are no useful comparative data available for ascertaining optimal therapy. Syphilis therapy during pregnancy is dual; it is given to eradicate maternal infection and to prevent congenital syphilis. The principal difficulty in defining successful treatment has been because fetal syphilis could not be confirmed. Although the prenatal diagnosis of severe fetal syphilis can be made by funipuncture, its clinical utility is not yet clear ([Wendel and associates, 1991](#)).

In retrospective analyses, benzathine penicillin G has been shown to cure early maternal infection and prevent neonatal syphilis in 98 percent of cases ([Zenker and Rolfs, 1990](#)). In a recent study of 340 pregnant women with syphilis, [Alexander and colleagues \(1999\)](#) reported six (1.8 percent) fetal treatment failures with maternal benzathine penicillin G therapy. Four of these six were in 75 women with secondary syphilis and the other two were in 102 women with early latent syphilis. [Conover and colleagues \(1998\)](#) reported a case of congenital syphilis with a penicillin regimen "exceeding [CDC¹ guidelines](#)." Thus, although the Centers for Disease Control guidelines may be up to 98 percent effective in prevention of congenital syphilis, there will be some treatment failures.

As shown in [Table 57-1](#), the current Centers for Disease Control and Prevention guidelines for treatment of syphilis in pregnancy include the same dosage schedule of benzathine penicillin G as for nonpregnant adults. Some authorities recommend a second dose of benzathine penicillin, 2.4 million units intramuscularly, 1 week after the initial dose, especially for women in the third trimester or for pregnant women with secondary syphilis. Pregnant women with a history of penicillin allergy can be skin tested to confirm the risk of immunoglobulin E (IgE)-mediated anaphylaxis. If skin tests are reactive, penicillin desensitization as described by [Wendel and associates \(1985\)](#) is recommended and is followed by benzathine penicillin G treatment. [Chisholm and colleagues \(1997\)](#) reported 16 pregnant women who underwent penicillin desensitization (11 oral and six intravenous procedures) prior to syphilis treatment. Both regimens were effective, but the oral route was easier to administer and was less expensive (\$144 versus \$319).

Unfortunately, there are no proven alternatives to penicillin therapy during pregnancy. Erythromycin, which may be curative in the mother, may not prevent congenital syphilis ([Fenton and Light, 1976](#); [Hashisaki and colleagues, 1983](#); [Wendel, 1988](#)). It is not currently recommended as a penicillin alternative. The cephalosporins, such as ceftriaxone, and the newer macrolide antibiotic, azithromycin, may prove useful but have not been adequately evaluated ([Rolfs, 1995](#)). Tetracyclines, including doxycycline, are effective for treatment of syphilis in the nonpregnant woman, but are generally not recommended during pregnancy because of the risk of yellow-brown discoloration of the fetal deciduous teeth.

There is concern that despite recommended treatment during pregnancy, some newborns still have obvious clinical stigmata of congenital syphilis. This of course depends on the duration of untreated syphilis to which the fetus is exposed. For example, in 1988, the Centers for Disease Control reported that up to 20 percent of newborns had stigmata despite maternal therapy. As expected, half of these method failures were in mothers not given treatment until the third trimester. In a recent study of 334 women with antepartum syphilis treated at Parkland Hospital, [Alexander and colleagues \(1999\)](#) showed that a treatment failure rate of 0.8 percent was generally confined to women treated after 26 weeks. It seems likely that fetal infections that fail therapy are of such duration and severity that there is already irreversible damage.

In all women with primary syphilis and about half with secondary infection, penicillin treatment is followed by the *Jarisch-Herxheimer reaction*. Uterine contractions frequently develop with this reaction, and they may be followed by evidence of fetal distress manifested as late fetal heart rate decelerations ([Klein and colleagues, 1990](#)). In a study of 50 pregnant women who received benzathine penicillin for syphilis, [Myles and colleagues \(1998\)](#) report a 40 percent incidence of the Jarisch-Herxheimer reaction. Of the 31 women monitored electronically, 42 percent developed regular uterine contractions (median onset 10 hours) and 39 percent developed variable decelerations (median onset 8 hours). All contractions resolved within 24 hours of therapy. [Lucas and co-workers \(1991\)](#) used Doppler velocimetry and demonstrated associated acute vascular-resistance changes. Obvious fetal involvement, characterized by ultrasonic evidence for ascites, is associated with almost universally adverse fetal outcome despite therapy.

[Hill and Maloney \(1991\)](#) and [Satin and colleagues \(1992\)](#) have described fetuses with hepatosplenomegaly, gastrointestinal tract obstruction, and placentomegaly. [Barton and co-workers \(1992\)](#) found that delivery and neonatal treatment may be the best option for near-term hydropic fetuses with congenital syphilis.

Prior to syphilotherapy, all women should be offered counseling and testing for antibody to human immunodeficiency virus (HIV). Both treponemal and nontreponemal tests are felt to be accurate for the diagnosis of syphilis in [HIV²-infected](#) patients. For these women, the [Centers for Disease Control and Prevention \(1998b\)](#) recommend the same treatment as for HIV-negative persons; that is, benzathine penicillin G, 2.4 million units intramuscularly for primary and secondary syphilis. Additional multiple doses of benzathine penicillin G—as given for late syphilis—are recommended by some authorities. Women with latent syphilis and HIV infection should be treated with three weekly doses of 2.4 million units of benzathine penicillin G. Clinical and serological follow-up to detect treatment failures is also recommended at 3, 6, 9, 12, and 24 months.

LUMBAR PUNCTURE. Whether to perform routine cerebrospinal fluid analysis has been controversial. Many asymptomatic patients have spinal fluid abnormalities with primary, secondary, and early latent syphilis, but most do not develop neurosyphilis after appropriate treatment. The [Centers for Disease Control and Prevention \(1998b\)](#) recommend lumbar puncture in latent syphilis of more than 1-year duration if there are neurological or ophthalmological symptoms, treatment failures, evidence of active tertiary syphilis—aortitis, gamma, or iritis—or if there is concomitant [HIV²](#) infection.

FOLLOW-UP. Any patient treated for syphilis needs conscientious follow-up. Sexual contacts within the last 3 months should be evaluated for syphilis and treated presumptively, even if seronegative. Maternal serological titers should be determined monthly and at delivery to confirm a serological response to treatment or to document reinfection in this high-risk group.

TREATMENT OF CONGENITAL SYPHILIS. Every infant with suspected or proven congenital syphilis should have a cerebrospinal fluid examination prior to treatment. After therapy, they should be followed at monthly intervals until nontreponemal serological tests become negative or serofast. The [Centers for Disease Control and Prevention \(1998b\)](#) recommend that symptomatic infants or those with abnormal spinal fluid examination be treated initially with aqueous penicillin G, 100,000 to 150,000 U/kg administered as 50,000 U/kg intravenously every 12 hours for the first 7 days of life. This is followed by similar intravenous treatment every 8 hours for a total of 10 days, or aqueous procaine penicillin G, 50,000 U/kg intramuscularly each day to complete a total of 10 days of penicillin treatment. Asymptomatic seropositive infants with a normal spinal fluid examination can be treated with a single dose of benzathine penicillin G, 50,000 U/kg intramuscularly. **Infants born to mothers treated with erythromycin for syphilis during pregnancy should be retreated as though they have congenital syphilis.**

GONORRHEA

The incidence of gonorrhea in the United States decreased by 70 percent from 1981 to 1996. The rate for 1998 was 133 cases per 100,000 population ([Centers for Disease Control and Prevention, 2000](#)). A similar rate was reported for 1999 ([Vastag, 2001](#)). The highest rate in women of all races was in the 15- to 19-year age group.

The prevalence of gonorrhea during pregnancy varies but may be as high as 7 percent and reflects the risk status of the population ([Wendel and Wendel, 1993](#)). Risk factors include being single, adolescence, poverty, drug abuse, prostitution, other sexually transmitted diseases, and lack of prenatal care. Gonococcal infection is also a marker for concomitant chlamydial infection in about 40 percent of infected pregnant women ([Christmas and associates, 1989](#)).

In most pregnant women, gonococcal infection is limited to the lower genital tract, including the cervix, urethra, and periurethral and vestibular glands. Acute salpingitis is rare, and [Yip and colleagues \(1993\)](#) found only 15 cases reported since 1950. They reviewed possible mechanisms, and a likely one is that salpingitis develops if cervical infection ascends before obliteration of the uterine cavity through fusion of the chorion and decidua at 12 weeks. Reactivated or persistent preexisting infection can cause tubo-ovarian abscess, but this seems unlikely.

There is some evidence that pregnancy alters the clinical presentation of gonorrhea. For example, some investigators have reported increased rates of oropharyngeal and anal infections during pregnancy ([Campos-Outcalt and Ryan, 1995](#)). Increased noncervical infection may be from altered sexual practices because of pregnancy, cultural customs, or both. Finally, pregnant women may account for a disproportionate amount of disseminated gonococcal infection in women ([Ross, 1996](#)). These observations may reflect heightened medical attention during pregnancy, increased gonococcal dissemination from engorged pelvic vasculature, or possibly the altered immunostatus of pregnancy.

Because of all of these factors, a screening test for gonorrhea is recommended at the first prenatal visit or prior to an induced abortion. In high-risk populations, the [Centers for Disease Control and Prevention \(1998b\)](#) recommend that a repeat culture be obtained after 28 weeks.

EFFECT ON PREGNANCY

Gonococcal infection may have deleterious effects on pregnancy outcome in any trimester. There is an association between untreated gonococcal cervicitis and septic spontaneous abortion, or infection after induced abortion ([Burkman and associates, 1976](#)). Preterm delivery, prematurely ruptured membranes, chorioamnionitis, and postpartum infection are more common in women with *Neisseria gonorrhoeae* detected at delivery ([Alger and associates, 1988](#)). [Maxwell and Watson \(1992\)](#) reported that expectant management of the culture-positive woman was reasonable even with prematurely ruptured membranes as long as antimicrobial treatment was given promptly.

[Sheffield and colleagues \(1999\)](#) recently reviewed clinical outcomes of 25 pregnant women admitted to Parkland Hospital for disseminated gonococcal infection. Their mean gestational age at presentation was 25 weeks, and all promptly responded to appropriate antimicrobial therapy. One stillborn infant and one spontaneous abortion were attributed to gonococcal sepsis.

TREATMENT

In many areas, antimicrobial-resistant *N gonorrhoeae*, particularly penicillinase-producing strains, have rendered some β -lactam drugs ineffective for therapy. Also disconcerting are the reports of quinolone-resistant *N gonorrhoeae* in several parts of the world ([Ehret and Judson, 1998](#); [Centers for Disease Control and Prevention, 1998b](#)). As shown in [Table 57-2](#), ceftriaxone is recommended for uncomplicated gonococcal infection during pregnancy. Spectinomycin as an initial treatment followed by erythromycin is recommended for women allergic to penicillin or β -lactam antibiotics ([American College of Obstetricians and Gynecologists, 1994b](#)). [Ramus and associates \(1996\)](#), in a study of 62 pregnant women with probable endocervical gonorrhea, reported that the regimens recommended by the Centers for Disease Control for the treatment of gonorrhea in pregnancy were effective. Intramuscular ceftriaxone (125 mg) and oral cefixime (400 mg) resulted in a cure rate of 93 percent and 97 percent, respectively.

Screening for syphilis and *Chlamydia trachomatis* should precede treatment, if possible. If chlamydial testing is unavailable, presumptive therapy is given. Treatment for sexual contacts and maternal test-of-cure cultures help to ensure efficacy of therapy. Because gonococcal reinfection is common, repeat screening in late pregnancy should be considered for women treated earlier during pregnancy ([American College of Obstetricians and Gynecologists, 1994b](#)).

DISSEMINATED GONOCOCCAL INFECTIONS. Gonococcal bacteremia may lead to petechial or pustular skin lesions, arthralgias, septic arthritis, or tenosynovitis. The [Centers for Disease Control and Prevention \(1998b\)](#) recommend ceftriaxone, 1000 mg intramuscularly or intravenously every 24 hours. Alternative initial regimens include cefotaxime or ceftizoxime, 1000 mg intravenously every 8 hours. Spectinomycin, 2 g every 12 hours, may be used in women allergic to β -lactam drugs. All of the preceding regimens should be continued for 24 to 48 hours after improvement and then therapy changed to cefixime, 400 mg orally two times daily, to complete a week of therapy. Ciprofloxacin is a recommended alternative to cefixime in the nonpregnant patient, but is contraindicated for pregnant and lactating women ([Chap. 38, p. 1021](#)).

For gonococcal *endocarditis*, therapy should be continued for at least 4 weeks, and for *meningitis*, 10 to 14 days ([Centers for Disease Control and Prevention, 1998b](#)). Endocarditis rarely complicates pregnancy, but it may be fatal ([Bataskov and colleagues, 1991](#)). [Pantanowitz and colleagues \(1998\)](#) recently reported a case of gonococcal arthritis and endocarditis in a 22-year-old woman with a threatened abortion.

[Varady and colleagues \(1998\)](#) reported on an unusual case of a gonococcal scalp abscess in a neonate delivered by cesarean. Membranes had been ruptured for 14 hours, and a scalp electrode had been in place for 2 hours before delivery.

TREATMENT OF NEONATES. All infants are given prophylaxis against eye infection ([Chap. 16, p. 396](#)). Infants born to untreated infected women are given ceftriaxone, 25 to 50 mg/kg, either intravenously or intramuscularly for one dose. Those who develop gonococcal ophthalmia should be hospitalized and evaluated for disseminated infection ([Erdem and Schleiss, 2000](#)). Gonococcal ophthalmia may be treated with the same single-dose ceftriaxone regimen as given for asymptomatic infants born to culture-positive women ([Centers for Disease Control and Prevention, 1998b](#)). Some pediatricians prefer to continue antibiotics until cultures have been negative for 48 to 72 hours. The mother and infant should also be evaluated for concomitant chlamydial infection. Isolation is recommended until treated for 24 hours. Topical antibiotic preparations are not appropriate. Both parents also should be treated for gonorrhea.

CHLAMYDIAL INFECTIONS

Chlamydia trachomatis is an obligate intracellular bacterium that has several serotypes, including those that cause *lymphogranuloma venereum*. The most commonly encountered strains are those that attach only to columnar or transitional cell epithelium and cause cervical infection.

MATERNAL INFECTIONS

Genital infection with *C trachomatis* is one of the most common sexually transmitted bacterial diseases in women of reproductive age in the United States. According to [Macmillan and colleagues \(1999\)](#), this is also true for the United Kingdom and Europe. *C trachomatis* infection is also common in pregnant women, and its incidence depends on the demographic makeup of the population. For example, the prevalence of symptomatic and asymptomatic genital infections in private obstetrical patients is below 2 percent, but is up to 25 percent in some groups of young, unmarried, inner-city women attending public clinics ([McGregor and French, 1991](#); [Ryan and colleagues, 1990](#)). In a review of nearly 2500 women who initiated prenatal care prior to 20 weeks, [Allaire and colleagues \(1998\)](#) reported a 15 percent prevalence of *C trachomatis*. Risk factors for chlamydial infection in pregnant women include age less than 25 years, presence or history of other sexually transmitted disease, multiple sexual partners, and a new sexual partner within 3 months ([American College of Obstetricians and Gynecologists, 1994b](#)).

DIAGNOSIS. Cultures are expensive and less accurate than newer methods. The direct fluorescent antibody (DFA) test has 90 percent sensitivity and 98 percent specificity compared with culture ([Korn, 2000](#)). Enzyme immunoassay (EIA) is less specific. DNA detection tests include polymerase chain reaction (PCR). [Witkin and associates \(1996\)](#) evaluated this test for identification of chlamydia from introital samples and found 97 percent sensitivity and 100 percent specificity. [Andrews and associates \(1996\)](#) reported that a ligase chain reaction assay (LCR) was both sensitive and specific for genitourinary infection in pregnant women.

SYMPTOMATIC INFECTION. Most pregnant women have subclinical or asymptomatic chlamydial infection. The organism may cause several clinical syndromes that include **urethritis**, **mucopurulent cervicitis**, and **acute salpingitis** ([Table 57-3](#)). Mucopurulent cervicitis is difficult to classify during pregnancy. It may be secondary to either chlamydial or gonococcal infection, or it may represent the normally stimulated cervical mucus.

ASYMPTOMATIC INFECTION AND PREGNANCY OUTCOME. There is no doubt that perinatal transmission is associated with neonatal **conjunctivitis** and **pneumonia** ([Hammerschlag and colleagues, 1989](#); [Salpietro and colleagues, 1999](#); [Schachter and co-workers, 1986](#)). There is vertical transmission to at least half of infants delivered vaginally to infected women ([McGregor and French, 1991](#)). While eye prophylaxis for gonococcal infection with silver nitrate, erythromycin, or tetracycline is effective, none of these prevent chlamydial conjunctivitis ([Centers for Disease Control and Prevention, 1998b](#)). When eye infection is identified, oral erythromycin, 50 mg/kg/day in four divided doses, is given for 10 to 14 days.

Although many investigators have examined the effects of asymptomatic chlamydial infection on pregnancy outcome, its role remains controversial. In one recent study, [Sozio and Ness \(1998\)](#) found no association with increased abortion. Some investigators have found that untreated maternal cervical chlamydial infection increases the risk for preterm delivery, prematurely ruptured membranes, and perinatal mortality ([Alger, 1988](#); [Claman, 1995](#); [Gravett, 1986](#); [Martius, 1988](#); [Ngassa, 1994](#), and their colleagues). Conversely, others have found that only women with recent chlamydial infection, confirmed by antichlamydial IgM antibody testing, are at risk for these adverse outcomes ([Berman and co-workers, 1987](#); [Sweet and associates, 1987](#)). Because of this confusion, the effects of treatment are also understandably controversial. For example, while [Cohen and colleagues \(1990\)](#) and [Ryan and associates \(1990\)](#) reported a reduction in adverse perinatal events in women treated with erythromycin, data from the Vaginal Infections and Prematurity Study Group demonstrated no such improvement ([Martin, 1990](#)). This latter study was a large, multicenter, randomized, placebo-controlled, blinded investigation carried out under the auspices of the National Institutes of Health.

[Sweet and colleagues \(1987\)](#) prospectively studied 270 pregnant women with untreated cervical infection and compared outcomes with chlamydia-negative controls. There were no differences in the incidences of preterm labor, prematurely ruptured membranes, chorioamnionitis, neonatal sepsis, or postpartum uterine infections. In women with IgM antibody to *C trachomatis*, however, preterm labor or prematurely ruptured membranes were more likely. [Berman and colleagues \(1987\)](#) also reported this association. [Andrews and colleagues \(2000\)](#) reported a carefully done case-control study from the Maternal-Fetal Medicine Units Network. They found that chlamydial infection at 24 weeks was associated with a two- to threefold increased risk for preterm birth.

Chlamydial infection does not appear to be associated with an increased risk of chorioamnionitis nor with pelvic infection after cesarean delivery ([Blanco and colleagues, 1985](#); [Gibbs and Schachter, 1987](#)). Conversely, delayed postpartum uterine infection with *C trachomatis* has been described by [Hoyme and associates \(1986\)](#). The syndrome, which develops 2 to 3 weeks postpartum, is distinct from early postoperative metritis. It is characterized by vaginal bleeding or discharge, low-grade fever, lower abdominal pain, and uterine tenderness.

NEONATAL INFECTIONS

CONJUNCTIVITIS. Ophthalmic chlamydial infections are one of the most common causes of preventable blindness in undeveloped countries. Inclusion conjunctivitis develops in as many as a third of neonates born to mothers with cervical infection. [Salpietro and colleagues \(1999\)](#) recently reported that 40 percent of cases of neonatal conjunctivitis in Italy were caused by *C trachomatis*. Symptomatic conjunctivitis tends to appear later than disease caused by *N gonorrhoeae*, and the two must be differentiated because treatment is not the same. According to [Crombleholme \(2000\)](#), the highest sensitivity and specificity is found with DNA amplification techniques discussed earlier.

PNEUMONITIS. *C trachomatis* is a relatively common cause of afebrile pneumonia in infants at 1 to 3 months of age ([Centers for Disease Control and Prevention, 1998b](#)). Bilateral pulmonary infiltrates and chronic cough are often associated with poor weight gain.

SCREENING

The role for routine screening tests for *C trachomatis* during pregnancy remains unclear. Currently, universal prenatal screening is not considered cost effective. Newer DNA probes and polymerase chain reaction may make detection cheaper and quicker. The [American College of Obstetricians and Gynecologists \(1994b\)](#) recommends targeted screening of high-risk populations. The [Centers for Disease Control and Prevention \(1998b\)](#) recommends screening for pregnant women less than 25 years old or those who have new or multiple sex partners. They also suggest that "periodic prevalence surveys" of chlamydial infection might be helpful. In a study of 149 pregnant women with lower genital tract chlamydia, [Miller \(1998\)](#) found that 17 percent had recurrent chlamydial colonization after treatment. Repeat culture in the third trimester would seem reasonable in women with positive initial cultures or for those at high risk.

TREATMENT

Currently recommended regimens for treatment of chlamydial infection in pregnant women are shown in [Table 57-4](#). Erythromycin base, 500 mg orally four times a day for 7 days is the primarily recommended regimen during pregnancy. For women who cannot tolerate erythromycin, the dosage is reduced by half and the duration of therapy doubled. Alternatively, the amoxicillin regimen may be given. In a randomized trial of treatment of *C trachomatis* in pregnancy, [Silverman and colleagues \(1994\)](#) reported cure rates of 82 percent for amoxicillin and 85 percent for erythromycin. Side effects were less frequent with amoxicillin (13 versus 32 percent). In another randomized trial during pregnancy, [Wehbeh and colleagues \(1998\)](#) reported that the cure rate for single-dose azithromycin was 95 percent. Only 7 percent of women receiving azithromycin had significant side effects compared with 39 percent of those given erythromycin. From their review of 11 randomized trials, [Brocklehurst and Rooney \(2000\)](#) concluded that erythromycin and amoxicillin were equally effective. Once again, amoxicillin was far better tolerated.

Erythromycin estolate and tetracyclines should not be used during pregnancy. Sex partners within the prior 30 days should be examined and treated for chlamydial infection.

LYMPHOGRANULOMA VENEREUM

There are several serovars of *C trachomatis* that cause lymphogranuloma venereum (LGV). The primary genital infection is transient and seldom recognized. Inguinal adenitis may follow and at times lead to suppuration. It may be confused with chancroid. Ultimately, the lymphatics of the lower genital tract and perirectal tissues may be involved, with sclerosis and fibrosis, which can cause vulvar elephantiasis and especially severe rectal stricture. Fistula formation involving the rectum, perineum, and vulva also may be quite troublesome.

For treatment during pregnancy, erythromycin, 500 mg four times daily, is given for 21 days ([Centers for Disease Control and Prevention, 1998b](#)). Although data regarding efficacy are scarce, some authorities recommend azithromycin given in multiple doses over 2 to 3 weeks. Some of these infections that we have encountered at Parkland Hospital have been long-standing, and there was little response to multiple antimicrobial regimens that in one case included erythromycin, sulfamethoxazole, tetracycline, and chloramphenicol.

HERPES SIMPLEX VIRUS

Management of pregnancy complicated by maternal herpesvirus genital infection, while much simplified compared with previous recommendations, remains problematic. There are currently no available rapid diagnostic tests that reliably document contemporary infection. Moreover, there are minimal data to estimate risks for the neonate exposed to recurrent maternal infection.

VIROLOGY

Two types of herpes simplex virus (HSV) have been distinguished based on immunological as well as clinical differences. Type 1 is responsible for most nongenital herpetic infections. In adults, however, HSV^3-1 primary infection involves the genital tract in a third of cases ([Langenberg and colleagues, 1999](#)). Type 2 virus is recovered almost exclusively from the genital tract and is transmitted in the great majority of instances by sexual contact. The incidence of antibodies specific for type 2 herpes increases with age and varies considerably with the population studied. It has been estimated that as many as 45 million people in the United States have been diagnosed with genital HSV-2 infection ([Centers for Disease Control and Prevention, 1998b](#)). In the absence of antibody, exposure to a sexual partner with active herpetic lesions will in the majority of instances result in clinical disease.

ANTIBODIES. Several assay systems are available commercially and in research settings to detect serum anti- HSV^4 antibody. While there currently is no reliable commercially available assay to differentiate HSV-1 from HSV-2 antibody, premarket testing of at least one assay is ongoing in early 2000. In a national seroepidemiological survey from 1976 to 1994, 25 percent of women had antibody to HSV-2 ([Fleming and colleagues, 1997](#)). The risks for type 2 antibody were greatest among black and previously married women. [Kulhanjian and colleagues \(1992\)](#) have proposed that serological screening of couples during pregnancy for HSV-2 antibodies would stimulate the need for sexual precautions if discordancy were found, that is, a seronegative woman with a positive partner.

CLINICAL INFECTION

Symptoms vary depending on whether there has been previous infection. Importantly, prior HSV^5-1 infection may modify a primary HSV-2 genital infection because of cross-reacting antibodies. According to the [American College of Obstetricians and Gynecologists \(1999\)](#), these HSV-2 infections clinically may be divided into three groups: **Primary infection** indicates no prior antibodies to HSV-1 or HSV-2. **Nonprimary first episode** defines newly acquired HSV-2 infection with preexisting HSV-1 cross-reacting antibodies. **Recurrent infection** is reactivation of prior HSV-2 infection in the presence of antibodies to HSV-2.

PRIMARY INFECTION. Only a third of newly acquired HSV^6-2 genital infections are symptomatic ([Langenberg and colleagues, 1999](#)). Other first episodes are mild or asymptomatic, because of some immunity from cross-reacting antibody from childhood-acquired type 1 infection. With primary infection, the typical incubation period of 3 to 6 days is followed by a papular eruption with itching or tingling which then becomes painful and vesicular, with multiple vulvar and perineal lesions that may coalesce ([Fig. 57-4](#)). Inguinal adenopathy may be severe. Transient systemic influenza-like symptoms are common and are presumably caused by viremia. Occasionally, hepatitis, encephalitis, or pneumonia may develop. [Frieden and colleagues \(1990\)](#) reported six cases of maternal encephalitis complicating pregnancy; only two women lived.

The vulvar and perineal vesicles are traumatized easily, eventually ulcerate, but usually do not become secondarily infected. Vulvar lesions are likely to be extremely painful and may cause considerable debility. Urinary retention may develop because of the pain induced by micturition or because of sacral nerve involvement. In 2 to 4 weeks, all signs and symptoms of infection disappear. Cervical involvement is common and may be inapparent clinically. Some cases are severe enough as to require hospitalization.

NONPRIMARY FIRST EPISODE. In some women, there is not full protection from previously existing HSV^7-1 antibody. These cases may present as a first clinical infection that does not behave like the primary infection described earlier. In general, these infections are characterized by fewer lesions, less systemic

manifestations, less pain, and briefer duration of lesion and viral shedding. In some cases, it may be impossible to differentiate clinically between the two types of first infection. Serological diagnosis is possible but of little clinical benefit.

RECURRENT INFECTIONS. During the latency period in which viral particles reside in nerve ganglia, reactivation is common and mediated through variable but poorly understood stimuli. Reactivation is termed recurrent infection and results in herpesvirus shedding. Most recurrent genital herpes is caused by type 2 virus ([Centers for Disease Control and Prevention, 1998b](#)). These lesions generally are fewer in number, less tender, and shed virus for shorter periods (2 to 5 days) than those of primary infection. Typically they recur at the same sites. Although commonly involved in primary disease, cervical involvement is less frequent with recurrent infections ([Brown and colleagues, 1985](#)).

In a study of 110 women with genital herpes infection, [Wald and associates \(1995\)](#) reported that 55 percent had subclinical shedding of HSV² at some time during a mean follow-up of 105 days. Subclinical shedding lasted for a mean of 1.5 days. Subclinical shedding often followed symptomatic recurrence, was more frequent in women with frequent symptomatic recurrences, and accounted for approximately a third of the total days of reactivation of infection. [Wald and colleagues \(2000\)](#) more recently reported that HSV-2 seropositive patients with no history of lesions had subclinical shedding in 3 percent of cases compared with 2.7 percent in seropositive individuals with a history of lesions. Undoubtedly, such subclinical shedding of virus is responsible for many sexually transmitted cases to partners who are seronegative ([American College of Obstetricians and Gynecologists, 1999](#)).

DIAGNOSIS

Recovery of virus by *tissue culture* is most optimal for confirmation of clinically apparent infection and asymptomatic recurrences. The sensitivity of culture is nearly 95 percent before the lesions undergo crusting. There are virtually no false positives. With symptomatic recurrences, about half of the cultures will be positive after 48 hours.

Cytological examination after alcohol fixation and Papanicolaou staining—the *Tzanck smear*—has a maximum sensitivity of 70 percent. False-positive cervical smears may be due to cytomegalovirus infection, which is common. The *polymerase chain reaction* has been prospectively studied as a method of detection of genital herpes DNA. [Cone and associates \(1994\)](#) found that the frequency of newborn exposure to herpesvirus secretions from seropositive mothers was almost eight times higher when polymerase chain reaction was used to identify viral DNA compared with culture techniques.

TREATMENT

Antiviral therapy with acyclovir, famciclovir, and valacyclovir has been utilized for treatment of first-episode genital herpes in nonpregnant women. Suppressive therapy with these agents has also been utilized for treatment of recurrent infections. Oral or parenteral preparations attenuate clinical infection as well as the duration of viral shedding. Valacyclovir results in higher plasma acyclovir levels than acyclovir when given in late pregnancy ([Kimberlin and colleagues, 1998](#)). For intense discomfort, analgesics and topical anesthetics may provide some relief, and severe urinary retention is treated with an indwelling bladder catheter.

Acyclovir appears to be safe for use in pregnant women. The manufacturer of acyclovir and valacyclovir, in cooperation with the Centers for Disease Control and Prevention, maintains a registry for exposure to these drugs during pregnancy (1.888.825.5249). More than 700 infants have been exposed to acyclovir during the first trimester, and there does not appear to be an increase in adverse fetal or neonatal effects ([Scott, 1999](#)).

Many women with HIV² infection also have genital herpes, and treatment failures with recommended doses of acyclovir have been reported. Higher dosages of acyclovir may be beneficial for immunoincompetent women with HIV infection and severe recurrent genital herpes ([Stone and Whittington, 1990](#)).

RECURRENT INFECTION. Other than suppression, acyclovir is of little benefit in recurrent genital herpes. It has been evaluated as suppressive therapy during pregnancy to prevent recurrences near term. [Scott and associates \(1996\)](#) randomized 46 women who had earlier first-episode infection to acyclovir (400 mg orally three times daily) or placebo beginning at 36 weeks. None of the 21 women given acyclovir compared with 9 of 25 (36 percent) given placebo had recurrent herpes at delivery. The incidence of asymptomatic viral shedding was not increased with acyclovir. Thus, prophylactic acyclovir treatment may decrease the frequency of cesarean delivery in women with recurrent herpes. In a randomized study of 63 pregnant women with recurrent genital herpes, [Brocklehurst and associates \(1998\)](#) reported that suppressive acyclovir significantly reduced the number of clinical recurrences but not the cesarean delivery rate. [Scott and Alexander \(1998\)](#) reported that acyclovir suppression in late pregnancy was cost effective. Suppressive therapy given orally reduces the signs and symptoms of recurrent infection but does not completely eliminate asymptomatic viral shedding ([Brocklehurst and colleagues, 1998](#); [Haddad and associates, 1993](#)).

In the pharmacokinetics study by [Kimberlin and colleagues \(1998\)](#), acyclovir was concentrated in the amniotic fluid but there was no evidence of preferential fetal drug accumulation. The drug readily crosses the placenta by passive transfer ([Gilstrap and colleagues, 1994](#); [Henderson and associates, 1993](#)).

CLINICAL COURSE DURING PREGNANCY

Approximately 80 percent of young women with recently acquired genital herpes infection will have an average of 2 to 4 **symptomatic** recurrences during pregnancy ([Brown, 1985](#); [Harger, 1989](#); [Vontver, 1982](#), and their colleagues). Concomitant cervical shedding is identified in about 15 percent of women with clinically evident vulvar recurrences.

[Brown \(1985\)](#) and [Arvin \(1986\)](#) and their co-workers found that about 10 percent of the recurrences in pregnancy will be **asymptomatic**, and these more frequently involve the perineum rather than the cervix. The incidence of positive cultures at any time during pregnancy or at delivery for nonpregnant women who had herpes is only 1 to 2 percent. Although clinical recurrences appear to be slightly more common in late pregnancy, asymptomatic cervical shedding of herpesvirus is unaffected by the duration of pregnancy. Additionally, **remote recurrences**—those on the buttocks, back, thigh, and anus—have low rates of concomitant cervical virus shedding, and this allows consideration for vaginal delivery ([Harger and colleagues, 1989](#); [Wittek and co-workers, 1984](#)).

VIRUS SHEDDING AT DELIVERY. The reported prevalence rates for isolation of genital tract herpesvirus vary considerably depending on the population studied, but equally important is whether women were included (or excluded) because of prior symptomatic infection. [Prober and colleagues \(1988\)](#) obtained specimens for culture from mothers and infants at the time of nearly 7000 deliveries without regard to the maternal history of genital herpes. Only 14 (0.2 percent) were positive for herpesvirus, and 12 of these women had recurrent infections. In a similar study, [Brown and associates \(1991\)](#) cultured nearly 16,000 women in early labor. Only 56 (0.35 percent) were positive, and a third of these had serological evidence for a recently acquired but subclinical first infection. Although a third of these infants developed neonatal infection, only 1 of 34 infants became infected when born to women with recurrent infection.

[Cone and associates \(1994\)](#), in a prospective study of 100 asymptomatic women with a negative culture, reported that herpes simplex virus was identified in nine women using polymerase chain reaction. None of the neonates born to these women manifested herpes infection. They concluded that newborn exposure to herpesvirus during labor and delivery in seropositive women is more frequent than previously thought.

FETAL AND NEONATAL DISEASE

First-episode infection in early pregnancy is probably not associated with an increased rate of spontaneous abortion. [Fagnant and Monif \(1989\)](#) reviewed the literature and described 15 cases of congenital herpetic infection acquired during early pregnancy. [Brown and Baker \(1989\)](#) found that late-pregnancy primary infection results in an increased incidence of preterm labor.

Infection is transmitted only rarely across the placenta or intact membranes. The fetus almost always becomes infected by virus shed from the cervix or lower genital tract. The virus either invades the uterus following membrane rupture or contacts the fetus at delivery. Newborn infection has three forms:

1. Disseminated, with involvement of major viscera ([Fig. 57-5](#)).
2. Localized, with involvement confined to the central nervous system, eyes, skin, or mucosa.
3. Asymptomatic.

Nearly half of infected neonates are preterm, and their risk of infection correlates with whether there is primary or recurrent maternal infection. [Nahmias and colleagues \(1971\)](#) reported a 50 percent risk of neonatal infection with primary maternal infection, but only 4 to 5 percent with recurrent infection. [Prober and](#)

[associates \(1987\)](#) reported that none of 34 neonates exposed to recurrent viral shedding at delivery became infected. This is thought to be due to a smaller viral load in maternal secretions with recurrent infection. It also likely is related to transplacentally acquired antibody, which decreases the incidence and severity of neonatal disease.

Localized infection is usually associated with a good outcome. Conversely, even with treatment with acyclovir or vidarabine, disseminated neonatal infection is associated with a mortality rate of at least 60 percent ([Whitley and colleagues, 1991](#)). Importantly, serious ophthalmic and central nervous system damage has been identified in at least half of survivors.

ANTEPARTUM MANAGEMENT. Because of the severity of neonatal infection, cesarean delivery has been used widely in instances when genital herpetic lesions are suspected. The premise that all neonatal infections can be avoided by carefully screening the obstetrical population has not been proven correct. As discussed earlier, a number of asymptomatic women will secrete virus at the time of delivery. While most have asymptomatic recurrent infection with correspondingly low virulence, some have nonprimary, first-episode infection without [HSV⁹-2](#) antibody. It seems reasonable to give acyclovir or valacyclovir suppressive therapy beginning at 36 weeks in women who have had herpetic lesions during pregnancy. Virological monitoring is not recommended.

According to the [American College of Obstetricians and Gynecologists \(1999\)](#), cesarean delivery is indicated in women with an active genital lesion or in those with a typical prodrome of an impending outbreak. Thus, cesarean delivery is performed only if primary or recurrent lesions are visualized near the time of labor or when the membranes are ruptured. [Roberts and colleagues \(1995\)](#) reported a decrease in the cesarean section rate in women with herpes during pregnancy from 59 percent to 37 percent after adoption of the 1988 guidelines of American College of Obstetricians and Gynecologists, which succinctly stated is, "no lesions, no cesarean."

RUPTURED MEMBRANES. In the absence of previous examination or instrumentation, there is no evidence that external lesions cause ascending membrane and fetal infection in the presence of ruptured membranes. The recommendation is to disregard the duration of membrane rupture in formulating a plan of delivery for women with perineal lesions. Unless there are other contradictory factors—for example, gross immaturity—then cesarean delivery is performed.

CARE OF THE NEONATE

An exposed infant of a mother known or suspected of having genital herpes should be isolated and cultures taken for herpes. It is not necessary to separate baby and mother when the mother has herpetic lesions. Instead, she is instructed in hand washing and to avoid any contact between her lesions, her hands, and the baby. Breast feeding is allowed under these conditions. Family members with oral herpetic lesions should avoid kissing the newborn and should use careful hand-washing techniques.

ACQUIRED IMMUNODEFICIENCY SYNDROME

Acquired immunodeficiency syndrome (AIDS) was first described in 1981 when a cluster of patients was found to have defective cellular immunity and *Pneumocystis carinii* pneumonia. Infections in women are increasing overall, and the proportion of women and adolescent girls tripled from 7 to 23 percent from 1985 to 1998. Since that time, worldwide prevalence of this devastating disease has progressed almost geometrically. In the United States through 1998, [Fauci \(1999\)](#) quotes estimates of 650,000 to 900,000 infected individuals and almost a half million deaths. By 1994, death caused by [HIV²](#) infection became the leading cause of death in persons aged 25 to 44 years ([Fig. 57-6](#)). As expected, perinatally acquired infection has also increased. Through 1993, the [Centers for Disease Control and Prevention \(1997b\)](#) estimated that 15,000 HIV-infected children were born to HIV-positive women in the United States.

Black women have a disparately increased infection rate, and in 1997, it was estimated that 1 in 160 African-American women were infected. In 1997 there were more cases of [AIDS¹⁰](#) in African-American men and women in the United States than any other racial/ethnic group ([Centers for Disease Control and Prevention, 1998d](#)). [Haverkos and colleagues \(1999\)](#) reported the relative risk for AIDS was 4.7 for African Americans compared with 1.0 for whites, 3.0 for Hispanics, 0.5 for Native Americans, and 0.4 for Asian/Pacific Islanders.

ETIOLOGY

Causative agents of the immunodeficiency syndrome are DNA retroviruses termed **human immunodeficiency viruses**, [HIV²-1](#) and HIV-2. Most cases worldwide in 1992 were caused by HIV-1 infection. While HIV-2 infection is endemic in West Africa, it is uncommon in the United States. Currently, the [Centers for Disease Control and Prevention \(1998b\)](#) does not recommend routine testing for HIV-2 except in blood donors and persons exposed to high-risk practices in HIV-2 endemic countries.

Retroviruses have genomes that encode *reverse transcriptase*, which allows DNA to be transcribed from RNA. The virus thus can make DNA copies of its own genome in host cells. Transmission is similar to hepatitis B virus, and sexual intercourse, especially among male homosexuals, is the major mode of transmission. The virus also is transmitted by blood or blood-contaminated products, and mothers may infect their infants.

The [Centers for Disease Control and Prevention \(1996a\)](#) reported that in 1994, women accounted for the most rapid increases in the number of cases. About half of cases among women are secondary to injected-drug use and a third are attributed to heterosexual contact. [Chirgwin and associates \(1999\)](#) found that two significant risk factors were nonparenteral drug use and anal intercourse. The pregnancy rate for this group was 55 per 100 person-years of follow-up. In a seven-city study of [HIV²](#) seroconversions among patients attending sexually transmitted disease clinics, [Weinstock and colleagues \(1998\)](#) reported that most infections are now transmitted heterosexually and are associated with drug use. There is also an increasing proportion of children with perinatally acquired [AIDS¹¹](#) born to women with heterosexually acquired infection. In 1994, The [Centers for Disease Control \(1994a\)](#) estimated a prevalence of HIV seropositivity among childbearing women in 1992 to be 1 to 2 per 1000.

PATHOGENESIS

The common denominator of clinical illness with [AIDS¹²](#) is profound immunosuppression, principally of cell-mediated immunity, which gives rise to a variety of opportunistic infections and neoplasms. Thymus-derived lymphocytes—*T lymphocytes*—defined phenotypically by the CD4 surface antigen, are the principal targets. The CD4 site serves as a receptor for the virus. Co-receptors are necessary for infection, and two chemokine receptors—CCR5 and CXCR4—have been identified to fill this role ([Kahn and Walker, 1998](#)). After attachment, the virus is internalized and uses *reverse transcriptase* to transcribe its genomic RNA and DNA.

Viral DNA thus is integrated into cellular DNA for the life of the cell, which is shortened by infection. At the same time, viremia can be detected and quantified using the viral-RNA assay. After initial infection, the level of viremia usually decreases to a *set-point*, and patients with the highest viral burden progress more rapidly to [AIDS¹³](#) and death ([Kahn and Walker, 1998](#)). After infection, over time the number of T cells drops insidiously and progressively, resulting eventually in profound immunosuppression. Monocyte-macrophages may also be infected, and microglial brain cell infection may cause neuropsychiatric abnormalities. [HIV²](#)-infected persons also have an increased incidence of neoplasms, notably Kaposi sarcoma, B-cell and non-Hodgkin lymphomas, and some carcinomas.

CLINICAL MANIFESTATIONS

The incubation period from exposure to clinical disease is usually within days to weeks. [Figure 57-7](#) illustrates the natural history of [HIV²-1](#) infection. Acute illness is similar to many other viral syndromes and usually lasts less than 10 days. Common symptoms include fever and night sweats, fatigue, rash, headache, lymphadenopathy, pharyngitis, myalgias, arthralgias, nausea, vomiting, and diarrhea ([Kahn and Walker, 1998](#)). After symptoms abate, the set-point of chronic viremia begins. Stimuli that cause further progression from asymptomatic viremia to the immunodeficiency syndrome are presently unclear, but the median time is about 10 years ([Fauci and Lane, 1994](#)).

When [HIV²](#)-positivity is associated with any number of clinical findings, then [AIDS¹⁴](#) is diagnosed. Generalized lymphadenopathy, oral hairy leukoplakia, aphthous ulcers, and thrombocytopenia are common. A number of opportunistic infections that may herald AIDS include esophageal or pulmonary candidiasis, persistent herpes simplex or zoster, condyloma acuminata, tuberculosis, cytomegalovirus, molluscum contagiosum, pneumocystis, toxoplasmosis, and others. Neurological disease is common, and about half of patients have central nervous system symptoms. A CD4+ count of less than 200/uL is also considered definitive for the diagnosis of AIDS.

SEROLOGICAL TESTING

The enzyme immunoassay assay (EIA¹⁵) is used as a screening test for HIV² antibodies. A positive screening test has a sensitivity of over 99.5 percent. A positive test is confirmed with either the Western blot or immunofluorescence assay (IFA). Although highly specific, the Western blot is less sensitive than immunoassay because more antibody is required for a positive result. Thus, immunofluorescence assay can be used to resolve an EIA-positive, Western blot-indeterminate sample. According to the [Centers for Disease Control and Prevention \(1998b\)](#), antibody can be detected in 95 percent of patients within 6 months of infection, and thus, antibody serotesting does not exclude earlier infection. For acute primary HIV infection, identification of viral p24 core antigen or viral RNA is necessary.

False-positive confirmatory results are rare, and in one study of almost 300,000 blood donors, no false-positive Western blot results were detected by using viral culture ([Centers for Disease Control and Prevention, 1995](#)). An indeterminate Western blot test can result from factors that include:

1. Recently infected individuals who are seroconverting.
2. End-stage HIV² disease.
3. Perinatally exposed infants who are seroconverting.
4. Nonspecific reactions of uninfected current or past pregnant women.

SCREENING

There is disagreement as to who should be screened, and more importantly, how positive results should be managed. Certainly it is reasonable to test all blood products, and this has been done since mid-1983. [Lackritz and associates \(1995\)](#) reported that the risk of HIV² transmission was one case for every 450,000 to 660,000 donations of screened blood. In 1992, the Food and Drug Administration mandated HIV-2 testing for all blood donors.

In 1991, the Institute of Medicine recommended universal, but voluntary, prenatal screening. The [Centers for Disease Control and Prevention \(1998b\)](#) as well as the American Academy of Pediatrics and the [American College of Obstetricians and Gynecologists \(1997\)](#) also recommend this approach. [Ecker \(1996\)](#) calculated that such testing was cost-effective in pregnant populations with an HIV² prevalence exceeding 9 per 1000. [Patrick and colleagues \(1998\)](#), however, in a retrospective study done in British Columbia, concluded that prenatal screening was cost-effective even in a low-prevalence setting.

[Grimes and associates \(1999\)](#) recently reviewed legal considerations of HIV² screening for pregnant women. They concluded that the best way to avoid liability is to offer HIV testing to all and to document such counseling. For women who initially decline testing, they recommend offering testing at each visit, and documenting such counseling.

BR>MATERNAL AND FETUS-INFANT INFECTION

To determine maternal HIV² seroprevalence, [Gwinn and colleagues \(1991\)](#) tested nearly 2 million newborns from 38 states born in 1988 and 1989. They estimated that 1.5 women per 1000 were infected nationwide; for New York City it was 5.8 per 1000; and for the District of Columbia it was 5.5 per 1000. [Lindsay and associates \(1991\)](#) showed that inner-city prenatal patients in Atlanta were more likely seropositive if they had not registered for prenatal care. Importantly, although in all of these studies women were from an inner-city minority population, only half were considered at high risk. These studies underpin recommendations that serological testing and counseling be offered to all pregnant women.

It is now well established that mother-to-infant transmission accounts for most HIV² infections among children. Transplacental transmission can occur early, and the virus has been identified in early pregnancies terminated by elective abortion ([Lewis and co-workers, 1990](#)). In most cases, however, transmission occurs at birth, and 15 to 25 percent of infants born to untreated HIV-infected mothers will be infected ([Centers for Disease Control and Prevention, 1998b](#)).

Vertical transmission is more common in preterm births, especially those associated with prolonged membrane rupture. Analyzing data from the Perinatal AIDS¹⁶ Collaborative Transmission Study, [Kuhn and colleagues \(1999\)](#) reported a 3.7 relative risk for intrapartum HIV² transmission with preterm delivery. [Landesman and associates \(1996\)](#) reported that HIV-1 transmission at birth was increased from 14 to 25 percent in women whose membranes were ruptured for more than 4 hours. Concurrent syphilis infection is also strongly associated with vertical perinatal HIV transmission ([Lee and colleagues, 1998](#)). Finally, there is evidence that breast feeding increases postnatal HIV-1 transmission by 10 to 20 percent ([Dunn and colleagues, 1992](#)). In a randomized clinical trial from Kenya, [Nduati and associates \(2000\)](#) reported a 16 percent transmission from breast feeding.

During the past several years, it has been found that perinatal HIV² transmission can be most accurately correlated with measurement of plasma viral-RNA burden ([Dickover and associates, 1996](#)). As shown in [Figure 57-8](#), in two studies, neonatal infection is around 5 percent with less than 1000 copies/mL and over 40 percent with levels greater than 100,000 copies/mL. [Mofenson and colleagues \(1999\)](#) reported findings from 480 pregnancies studied by the Pediatric AIDS¹⁷ Clinical Trials Group. Using multivariate analysis, they found that plasma HIV-1 RNA level was the best predictor of risk for perinatal transmission. Importantly, zidovudine therapy that reduced these levels to below 500 copies/mL minimized the risk. They also observed that infusions of HIV-1 hyperimmune globulin did not alter the risk of transmission.

Many women who are delivered of infants who subsequently develop AIDS¹⁸ were asymptomatic during pregnancy. According to the [Centers for Disease Control and Prevention \(1998b\)](#), maternal morbidity and mortality are not increased by pregnancy in seropositive but otherwise asymptomatic women. Conversely, adverse fetal outcomes may be increased with maternal HIV² infection. For example, in a review of 634 women who delivered after 24 weeks, [Stratton and colleagues \(1999\)](#) reported that adverse pregnancy outcomes are common in HIV-infected women and are associated with CD4 proportion of less than 14 percent. The rate of preterm birth was 20 percent, and fetal growth restriction was identified in 24 percent. [Langston and associates \(1995\)](#) reported increased stillbirths with maternal HIV infection.

MANAGEMENT DURING PREGNANCY

Counseling is mandatory for the HIV²-positive woman. This is preferable early in pregnancy, and if she chooses to continue pregnancy, ongoing counseling for psychological support is important. The evolution of management during pregnancy has followed advances made in treatment of nonpregnant persons with HIV infection. Current standards dictate that the pregnant woman and her fetus are entitled to the most efficacious therapy available. Because of the devastating consequences of this infection if untreated, a shift has occurred from an exclusive focus on fetal protection to a more balanced approach to treatment of mother and fetus ([Kass and co-workers, 2000](#)).

In just a short time, major advances in HIV² therapy have been made. A number of investigations have shown that a combination of **nucleoside analogs**—zidovudine, didanosine, zalcitabine, or lamivudine—given along with a **protease inhibitor**—indinavir, ritonavir, or saquinavir—is highly effective in suppressing HIV-RNA levels ([Carpenter and associates, 1996](#)). Short-term survival is improved and morbidity is reduced in asymptomatic HIV-infected patients given triple chemotherapy ([Cameron, 1998](#); [Collier, 1996](#); [Gulick, 1997](#); [Hammer, 1997](#); [Hogg, 1999](#); [Montaner, 1998](#), and their colleagues). Triple chemotherapy in 2001 is standard first-line therapy for nonpregnant adults in the United States.

Although multidrug regimens are efficacious for treatment of HIV²-infected patients, there are few studies regarding their use during pregnancy. Considering the high mortality and morbidity associated with this disease, however, the [Centers for Disease Control and Prevention \(1998d\)](#) recommends that combination antiretroviral therapy be offered to pregnant women. These guidelines were updated for the United States Public Health Service by the [Perinatal HIV Guidelines Working Group \(2000, 2001\)](#). They undoubtedly will be updated frequently to keep pace with use of new antiretroviral drugs.

The earliest studies documented the efficacy of perinatal zidovudine in decreasing HIV² transmission ([Connor and colleagues, 1994](#)). Although having no known maternal advantages, the Protocol 076 regimen decreased perinatal infection from 25 to 8 percent. Regimens now known to have maternal benefits have been combined with zidovudine prophylaxis intrapartum and are shown in [Table 57-5](#).

The Working Group recommends measurement of CD4+ T-lymphocyte counts and HIV²-1 RNA levels approximately each trimester, or about every 3 to 4 months. These are used to make decisions to begin antiretroviral therapy, to alter therapy, to decide route of delivery, or to begin prophylaxis for *Pneumocystis carinii* pneumonia.

Even with treatment, noninfectious maternal complications are increased in these women and their infants. [Lorenzi and colleagues \(1998\)](#) reported that 29 of 37 (78 percent) pregnant women treated with two reverse transcriptase inhibitors, with or without protease inhibitors, had one or more adverse events. Almost half of their infants (14 of 30) had adverse events and preterm delivery was frequent. At least two follow-up studies of children from the Pediatric [AIDS¹⁹](#) Clinical Trial Group 076 Study found no adverse effects in children at 18 months and up to a mean of 5.6 years after zidovudine exposure ([Culnane and associates, 1999](#); [Sperling and colleagues, 1998](#)).

Testing for other sexually transmitted diseases and for tuberculosis is done. Vaccination is given for hepatitis B, influenza, and perhaps pneumococcal infection. If the CD4+ count is below 200/uL, primary prophylaxis for *P carinii* pneumonia is recommended with either sulfamethoxazole-trimethoprim or aerosolized pentamidine. Pneumonia is treated with oral or intravenous sulfamethoxazole-trimethoprim or pentamidine. Other symptomatic opportunistic infections that may develop include toxoplasmosis, herpesvirus infections, and candidiasis.

The Centers for Disease Control and Prevention, and the Infectious Disease Society of America (1999b) have published a symposium on guidelines for prevention of opportunistic infections in persons infected with [HIV²](#).

PREVENTION OF TRANSMISSION. Precautions for antepartum, peripartum, and pediatric care of infected mothers and infants are similar to those for hepatitis B, with avoidance of exposure to blood and body fluids. **If heightened awareness of these precautions is reserved for women known to be seropositive, a large number of women with incubating infection or who are asymptomatic but undiagnosed will pose a larger threat to medical personnel.**

The [Centers for Disease Control \(1987b\)](#) emphasize that because medical history and examination cannot identify reliably all patients infected with immunodeficiency virus or other blood-borne pathogens, blood and body-fluid precautions should be used consistently in all patients. These precautions are as follows:

1. All health-care workers who participate in invasive procedures, including surgical or obstetrical procedures, must use appropriate barrier precautions to prevent skin and mucous-membrane contact with blood and other body fluids of all patients. Gloves, surgical masks, and protective eyewear (goggles) must be worn for all invasive procedures that commonly result in the generation of droplets, splashing of blood or other body fluids, or the generation of bone chips. Fluid-resistant gowns or aprons that provide an effective barrier should be worn during invasive procedures that are likely to result in the splashing of blood or other body fluids. Those who perform or assist in vaginal or cesarean deliveries should wear gloves and gowns when handling the placenta or the infant until blood and amniotic fluid have been removed from the infant's skin, and should wear gloves during care of the cord. Mouth-suction devices for clearing the airway should be avoided.

2. If a glove is torn or there is a needle-stick or other injury, the glove should be removed and a new glove used as promptly as patient safety permits. The needle or instrument involved in the incident also should be removed from the sterile field.

These "universal precautions" were soon followed by "standard precautions," which added a body substance isolation policy. Such substances include:

1. Blood.
2. All body fluids, secretions, and excretions (except sweat) regardless of whether they contain visible blood.
3. Nonintact skin and mucous membranes ([Garner, 1996](#); [West and Cohen, 1997](#)).

Somewhat disconcerting is a recent report by [Ganguly and Sinnott \(1999\)](#) involving a survey of 150 medical students and exposure to body fluids. Although most of the students followed universal guidelines, 62 reported 101 exposures to body fluids and nine were with [HIV²](#)-positive specimens!

For health-care workers exposed significantly to contaminated fluids—for example, a needle-stick injury—postexposure prophylaxis is recommended by the [Centers for Disease Control and Prevention \(1996b\)](#). Treatment is given with zidovudine, 200 mg three times a day, and lamivudine, 150 mg twice a day for 4 weeks. If the source patient has advanced [AIDS²⁰](#), a high load of [HIV²](#), or has been treated with nucleoside analogs, a protease inhibitor such as indinavir, 800 mg three times daily, is added.

PREVENTION OF VERTICAL TRANSMISSION. The two principal approaches suggested for prevention of maternal-infant transmission of [HIV²](#) infection are antiretroviral therapy and cesarean delivery. Use of treatment regimens shown in [Table 57-5](#) and discussed earlier will substantially lower vertical transmission of virus ([Boucher, 1996](#); [Connor, 1994](#); [Matheson, 1995](#), and all their colleagues). [Mauskopf and colleagues \(1996\)](#) have calculated that the method is cost-effective.

In a study regarding the efficacy of abbreviated regimens of zidovudine prophylaxis on perinatal transmission, [Wade and colleagues \(1998\)](#) reported that perinatal transmission rate was 6 percent if zidovudine was begun in the prenatal period, 10 percent if given only intrapartum, 9 percent if given to the newborn within the first 48 hours, and 19 percent if started on day 3 or later. [Lallemant and co-workers \(2000\)](#) also confirmed the efficacy of maternal treatment beginning at 28 weeks. [Stiehm and colleagues \(1999\)](#), reporting for the Pediatric [AIDS²¹](#) Clinical Trials Group Study 185 Team, found that zidovudine prophylaxis is also highly effective in reducing perinatal transmission in women with advanced disease.

CESAREAN DELIVERY. In a retrospective study, the [European Collaborative Study Group \(1994\)](#) reported that elective cesarean delivery decreased the risk of vertical transmission by approximately 50 percent. The [European Mode of Delivery Collaboration \(1999\)](#) was a randomized trial of cesarean versus vaginal delivery for [HIV²](#)-positive women. Of 436 women initially randomized, infection status was available from 370 infants. HIV-infection developed in 3 of 170 newborns (1.8 percent) of mothers assigned cesarean delivery versus 21 of 200 newborns (10.5 percent) of mothers assigned vaginal delivery ($P < .001$). Importantly, when analyzed according to antiretroviral therapy, there was a nonsignificant difference in the rate of transmission in women given zidovudine and comparing cesarean with vaginal delivery (2.1 versus 3.3 percent).

A recent meta-analysis of 15 prospective cohort studies was published by the [International Perinatal HIV Group \(1999\)](#). A total of 8533 mother-infant pairs were available for analysis. Vertical [HIV²](#) transmission was reduced significantly to less than half when cesarean was compared with other modes of delivery. When antiretroviral therapy was given in the prenatal, intrapartum, and neonatal periods along with cesarean delivery, the likelihood of vertical transmission was reduced by 87 percent compared with other modes of delivery and without antiretroviral therapy.

Based on these findings, as well as others not cited, the [American College of Obstetricians and Gynecologists \(2000\)](#) concluded that scheduled cesarean delivery should be discussed and recommended for [HIV²](#)-infected women with an HIV-1 RNA load of greater than 1000 copies/mL. This is whether or not antiretroviral therapy is ongoing. Scheduled delivery may be done as early as 38 weeks to lessen the chances of membrane rupture.

Others have expressed concern that morbidity may be significantly increased in [HIV²](#)-infected women undergoing cesarean delivery. [Stringer and colleagues \(1999\)](#) as well as [Star and co-workers \(1999\)](#) made a plea for restraint regarding routine prophylactic cesarean delivery for prevention of vertical transmission. They concluded that combination antiretroviral therapy may reduce the risk of vertical transmission to as low as 2 percent or less. Indeed, [Morris and associates \(1999\)](#) reported no perinatal transmission in 76 women receiving highly active antiretroviral therapy (HAART). Our experiences at Parkland Hospital are similar, and perinatal transmission in women taking [HAART²²](#) has been less than 2 percent. Accordingly, prophylactic cesarean delivery would be of benefit for only a small number of treated women.

BREAST FEEDING. Breast milk increases the risk of neonatal transmission and in general is not recommended in [HIV²](#)-positive women. Cited previously was the randomized trial from Ghana by [Nduati and co-workers \(2000\)](#). Transmission of HIV-1 infection was found to be 16 percent. It has been estimated that one to two thirds of maternal transmission in breast-fed infants is from breast milk ([Van de Perre, 1999](#)). Despite this, in underdeveloped countries, formula feeding may be impractical and associated with increased mortality from diarrheal and respiratory infections ([De Cock and colleagues, 2000](#)). The World Health Organization and [United Nations Children's Fund \(1998\)](#) have recommended continuing breast-feeding promotion for women living in settings where infectious diseases and malnutrition are the primary causes of infant deaths, such as in many developing countries.

HUMAN PAPILLOMAVIRUS

Genital papillomavirus infection, either symptomatic or asymptomatic, is common ([Hagensee and colleagues, 1999](#)). Of 2597 high-risk pregnant women enrolled in the

New Orleans Center of the Vaginal Infections and Prematurity Study, 28 percent were seropositive for HPV²³-16 capsid antibodies. The most important sequela is development of cervical, vaginal, and vulvar neoplasia, which is discussed in [Chapter 55 \(p. 1448\)](#). Several types of human papillomaviruses (HPV) cause mucocutaneous warts or **condylomata acuminata**. Genital warts, are usually caused by HPV types 6 and 11, but may also be caused by 16, 18, and 30s, 40s, 50s, and 60s groups ([Ferenczy, 1995](#)). Cervical intraepithelial neoplasia and cancer risk is highest with 16, 18, 45, and 56, and intermediate with 31, 33, 35, 39, 51, 52, 58, and 66 ([American College of Obstetricians and Gynecologists, 1994a](#)). The epidemiology and pathophysiology of condylomata acuminata has been extensively reviewed by the [Centers for Disease Control and Prevention \(1999c\)](#).

Viral types 6 and 11 can cause **laryngeal papillomatosis** in children, and evidence is consistent that in some cases the virus may be transmitted by aspiration of infected material at delivery. The rate of perinatal viral transmission is unclear, but all agree that symptomatic disease in children is rare. For example, [Watts and associates \(1998\)](#) found evidence of virus in only 5.3 percent of specimens from neonatal oral or nasopharyngeal, anal, and genital areas. [Tseng and associates \(1998\)](#), in a study of 301 pregnant women with papillomavirus, reported that the overall transmission for 16/18-type virus was 40 percent (27 of 68 newborns). The rate was significantly higher for those delivered vaginally compared with cesarean deliveries (51 versus 27 percent). [Tenti and co-workers \(1999\)](#) documented a 30 percent transmission rate of virus to the neonatal oropharynx. Importantly, they showed that the virus was cleared by 5 weeks. [Manns and collaborators \(1999\)](#) documented that only 3 percent of infants were seropositive to HPV²⁴-16 by 1 to 2 years.

CONDYLOMATA ACUMINATA

For unknown reasons, genital warts frequently increase in number and size during pregnancy, sometimes filling the vagina or covering the perineum, making it difficult to perform vaginal delivery or episiotomy ([Fig. 57-9](#)). In women without grossly visible lesions, [Snyder and co-workers \(1990\)](#), but not [Goldaber and associates \(1993\)](#), found an association with papillomavirus infection and episiotomy breakdown. Certainly, the mucorrhea throughout pregnancy offers ideal moist conditions for viral growth. Accelerated viral replication with advancing pregnancy was hypothesized earlier to explain the growth of perineal lesions, progression of some to cervical neoplasm, and increased detection of cervical viral DNA in some studies ([Gary and Jones, 1985](#); [Rando and co-workers, 1989](#)). More recent data from [Fife and colleagues \(1999\)](#) substantiates this. They studied 232 women and found 31 percent were positive for papillomavirus DNA in the first trimester and 36 percent positive in late pregnancy. In paired samples from 83 women comparing first-trimester viral identification with postpartum specimens, there was a significant decline in positivity from 40 to 27 percent.

Because papillomavirus infection can be subclinical and multifocal, most women with vulvar lesions also have cervical infection, and vice versa ([Spitzer and colleagues, 1989](#)). Vulvar lesions often improve rapidly or disappear postpartum, possibly related to loss of either vascularity, excessive moisture, or the alleged immunosuppression of pregnancy.

TREATMENT

While treatment during pregnancy may be very unsatisfactory, it is usual for these lesions to clear rapidly following delivery. During pregnancy, washing of the external genitalia, plus cleansing of the vagina by gentle douching, followed by thorough drying of the external genitalia, performed at least once daily, may inhibit proliferation of the warts as well as minimize discomfort.

Because lesions commonly regress after delivery, it is not always necessary to try to eradicate them during pregnancy. If they produce discomfort, then they are treated. Therapy is directed toward minimizing toxicity to the mother and fetus and debulking the genital warts in the late second or third trimester so that recurrence is less likely prior to delivery. While there are several agents available for use in nonpregnant women, pregnancy limits their use.

Trichloroacetic or bichloroacetic acid, 80 to 90 percent, applied topically once a week, is an effective regimen for external warts. Some clinicians prefer **cryotherapy** or **laser ablation** of lesions in pregnancy ([Bergman and colleagues, 1984](#); [Ferenczy, 1984](#)). [Schwartz and associates \(1988\)](#) reported good results in 31 of 32 women treated with combination laser and 85 percent trichloroacetic acid therapy.

Podophyllin resin, 5-fluorouracil cream, imiquimod cream, and interferon therapy should not be used in pregnancy because of concerns about maternal and fetal toxicity ([American College of Obstetricians and Gynecologists, 1994a](#); [Centers for Disease Control and Prevention, 1998b](#)).

Occasionally, condylomata acuminata attain enormous size, as shown in [Figure 57-9](#), and these may even necessitate cesarean section. If the woman is seen several weeks before delivery, the large lesions sometimes can be removed by excision, electrocautery, cryosurgery, or laser ablation. [Matsunaga and colleagues \(1987\)](#) reported successful results in 51 women with rather extensive cervical or labial lesions. Enthusiasm has been expressed for use of the carbon-dioxide laser during pregnancy to remove large lesions under anesthesia ([Ferenczy, 1984](#)).

NEONATAL INFECTION

An indeterminate, but probably small, number of infants and children born to women with genital papillomavirus lesions will become infected and develop **laryngeal papillomatosis**. In one study, over 44,000 children were followed for 7 years, and there were no cases of laryngeal papillomatosis identified ([Shah and colleagues, 1986](#)). When they do develop, these papillomas are usually found on the true vocal cords, and HPV²⁵-6 or -11 was identified in 92 percent of 57 cases ([Abramson and colleagues, 1987](#)). They are persistent, recurrent, and disfiguring. The question has been posed whether cesarean section might avoid infection of the fetus-infant, but this is not recommended currently ([American College of Obstetricians and Gynecologists, 1994a](#); [Centers for Disease Control and Prevention, 1998e](#)). In at least one case, elective repeat cesarean section was done at term; however, the child developed extensive respiratory papillomatosis at 7 months ([Shah and associates, 1986](#)). [Puranen and associates \(1996\)](#), in a study of 98 children of infected mothers, found that a third of these children had positive oral scrapings for papillomavirus DNA. One child developed papilloma caused by HPV-16, which was the same type found in the birth canal at delivery.

CHANCROID

Haemophilus ducreyi can cause painful, nonindurated genital ulcers, or soft chancre, at times accompanied by painful inguinal lymphadenopathy. While common in some developing countries, it had become rare in the United States. In 1987, however, its incidence was increased tenfold over the previous 10 years, and drug use and sex-for-drugs were shown to be important risk factors for infection ([Schmid and co-workers, 1987](#)). Importantly, the infection is a high-risk cofactor for HIV² and syphilis transmission (Centers for Disease Control and Prevention, 1998e).

Diagnosis by culture is difficult because appropriate media is not widely available. Instead, clinical diagnosis is made when typical painful genital ulcer(s) are darkfield negative and herpesvirus tests are negative. Recommended treatment is erythromycin base, 500 mg orally four times daily for 7 days; ceftriaxone, 250 mg in a single intramuscular dose; or azithromycin, 1 g orally as a single dose ([Centers for Disease Control and Prevention, 1998b](#)).

TRICHOMONAS INFECTIONS

Trichomonas vaginalis was identified in 13 percent of nearly 14,000 women cultured at midpregnancy by the Vaginal Infections and Prematurity Study Group ([Cotch and colleagues, 1991](#)). Race-specific prevalence was 23 percent for blacks, 6.6 percent for Hispanics, and 6.1 percent for white women. Using polymerase chain reaction, [Witkin and co-workers \(1996\)](#) detected trichomonas in 10 percent of 300 prenatal patients. Symptomatic infection is much less common, and vaginitis is characterized by symptoms of a yellow discharge, abnormal odor, and vulvar pruritus. These women usually have a purulent vaginal discharge, vulvovaginal erythema, and *colpitis macularis* or "strawberry cervix."

Trichomonads are demonstrated readily in a wet mount of vaginal secretions as flagellated, ovoid, motile organisms that are somewhat larger than leukocytes. The sensitivity of this technique depends on the concentration of organisms, the degree of dilution, and the experience of the examiner, but is generally considered to be about 85 percent. Trichomonads are identified most accurately by culture using Diamond medium; however, [DeMeo and associates \(1996\)](#) have shown that a DNA probe test was 90 percent sensitive and 99.8 percent specific.

The Vaginal Infections and Prematurity Study Group ([Cotch and associates, 1997](#)) used multivariate analysis and reported significant associations between trichomoniasis and preterm prematurely ruptured membranes, preterm delivery, and low-birthweight infants. According to [Goldenberg and colleagues \(1997\)](#), the association of preterm delivery with antepartum colonization with *T vaginalis* is difficult to assess because of commonly associated risk factors. Further prospective investigation is warranted before adopting widespread screening and treatment to eradicate this organism in hope of decreasing its possible deleterious effects on pregnancy outcome.

TREATMENT

Metronidazole, the only trichomonocidal drug available in the United States, is quite effective in eradicating *T vaginalis*. Oral administration is the preferred route. [Lossick \(1990\)](#) reviewed clinical experiences with metronidazole and found that 250 mg given three times daily for 7 days, or 2 g as a single dose, had median cure rates of 92 and 96 percent, respectively. Unfortunately, there are few data regarding efficacy of any regimen in pregnancy. According to the [Centers for Disease Control and Prevention \(1998b\)](#), pregnant women can be treated with a 2-g single dose of oral metronidazole.

Men apparently have transient infection with *T vaginalis*. Although the need for concomitant treatment is uncertain, most investigators have found higher relapse rates in women whose partners were not treated. [Lossick \(1990\)](#) recommends that steady sex partners be treated, and the [Centers for Disease Control \(1998b\)](#) recommends that all partners be treated.

OTHER SEXUALLY TRANSMITTED DISEASES

There are many more infections and infestations that can be acquired as the consequence of sexual intercourse. Among others, these include hepatitis B and C, *Candida vulvovaginitis*, *scabies*, and *pediculosis pubis*. These infections are discussed elsewhere. Sexual partners at risk of fecal-oral transmission may acquire any of a number of enteric infections.

TABLE 57-1. Recommended Treatment for Pregnant Women with Syphilis

Category	Treatment
Early syphilis ^a	Benzathine penicillin G, 2.4 million units intramuscularly as a single injection; some authorities recommend a second dose 1 week later
Syphilis of more than 1-year duration ^b	Benzathine penicillin G, 2.4 million units intramuscularly weekly for 3 doses
Neurosyphilis ^c	Aqueous crystalline penicillin G, 3-4 million units intravenously every 4 hours for 10-14 days <i>or</i> Aqueous procaine penicillin, 2.4 million units intramuscularly daily, plus probenecid 500 mg orally four times daily, both for 10-14 days

^a Primary, secondary, and latent syphilis of less than 1-year duration.

^b Latent syphilis of unknown or more than 1-year duration; cardiovascular or late benign syphilis.

^c Some experts administer benzathine penicillin, 2.4 million units intramuscularly, after completion of the neurosyphilis treatment regimens.

TABLE 57-5. Antiretroviral Therapy Regimens

Timing	Regimens
Antepartum —combination therapy with two nucleoside analog reverse transcriptase inhibitors plus either a non-nucleoside analog or a protease inhibitor. The regimen should include: Zidovudine, 100 mg five times daily, beginning at 14-34 wk and continued throughout pregnancy	Nucleoside analogs Zidovudine (ZDU) Zalcitabine Didanosine Stavudine Lamivudine (3TC) Abacavir
<i>plus</i> Another nucleoside analog and either a non-nucleoside analog or a protease inhibitor	Non-nucleoside analogs Nevirapine Delavirdine Efavirenz Protease inhibitors Indinavir Ritonavir Saquinavir Nelfinavir Amprenavir
Intrapartum —chemoprophylaxis 1. Woman has taken above regimen(s) during pregnancy 2. No prior therapy	Zidovudine, 2 mg/kg given intravenously over 1 hour, followed by continuous infusion of 1 mg/kg/hr until delivery Nevirapine, single dose and another dose for infant at 48 h Zidovudine orally plus lamivudine during labor; 1 week ZDU/3TC for newborn Zidovudine intravenous regimen plus 6-wk ZDU for newborn Nevirapine plus zidovudine regimens
Postpartum —no antiretroviral therapy during pregnancy or intrapartum From Perinatal HIV Guidelines Working Group (2000, 2001).	Infant: zidovudine 6-week regimen Mother: evaluation for combination therapy

SECTION XII - FAMILY PLANNING

58. Contraception

The practice of obstetrics in the United States has been influenced by forces from outside the medical community more than any other specialty. In no other branch of medicine are social, religious, and political forces more obvious than in family planning. Although the majority of fertile American women would prefer to avoid pregnancy in any one given year, they and their physicians are confronted continuously by these forces. Women's health-care providers must continue to counsel and prescribe in an area in which confusion is common, change seems continual, and scientific evidence is all too often ignored by legal, legislative, and judicial communities. To add to this, unbalanced media coverage of contraceptive technologies has been detrimental ([Entwistle and colleagues, 2000](#)).

Even in some affluent industrialized countries, women are denied access to family planning services. In the United States, access for indigent women to these services is frequently a political and not medical decision. To correct these inequities, women must make their opinions known to legislators, to the judiciary, and to the news media. Such efforts can be effective, as exemplified by the recent approval of oral contraceptives by the Japanese government after a 35-year delay ([American College of Obstetricians and Gynecologists, 1999b](#)).

There currently are powerful and effective methods of regulating fertility. None is completely without side effects and some danger—for example, latex condoms can initiate anaphylactic reactions. **Thus, while there is no totally safe contraceptive method, and the lack of contraception is even more dangerous, both are less dangerous than driving an automobile for 1 year.** Some of these risks are shown in [Table 58-1](#). Those who prescribe contraceptives must be familiar with currently available drugs and methods and their side effects. We must strive to reduce these side effects and risks to a minimum, to recognize and manage them, and we must be aware that one of the major risks of contraception failure is unplanned pregnancy.

WHO NEEDS CONTRACEPTION?

When no contraception is used by presumably fertile sex partners, about 90 percent of women will conceive within 1 year. Young women, regardless of age, who do not want to be pregnant are best advised to use contraception whenever they begin sexual activity. Some girls—perhaps the majority—ovulate before their first menstrual period.

Contraceptive advice for the woman nearing menopause is a more difficult question because it is impossible to predict when fertility has ended. Results of a study by [Metcalf \(1979\)](#) indicate that *when menstruation remained regular, there was evidence of ovulation in almost every cycle*. Oligomenorrhea or increasing cycle length was associated with a diminished frequency, but not complete cessation of ovulation. Even the presence of hot flashes, amenorrhea, and elevated gonadotropin levels do not absolutely guarantee against subsequent ovulation. Primordial follicles with apparently normal oocytes have been observed in ovaries from women over 50 years of age.

Even so, pregnancies are rare in women over 50. Therefore, older women are probably best advised that regular menstrual periods imply recurrent ovulation irrespective of age. A woman younger than 50 who has not menstruated for 2 years is very unlikely to ovulate spontaneously, although there are reported instances ([Szlachter and co-workers, 1979](#)).

CONTRACEPTIVE METHODS

Methods of variable effectiveness currently employed include:

1. Oral steroidal contraceptives.
2. Injected or implanted steroidal contraceptives.
3. Intrauterine devices.
4. Physical, chemical, or barrier techniques.
5. Withdrawal.
6. Sexual abstinence around the time of ovulation.
7. Breast feeding.
8. Permanent sterilization.

Current contraceptive use by men and women is presented in [Figure 58-1](#). Estimates of the failure rate *during the first year of use* with each of these techniques are given in [Table 58-2](#). Effective education, as well as motivation, undoubtedly would have appreciably reduced the cited failure rates ([Vessey and co-workers, 1982](#)). Mature women who continued to use one technique for a long time typically experienced very low failure rates.

Elective abortion is not a contraceptive technique. It serves, at times, as a less than ideal remedy for contraceptive failure or neglect ([Chap. 33, p. 869](#)).

HORMONAL CONTRACEPTIVES

When introduced in 1960, hormonal contraceptives represented a dramatic departure from previous traditional methods. These contraceptives are available in a variety of oral, injectable, and implantable forms. Oral contraceptives are a combination of estrogen and progestin or a progestin only—the *mini pill*. Injectable or implantable contraceptives contain progestins alone or a combination of estrogen and progestin. In 1995, 10.4 million women in the United States used an oral contraceptive for fertility control ([Piccinino and Mosher, 1998a, 1998b](#)).

ESTROGEN PLUS PROGESTIN CONTRACEPTIVES

Combined estrogen-progesterone contraceptives may be given orally, by intramuscular injection, or by patch. The oral contraceptives are used most commonly and often consist of a combination of an estrogen and a progestational agent taken daily for 3 weeks and omitted for 1 week, during which time there is withdrawal uterine bleeding. Injectable combined agents are discussed on page 1535. Currently under testing in the United States is a contraceptive patch (EVRA) containing 17-deacetylnorgestimate and ethinyl estradiol ([Creasy and associates, 2000](#)).

MECHANISMS OF ACTION. The contraceptive actions of steroidal medications are multiple, but the most important effect is to prevent ovulation by suppression of hypothalamic gonadotropin-releasing factors. This prevents pituitary secretion of follicle-stimulating and luteinizing hormones.

Estrogen alone in sufficient dose will inhibit ovulation by suppressing gonadotropins. It also likely inhibits implantation by altering normal endometrial maturation. Estrogen accelerates ovum transport; however, progestins cause slowing. Thus, their possible role in altered tubal and uterine motility is unclear.

Progestins produce thick, scanty, cellular cervical mucus that impairs sperm transport. Also, sperm capacitation is likely inhibited. Similar to estrogens, progestins produce an endometrium that is unfavorable to blastocyst implantation. Finally, progestins also can inhibit ovulation by suppressing gonadotropins.

The net or combined effect of estrogen and progestin with respect to contraception is extremely effective ovulation suppression, sperm penetration blockage by cervical mucus, and unfavorable endometrium for implantation if the first two mechanisms fail. Estrogen plus progestin combined oral contraceptives, *if taken daily for 3 weeks out of every 4*, provide virtually absolute protection against conception.

PHARMACOLOGY ESTROGENS. In the United States, the only estrogens available are *ethinyl estradiol* and its 3-methyl ether, *mestranol* (Fig. 58-2). To be bioactive, the methyl group at carbon 3 of mestranol must be removed by hepatic conversion into ethinyl estradiol. The exact conversion factor for potency of ethinyl estradiol to mestranol is not known, but it probably is 1.2 to 1.5. The vast majority of all prescriptions for combined oral contraceptives in the United States are for 35-ug doses or less of estrogen, and *all of these contain ethinyl estradiol*.

PROGESTINS. Only 19-nortestosterone derivatives are currently used for progestins because derivatives of 17 α -acetoxyprogesterone in high doses produce breast tumors in female beagles. Of the compounds currently available in the United States (Fig. 58-2), only norgestrel has two isomers. Levonorgestrel is the bioactive isomer; *Nordette* contains 0.15 mg of this compound and *Alesse* contains 0.1 mg. *Lo/Ovral* contains 0.3 mg of dl-norgestrel (a combination of dextro and levo forms), of which only half is in the active levo form. Two newer progestins, *desogestrel* and *norgestimate*, are now available (Fig. 58-2). A third progestin, *gestodene*, is used in Europe. Even low doses of these compounds are associated with minimal metabolic changes but excellent cycle control (Akerlund and colleagues, 1993). Several new progestins with low androgenic properties and minimal effects on lipids are in the process of approval and subsequent marketing in the United States.

All progestins were initially chosen because of their progestational potencies, but now they are compared for estrogenic, antiestrogenic, and androgenic effects. These actions for each are generally considered when prescribing for a specific woman (Table 58-3). For example, if a low androgenic effect were desired for a woman because of acne, a good choice would be one containing 35 ug of ethinyl estradiol and 0.4 to 0.5 mg of norethindrone. Another would be *Ortho-Cyclen*; it contains 0.25 mg of norgestimate, which has less androgenic effect than any other currently available progestin. This is followed closely by desogestrel-containing agents, which have low affinity for testosterone receptors and high affinity for progesterone receptors (Burkman 1993; Collins, 1993; Phillips and colleagues, 1992).

It is apparent that these progestins also have profound effects on plasma lipids, lipoproteins, clotting factors, vessel disease, diabetes, and a variety of nonendocrine effects, which are discussed later.

DOSAGE AND ADMINISTRATION. Since oral contraceptives have come into use, the amounts of estrogen and progestin have been reduced remarkably. This is important, because most adverse effects are dose related. The lowest acceptable dose is governed by the ability to prevent unacceptable breakthrough bleeding. Daily estrogen content is usually 20 to 35 ug of ethinyl estradiol. None of the products sold in the United States contains more than 50 ug. The amount of progestin varies in two ways:

1. Among older, now well-evaluated formulations, progestin dose remains constant during the cycle (monophasic).
2. In some newer preparations, progestin and estrogen dosage varies during the cycle (biphasic and triphasic).

To prevent ovulation induction, and to help recognize preexisting early pregnancy, it is generally recommended that women begin oral contraceptives within the first 7 days of the menstrual cycle. Many women, however, start their use after delivery or abortion, before return of menses. If their use is initiated at any time other than during or immediately after a normal menstrual cycle, or within 3 weeks of delivery, another means of birth control should be used throughout the first week to avoid the risk of pregnancy due to induced ovulation.

To obtain maximum protection and promote regular use of oral contraceptives, most suppliers offer dispensers that provide 21 sequentially and individually wrapped, color-coded tablets containing hormones, followed by seven usually inert tablets of another color (Fig. 58-3). It is important for maximum contraceptive efficiency and for peace of mind that each woman adopt an effective scheme for assuring daily (or nightly) self-administration. One technique is to keep a pill supply and toothbrush close to each other and to swallow a pill at tooth brushing time, either in the morning or in the evening. If one dose is missed, nothing serious is likely to happen if higher dose monophasic estrogen and progestin pills are used. It may be desirable to double the next dose to minimize breakthrough bleeding and to stay on schedule. If several doses are missed or lower dose pills are used, another form of effective contraception (a barrier technique) should be used. The pill can be restarted after withdrawal bleeding. Without bleeding, the possibility of pregnancy must be considered and excluded prior to resumption of oral contraceptive use.

PHASIC PILLS. These preparations were developed in an effort to reduce the amount of total progestin per cycle without sacrificing contraceptive efficacy or cycle control. The reduction is achieved by beginning the contraceptive cycle with a low dose of progestin, and increasing this later in the cycle. For example, a monophasic combined pill containing 35 ug of ethinyl estradiol plus 1.0 mg of norethindrone (*Ortho 1/35*; *Norinyl 1/35*) supplies 21 mg of progestin per cycle versus a similar triphasic combination (*Ortho 7/7/7*), which supplies 15.75 mg of norethindrone per cycle (Table 58-3). Another nonphasic formulation (*Ovcon 35*), however, supplies only 8.4 mg of norethindrone per cycle.

Triphasic formulations are highly effective in preventing pregnancy (Ellis, 1987; Toews and colleagues, 1987). The theoretical advantage is a reduction in metabolic changes attributable to progestin, and thereby a reduction in adverse effects. Unfortunately, beneficial effects of oral progestins may also be reduced. Estrogen dose may be kept constant, or it may be increased temporarily later in the cycle. Examples include *Triphasil* and *Estrostep*, where ethinyl estradiol doses are 30/40/30 and 20/30/35 ug per each 7-day period, respectively. In all such preparations, however, estrogens are kept between 20 and 40 ug of ethinyl estradiol.

Despite the cited advantages, both theoretical and actual, there are distinct disadvantages to triphasic formulations (Hatcher and colleagues, 1990; Woods and associates, 1992). These include:

1. Confusion due to multicolored pills.
2. Breakthrough bleeding (spotting), which almost is doubled compared with nonphasic pills.
3. Loss of flexibility due to difficulty in "doubling up" if a pill is missed.

Still, compliance has been good even in teenaged women.

The problem of breakthrough bleeding has been addressed by the use of *Mircette*, which provides 21 days of pills containing ethinyl estradiol (20 ug) and desogestrel (150 ug). These 21 tablets are followed for 2 days with inert tablets, then for 5 days with tablets containing 10 ug of ethinyl estradiol. This schedule appears to decrease breakthrough bleeding.

DRUG INTERACTIONS. Oral contraceptives interfere with the actions of some drugs (Tables 58-4 and 58-5). Conversely, some drugs decrease the contraceptive effectiveness of combination oral contraceptives (Table 58-6). Phenytoin and rifampin are believed to increase breakthrough bleeding and reduce contraceptive effectiveness of pills containing less than 50 ug of ethinyl estradiol (Hatcher and colleagues, 1998). The mechanism is not entirely clear, but phenytoin stimulates hepatic enzymes that might accelerate the enzymatic degradation of these synthetic hormones. Other agents, such as barbiturates, are known to induce hepatic hydroxylases (Aronson, 1993; Shenfield, 1993). Some broad-spectrum antibiotics such as ampicillin and tetracycline are still listed in labelings as reducing the efficacy of oral contraceptives; however, this likely is not true. Because vitamin C competes for active sulfate in the intestinal wall and increases the bioavailability of ethinyl estradiol, erratic use of vitamin C can result in breakthrough bleeding (Kubba and Guillebaud, 1993).

SAFETY. In general, oral contraceptives, when appropriately monitored, as outlined later in this discussion, have proven to be relatively safe for most women (Table 58-1). The possibility of adverse effects from "The Pill" has received so much attention for so long that the major adverse effect among users may be the anxiety created by almost incessant publicity! Unfortunately, physicians as well as the public are frequently confused by the many and often conflicting reports.

BENEFICIAL EFFECTS. The combined estrogen plus progestin pill is the most effective **reversible** form of contraception available. Failure rates of 0.32 per 100 woman-years or lower have been documented (Vessey and co-workers, 1982). Other reported beneficial effects include increased bone density; reduced menstrual blood loss with less anemia; fewer ectopic pregnancies; less dysmenorrhea associated with endometriosis; fewer functional ovarian cysts and salpingitis; fewer premenstrual complaints; less endometrial and ovarian cancer; reduction in various benign breast diseases; improvement in hirsutism; improvement of acne; prevention of atherogenesis; decreased incidence and severity of pelvic inflammatory disease; and improvement in rheumatoid arthritis (Burkman and colleagues, 2000; Guillebaud, 1997; Hatcher and associates, 1998; Rosenfield and Broholm, 1994; Sulak and Kaunitz, 1999).

BONE MASS DENSITY. Most studies show a small positive effect on bone mass in women who use oral contraceptives (Burkman, 1994; Sulak and Kaunitz, 1999). In a cross-sectional international study, Petitti and co-workers (2000) showed significantly increased bone mass after only 6 months of use. In a population-based Australian study, Pasco and colleagues (2000) found a cumulative increase in bone density with duration of use. Berenson and associates (2000) performed a prospective study and showed a slight increase at 1 year with two agents.

POSSIBLE ADVERSE EFFECTS METABOLIC EFFECTS. Oral contraceptives have a wide range of metabolic effects that are often combined and overlapping. Metabolic changes, often qualitatively similar to those of pregnancy, have been identified in women taking oral contraceptives. For example, plasma thyroxine and thyroid-binding proteins are elevated. Plasma cortisol concentration increases with a nearly comparable increase in transcortin. It is extremely important, therefore, that these pregnancy-like effects be considered when evaluating laboratory tests.

LIPOPROTEINS AND LIPIDS. The combination oral contraceptives increase triglycerides and total cholesterol. Estrogen decreases concentration of low-density lipoprotein (LDL) cholesterol and increases high-density lipoprotein (HDL) cholesterol. Some progestins cause the reverse ([Stadel, 1981](#)). The importance of such changes in the genesis of *arterial vascular disease* such as myocardial infarction or stroke is not clear but is cause for concern ([Knopp, 1988](#); [Mishell, 1988](#)). The adverse changes noted in HDL^1-LDL^2 ratios are the consequences of the 19-nortestosterone progestins, and these changes are likely related to the specific progestin and its dose ([Kauppinen-Makelin and colleagues, 1992](#)). Progestins can alter relative amounts of total HDL, HDL₂, and HDL₃, and it is the HDL₂ fraction that provides cardiovascular protection ([Miller and co-workers, 1982](#); [Tikkanen and associates, 1982](#)). Therefore, estrogen and progestin effects on specific HDL₂ fraction may be of special importance because these drugs may alter cardiovascular risks even though total HDL cholesterol values are increased or unchanged.

The lipid effects of combination contraceptives are time and dose dependent. Maximal effects of progestins are usually best measured after 6 months of use ([Akerlund and associates, 1994](#); [Burkman, 1993](#)). The use of monophasic contraceptives containing 150 ug desogestrel and 30 ug of ethinyl estradiol (Desogen, Ortho-Cept) reduced LDL^2 cholesterol 15 percent while levonorgestrel preparations caused no significant changes. No significant change in LDL cholesterol resulted from the use of triphasic and high-dose monophasic compounds containing norethindrone ([Burkman, 1993](#)). Desogestrel-containing compounds do not decrease HDL^1_2 cholesterol while they increase total HDL cholesterol. If lipoproteins are a concern, compounds containing desogestrel or possibly norgestimate can be used.

Lipoprotein (a) or Lp(a) has been identified as an atherogenic lipoprotein ([Bartens and Wanner, 1994](#)). Estrogens appear to exert a favorable response by reducing circulatory levels of lipoprotein (a). Its atherogenic action appears to be mediated by reduction of plasminogen activation. Decreased plasmin then results in reduced activation of transforming growth factor-beta (TGF- β), which is a powerful inhibitor of smooth muscle cell proliferation. If TGF- β^3 were reduced in arteries with intimal injury, smooth muscle would proliferate, resulting in a narrowing of the artery.

CARBOHYDRATE METABOLISM. Oral contraceptives decrease glucose tolerance in a significant percentage of users, apparently as a direct consequence of the estrogen dose used ([Wynn and Godsland, 1986](#)). Progestins usually are observed to increase insulin secretion and create insulin resistance ([Wynn and Nithyanathan, 1982](#)). Because of these effects, contraceptive steroids may intensify preexisting *diabetes* or may prove sufficiently diabetogenic to induce clinically apparent disease in susceptible women. The risk of the latter appears low because in the great majority of women the effect on carbohydrate metabolism is slight ([Phillips and Duffy, 1973](#)). As with pregnancy, diabetogenic effects are often reversible when oral contraceptives are terminated. [Speroff \(2000a\)](#) has provided an excellent review of this subject.

Estrogen-progestin oral contraceptive use by women who had *gestational diabetes* has been discouraged by some. Concern centers around the possible acceleration of the appearance of insulin-dependent diabetes. According to [Kalkhoff \(1980\)](#), the incidence of diabetes among normal women taking these contraceptives is almost identical to that in a general population. Conversely, the incidence of diabetes among women with previous gestational diabetes taking these contraceptives is increased tenfold. Whether oral contraceptives hasten the onset of permanent disease in gestational diabetics is still an important unanswered question.

There is also concern about contraceptive use in women with previous gestational diabetes and possible associations between mild hyperglycemia or hyperinsulinemia and increased cardiovascular risk. [Skouby and associates \(1985\)](#) studied a small group of women with previous gestational diabetes who were using a triphasic pill containing levonorgestrel (Triphasil, Tri-Levlen). They found that glucose, insulin, and glucagon response, as well as serum cholesterol, high-density lipoproteins, and low-density lipoproteins were unchanged compared with pretreatment values. In contrast, [Wynn and Godsland \(1986\)](#), in a long-term study of women taking 30 ug of ethinyl estradiol and 0.15 mg of levonorgestrel (*Nordette*), reported that there was a progressive deterioration of glucose tolerance. There was less effect when 1 mg norethindrone was given. Thus, norgestrel appears to have the greatest antagonizing effect on insulin and glucose metabolism, and this effect becomes more pronounced over time. If combination oral contraceptives are used in women with a history of gestational diabetes, compounds containing low-dose estrogen (20 ug) and desogestrel should be considered.

PROTEIN METABOLISM. Estrogens increase hepatic production of a variety of *globulins*. Increased *angiotensinogen* production appears to be dose related, and its conversion by renin to angiotensin I has been suspected to be associated with so-called "pill-induced" hypertension (p. 1529). *Fibrinogen*, and likely factors II, VII, IX, X, XII, and XIII, are increased in direct proportion to estrogen dose (Comp, 1996; [Kaunitz, 1999b](#)). The relationship of these increased clotting factors to venous and arterial thrombosis is discussed on page 1528, but the incidence of both forms of thrombosis appear to be estrogen dose related ([Mann, 1982](#)).

LIVER DISEASE. *Cholestasis* and *cholestatic jaundice* are uncommon complications in users of oral contraceptives; the signs and symptoms clear when the medication is stopped. It appears that oral contraceptives may accelerate the development of gallbladder disease in women who are susceptible, but there is no overall increased long-term risk ([Royal College of General Practitioners, 1982](#); [Strom and colleagues, 1986](#)). There is no reason to withhold oral contraceptives from women recovered from viral hepatitis.

NEOPLASIA. Hormonal contraception as a cause of cancer appears to be unlikely ([Cancer and Steroid Hormone Study, 1986, 1987a, 1987b](#); [Prentice and Thomas, 1987](#); [Schlesselman and colleagues, 1988](#)). In fact, a protective effect against ovarian and endometrial cancer has been shown in these studies. There are, however, conflicting reports concerning the risks of premalignant and malignant changes of the liver, pituitary, cervix, and breast.

HEPATIC HYPERPLASIA AND CANCER. Use of estrogen plus progestin contraceptives has been linked circumstantially with the development of *hepatic focal nodular hyperplasia* and actual tumor formation that most often, but not always, is benign. This association has been observed in women using high-dose estrogen-containing formulations (usually mestranol) for prolonged periods. [Neuberger and associates \(1986\)](#) reported an association between prolonged oral contraceptive use and *hepatocellular carcinoma* in women younger than age 50. In contrast, conclusions derived from a multicenter [World Health Organization study \(1989a\)](#) support the view that there is no increased risk of hepatic cancer.

Benign hepatic nodules have extensive proliferation of large and small thin-walled blood vessels. The lesions on rupture can be complicated by bleeding, hemoperitoneum, and shock, which proved fatal in 8 of 24 cases cited by [Antoniades and colleagues \(1975\)](#). The liver may become enlarged to palpation, and imaging studies disclose a space-occupying lesion(s). If identified before rupture, stopping the oral contraceptives and resection of the lesion has been recommended. Some liver lesions appear to disappear spontaneously after discontinuing oral contraceptives. Increased growth and vascularity during pregnancy or the puerperium, leading to rupture and death, have occurred ([Kent and co-workers, 1978](#)). The use of newer, low-dose combination oral contraceptives appears to have reduced the incidence of this unusual condition ([Waetjen and Grimes, 1996](#)).

PITUITARY ADENOMAS. According to the [Pituitary Adenoma Study Group \(1983\)](#), oral contraceptives do not increase the risk of pituitary *prolactinomas*. Awareness that these neoplasms may cause menstrual irregularities, along with imaging technology to visualize them, has resulted in their diagnosis before steroidal contraceptives are given.

CERVIX. There is a correlation between the risk of preinvasive cervical cancer and oral contraceptive use, and the risk of invasive cancer increases after 5 years of use ([Thomas and Ray, 1996](#); [Vessey and associates, 1983b](#); [Zondervan and co-workers, 1996](#)). It is unclear if these associations are causally related. For example, oral contraceptive users do not have the benefit of barrier or spermicidal protection from the human papillomavirus, and they more frequently are screened cytologically for cervical cancer ([Butterworth and associates, 1992](#)).

BREAST CANCER. It is unclear whether oral contraceptives contribute to the development of *breast cancer*. In the largest study, no increased risk for breast cancer among oral contraceptive users was demonstrated ([Cancer and Steroid Hormone Study, 1986](#)). Moreover, risk did not vary according to preparation or duration of use. Whereas a New Zealand study ([Paul and colleagues, 1986](#)) confirmed these findings, a Swedish study ([Meirik and associates, 1986](#)) suggested a slightly increased risk of breast cancer among women who used oral contraceptives for 12 or more years. Gabrick and co-workers (2000) reported a higher risk in women with a strong family history, but this was with older preparations with high-dose estrogens. The [Collaborative Group on Hormonal Factors in Breast Cancer \(1996\)](#) studied more than 53,000 women with breast cancer. They found a small but significantly increased relative risk of breast cancer in women taking combined oral contraceptives or within 10 years of stopping. For current users, the risk was 1.24, it was 1.16 for those 1 to 4 years after stopping, and 1.07 for those 5 to 9 years after stopping.

When breast tumors were discovered in the 1996 collaborative study, the tumors were reported to be less aggressive and to be detected at an earlier stage. Moreover, the risk was not influenced by early use, duration of use, use prior to pregnancy, the dose or type of hormone used. Because oral contraceptives did not

appear to alter risk factors in women with and without a family history of breast cancer.

Long-term studies of the newer, low-dose oral contraceptives have not yet been performed. The 1 in 9 attack rate of breast cancer would make it difficult for a small increased risk to be detected. The [Food and Drug Administration \(1984\)](#) has not changed its recommendations regarding oral contraceptive prescribing and the risks for breast cancer. [Speroff \(2000b\)](#) performed a scholarly evidence-based review of 54 epidemiological studies that addressed this problem. He concluded that there was no evidence that oral contraceptives, including high-estrogen or high-progesterone dose, increased breast cancer risk even with prolonged use.

NUTRITION. Aberrations in the levels of several *nutrients*, similar to changes induced by normal pregnancy, have been described for women who use oral contraceptives. Lower plasma levels in users compared with nonusers have been described by some investigators for ascorbic acid, folic acid, vitamin B₁₂, niacin, riboflavin, and zinc.

PYRIDOXINE DEFICIENCY. Biochemical changes compatible with vitamin B₆ (pyridoxine) deficiency have been documented with oral contraceptive use. These are similar to those of normal pregnancy ([Wynn, 1975](#)). Estrogens induce the rate-limiting liver enzyme, *tryptophan oxygenase*, which enhances tryptophan metabolism in a way that suggests pyridoxine deficiency (also see discussion of *depression*, p. 1530). The similarity of changes in tryptophan and pyridoxine metabolism to those of normal pregnancy strongly implies that estrogen-progestin contraceptives do not induce clinically significant pathological changes.

CARDIOVASCULAR EFFECTS. There are a number of uncommon but significant cardiovascular risks associated with hormonal contraceptive use.

THROMBOEMBOLISM. The risk of *deep vein thrombosis* and *pulmonary embolism* has been estimated to be increased by 3- to 11-fold in women who use oral contraceptives ([Realini and Goldzieher, 1985](#); [Stadel, 1981](#)). Contraceptive use during the month before an operative procedure appears to significantly increase the risk of postoperative thromboembolism. These risks clearly are estrogen-dose related, and the risk decreases with the use of formulations containing 20 to 35 ug of ethinyl estradiol ([Westhoff, 1998](#)).

In the mid-1990s, there was a 1.5- to 2-fold increased risk reported for venous thromboembolism associated with contraceptives containing either desogestrel or gestodene when compared with those containing levonorgestrel or norethindrone ([Bloemenkamp and colleagues, 1995](#); [Jick and associates, 1995](#); [Spitzer and co-workers, 1996](#); [World Health Organization, 1995](#)). These findings were not confirmed in subsequent reports, which show that desogestrel, gestodene, levonorgestrel, and norgestimate all have similar low risks of association with venous thromboembolism ([Association of Professors of Obstetrics and Gynecology, 1999](#); [Farmer and associates, 1998](#); [Kaunitz, 1999b](#); [Speroff, 1998](#); [Westhoff, 1998](#)).

[Mishell \(2000\)](#) performed a scholarly evidence-based review of the risks of venous thromboembolism in oral contraceptive users. After analyzing six epidemiologically sound studies, he considered that the risk is increased three- to fourfold in users (but not former users). Importantly, the baseline risk is low—about 1 per 10,000 woman-years—and thus the incidence with oral contraceptives of 1.0 to 3.0 per 10,000 woman-years is small. Moreover, it is half that of the 5.7 per 10,000 woman-years incidence estimated for pregnancy.

The mechanism by which estrogen-progestin contraceptives enhance the risk of venous thrombosis and thromboembolism is unclear. Development of distinctive vascular intimal and medial lesions with associated occlusive thrombi has been described ([Irey and co-workers, 1970](#)). Moreover, platelet aggregation may be accelerated, and both plasma antithrombin III activity and endothelial plasminogen activator are likely to be reduced. The enhanced risk of thromboembolism appears to decrease rapidly once the contraceptive is stopped. Women who develop thromboembolism while taking estrogen-containing contraceptives, however, also appear to be at increased risk during pregnancy and the early puerperium. Those most at risk for venous thrombosis and embolism include women with the factor V Leiden mutation and those with protein C and S deficiencies ([Comp, 1996](#)). Other clinical factors that increase the risk of venous thrombosis and embolism are hypertension, obesity, diabetes, smoking, and a sedentary lifestyle ([Hatcher and associates, 1998](#)).

STROKE AND ARTERIAL THROMBOSIS. According to the [World Health Organization Collaborative Study \(1998\)](#), ischemic and hemorrhagic strokes are uncommon in nonsmoking women younger than 35. The incidence is 10 and 24 events per 1 million woman years, respectively. The earlier reports by [Lidegaard \(1993, 1998\)](#) that the risk of cerebral thromboembolism was increased in women using low-dose estrogen contraceptives stimulated a number of focused studies. At least five subsequent studies concluded that the use of such compounds by healthy, nonsmoking women is not associated with an increased risk of thrombotic or hemorrhagic strokes ([Mishell, 2000](#); [Petitti and co-workers, 1996](#); [Schwartz and associates, 1998](#); [World Health Organization Collaborative Study, 1996](#)). Importantly, women who have hypertension, or who smoke, or have migraine headaches have an increased risk of hemorrhagic and thrombotic strokes ([Mishell, 2000](#); [Schwartz and colleagues, 1998](#)).

HYPERTENSION. An association between oral contraceptives and hypertension was apparent by the late 1960s. Several reports appeared of the occasional woman who, while using an estrogen-progestin contraceptive, became overtly hypertensive. Usually blood pressure returned to normal when the medication was stopped. Oral contraceptives, presumably in response to estrogen, were shown to increase plasma angiotensinogen (renin substrate) to levels near those found in normal pregnancy. Although the great majority of women using oral contraceptives demonstrate these changes, most do not become hypertensive. Progestin appears to contribute to the hypertension. [Weir \(1982\)](#) observed that women who developed hypertension while taking estrogen-progestin oral contraceptives and who become normotensive after stopping the contraceptive, redeveloped hypertension when oral contraception was reinstated, even if the contraceptive employed contained no estrogen.

Unfortunately, normotensive women who are destined to become hypertensive in response to oral contraceptives usually cannot be identified in advance. The development of hypertension during pregnancy does not preclude subsequent use of oral contraceptives.

MYOCARDIAL INFARCTION. Oral contraceptives containing low-dose estrogen and low-androgenic progestins are not associated with an increased risk of myocardial infarction in nonsmokers ([Lewis, 1996](#); [Petitti, 1998](#); [Sidney, 1996, 1998](#), and their colleagues; [Mishell, 2000](#); [World Health Organization Collaborative Study, 1997a](#)). The [American College of Obstetricians and Gynecologists \(1994\)](#) cited no contraindication for oral contraceptives in nonsmoking women past age 35. Finally, the Food and Drug Administration revised their labeling of oral contraceptives to remove restrictions for nonsmoking women past age 40 ([Contraception Report, 1992](#)).

It must not be forgotten that smoking is an independent risk factor for myocardial infarction, which is enhanced synergistically by oral contraceptives. The two critical points with respect to smoking and oral contraceptives appear to be more than 15 cigarettes per day for current and past smokers and age over 35 ([Craft and Hannaford, 1989](#)).

MIGRAINE HEADACHES. The frequency and intensity of attacks of *migraine headaches* may improve or worsen. Most clinicians prefer to avoid these contraceptives in such women, not only because they are likely to be unacceptable but also because some migraines are indistinguishable from mild or impending stroke. Moreover, it appears likely that even a history of migraine headaches is associated with an increased risk of thrombotic and hemorrhagic strokes ([American College of Obstetricians and Gynecologists, 2000](#); [Schwartz and co-workers, 1998](#)).

EFFECTS ON REPRODUCTION POSTPILL AMENORRHEA. When combination contraception is discontinued, ovulation usually resumes promptly. Similar to the postpartum period, within 3 months after discontinuance, at least 90 percent of women who previously ovulated regularly will have done so again. [Bracken and associates \(1990\)](#) observed a reduced conception rate for at least six cycles after stopping these contraceptives.

CONGENITAL DEFECTS. In earlier studies, fetal limb-reduction deformities were reported in pregnancies conceived while taking, or soon after taking, combination oral contraceptives ([Janevich and co-workers, 1974](#)). Subsequently, [Rothman and Louik \(1978\)](#) and [Savolainen and associates \(1981\)](#) found no increased major malformations in infants whose mothers recently had used oral contraceptives. Similarly, [Lammer and Cordero \(1986\)](#) found no association between major malformations and contraceptive exposure in early pregnancy ([Chap. 38, p. 1017](#)). Even so, the woman who thinks that she may be pregnant should be advised to stop the oral contraceptive- *but use another contraceptive technique*—until it can be established whether or not she is pregnant.

LACTATION. Use of combined oral contraceptive hormones by nursing mothers reduces the amount of *breast milk*. Only very small quantities of the hormones are excreted in milk. Because progestin-only oral contraceptives have little effect on lactation and provide excellent contraception, they are preferred for up to 6 months in women who are using breast feeding exclusively (p. 1531). After 6 months, a backup barrier technique should be added ([Kaunitz, 1997](#)). A woman who is only breast feeding intermittently should have effective contraception beginning as soon as 3 weeks postpartum ([Kaunitz, 1997](#)).

OTHER EFFECTS. *Cervical mucorrhea*, likely due to cervical ectopy, is fairly common in response to the estrogen component ([Critchlow and colleagues, 1995](#)). The mucus at times may be irritating to the vagina and vulva. *Vaginitis* or *vulvovaginitis*, especially that caused by *Candida*, also may develop. Antibiotic therapy in pill

users increases the frequency of such infections.

Hyperpigmentation of the face and forehead (*chloasma*) is more likely in women who demonstrated such a change during pregnancy ([Chap. 54, p. 1430](#)). Almost all women using combination contraceptives have increased pigmentation of breast areola and perineum. Acne may improve or, at times, be aggravated, often dependent on the androgenic property of the progestin used ([Table 58-3](#)). Combined contraceptives suppress gonadotropins and thus diminish ovarian androstenedione secretion and resultant testosterone production. If a low androgenic progestin such as desogestrel or norgestimate is used in the combination pill, overall androgen effect is reduced and acne will likely improve.

Uterine *myomas* most likely are not increased in size by oral contraceptives ([Parazzini and colleagues, 1992](#)).

Weight gain has been a troublesome complaint from women who use oral contraceptives, although an increase in weight is far from uniform. Some of the weight may be caused by fluid retention, but it is likely to be a consequence of increased dietary intake.

Low-dose estrogen formulations are not associated with *depression*, but oral contraceptives containing 50 ug or more of estrogen were associated with depression ([Kay, 1984](#)). [Goldzeiher and Zamah \(1995\)](#) reported that depression is more likely to improve with low-dose oral contraceptives.

Preliminary studies from the Centers for Disease Control and Prevention have not shown a significantly increased rate of human immunodeficiency virus (HIV) infection in women using hormonal contraceptives ([National Institute of Child Health and Human Development, 1996](#)). Clearly, hormonal contraception does not prevent the transmission of the virus that causes acquired immunodeficiency syndrome (AIDS) or any other known viral infection.

RISK OF DEATH. The risk of death from oral contraceptives is very low if the woman is younger than 35, has no systemic illness, and does not smoke ([Table 58-7](#)). [Porter and associates \(1987\)](#) reported their experiences with nearly 55,000 woman-years of oral contraceptive use in the Group Health Cooperative of Puget Sound and attributed only one death to their use. The risk of dying as the consequence of using an oral contraceptive certainly is less than that of pregnancy, even though the risk with the latter is quite low ([Tables 58-1 and 58-7](#)).

Similar results have been reported from England. [Vessey and colleagues \(1989\)](#), in a 20-year follow-up study of over 17,000 women, reported that the overall relative risk of death in women taking oral contraceptives was 0.9 compared with women of similar age using barrier methods. Deaths due to cancer and their relative risk were breast, 0.9; cervix, 3.3; and ovary, 0.4. The death risk from cardiovascular disease was 1.5, and most cardiovascular deaths were in smokers.

POSTPARTUM USE. Women who do not breast feed, and especially those who have undergone abortions, may ovulate before 6 to 7 weeks after pregnancy ([Chap. 17, p. 418](#)). There is an advantage, therefore, to starting oral contraceptives before the traditional "6-weeks postpartum check." On the other hand, increased risks of adverse effects, especially venous thromboembolism, might be anticipated from use of estrogen-progestin contraceptives earlier in the puerperium. The use of 35-ug or smaller estrogen doses has reduced this risk greatly, and thus far, in our now extensive experience in which oral contraceptives have been started during the third week postpartum, there has been no evidence of increased morbidity or mortality.

COST. The price of oral contraceptives has increased remarkably, and this likely does not reflect the cost of the ingredients. The typical cost of oral contraceptives and other forms of contraception are listed in [Table 58-8](#). Fixed dose estrogen-progestin contraceptives containing norethindrone and either 35 or 50 ug of estrogen are available as *generic products*. Because regulations allow a 25 percent variance in bioavailability, poor cycle control might follow their use in women as they change from one generic manufacturer to another.

CONTRAINDICATIONS. If a contraindication is listed, combined oral contraceptive pills should probably never be used for contraception ([Table 58-9](#)).

PROGESTATIONAL CONTRACEPTIVES

ORAL PROGESTINS. So-called *mini-pills* ([Table 58-3](#)) consist solely of 350 ug or less of a progestin used daily. They have not achieved widespread popularity because of a much higher incidence of irregular bleeding and a higher pregnancy rate. They impair fertility without always inhibiting ovulation. This likely results from inducing cervical mucus that impedes sperm penetration and from altering endometrial maturation sufficiently to thwart successful blastocyst implantation. Contraceptive effectiveness is greatest if there is ovulation suppression that paradoxically results in an increased incidence of abnormal uterine bleeding. Therefore, if menses are not disturbed, or only minimally disturbed, ovulation is likely not suppressed, and the pregnancy risk is greater. Actual pregnancy rates with progestin-only pills range from 1.1 to 9.6 pregnancies per 100 women in the first year ([Trussell and Kost, 1987](#)). [Guillebaud \(1985\)](#) reported a lower rate of 0.9 pregnancies per 100 married women with a decreasing rate observed with advancing age (25 to 29 years, 3.1; 30 to 34 years, 2.0; 35 to 39 years, 1.0; 40 or older, 0.3 pregnancies per 100 married women).

The contraceptive effectiveness of oral progestin-only contraceptives is decreased by barbiturates, rifampin, and likely by carbamazepine. Phenytoin also decreases the contraceptive effectiveness of progestin-only pills, and the phenytoin anticonvulsant effect also may be increased. The best management is to use backup contraceptives or increase the dose for women taking carbamazepine and phenytoin. For women taking barbiturates or rifampin, oral progestin-only pills should not be used, and these women should use an alternate method of contraception ([Frederiksen, 1998](#)).

Women taking carbamazepine, phenytoin or rifampin should not use levonorgestrel implants (Norplant). In such cases an alternate method of contraception must be used ([Frederiksen, 1998](#)). Finally, depot medroxyprogesterone contraceptive effectiveness is decreased in women taking aminoglutethimide. An alternate contraceptive method also must be used in these women.

BENEFITS. Benefits are similar to those described earlier for the combined oral contraceptives. In addition, these formulations have not been shown to increase the risk of cardiovascular disease or malignancy ([Guillebaud, 1985](#)). They are less likely to increase blood pressure or cause headaches ([Vessey and colleagues, 1985](#)). They have minimal effects on carbohydrate metabolism and allegedly cause less depression, dysmenorrhea, and premenstrual symptoms. When used by lactating women, these agents are virtually 100 percent effective for up to 6 months, and they have little effect on milk production ([Betrabet and colleagues, 1987](#); [Shikary and associates, 1987](#)). Smokers who cannot use combined oral contraceptives after age 35 can use these agents. Finally, they can be used in women with altered glucose tolerance and, **with caution**, in women who had hypertension or headaches while taking combination oral contraceptives.

DISADVANTAGES. The major disadvantages are contraceptive failure and an increased incidence of ectopic pregnancy when contraception fails. Irregular uterine bleeding is a distinct disadvantage and can consist of amenorrhea, spotting, breakthrough bleeding, and prolonged periods of amenorrhea or menorrhagia. Ovarian functional cysts develop with a greater frequency in women using these agents. Another disadvantage is that they must be taken at the same or nearly the same time daily ([Guillebaud, 1985](#)). *If a progestin-only pill is taken even 3 hours late, a backup form of contraception must be used for the next 2 days* ([American College of Obstetricians and Gynecologists, 1994](#)).

CONTRAINDICATIONS. Progestin-only pills are contraindicated in women, especially older women, with unexplained uterine bleeding. A history of a previous ectopic pregnancy or previous functional ovarian cysts should also be considered a relative contraindication. The Food and Drug Administration has required the same package insert labeling of contraindications for both combination and progestin-only oral contraceptives.

INJECTABLE PROGESTIN CONTRACEPTIVES. The advantages of injected progestins include a contraceptive effectiveness comparable with or better than combined oral contraceptives, long-lasting action with injections required only 4 to 6 times a year, and minimal impairment of lactation ([American College of Obstetricians and Gynecologists, 1994](#)). Depot medroxyprogesterone acetate (*Depo-Provera*) and norethindrone ethantrate (*Norgest*) have been used effectively world wide for many years. *Depo-Provera* was approved for contraceptive use in the United States in 1992, however, *Norgest* is not yet available. The mechanisms of action of both drugs appear to be multiple and include ovulation inhibition, increased cervical mucus viscosity, and production of an endometrium unfavorable for ovum implantation ([Mishell, 1996](#)).

BENEFITS AND DISADVANTAGES. These are similar to those for oral progestins. [Cushman and associates \(1996\)](#) reported that women attending urban family planning clinics rated injectable contraceptives as less convenient and thought them to be less effective than pill or Norplant users. The disadvantages include prolonged amenorrhea, uterine bleeding during and after use, and prolonged anovulation after discontinuation. Return of fertility is delayed but not prevented. Triglycerides and HDL¹ cholesterol are both reduced in long-term users, but LDL² cholesterol is not increased ([Deslypere and associates, 1985](#)). These agents modify glucose metabolism only slightly in long-term users. As might be expected, the incidence of iron-deficiency anemia is decreased in long-term users, likely as a result of prolonged amenorrhea. The reported risks of breast cancer are conflicting. [Skegg and colleagues \(1995\)](#) pooled the results of the New Zealand and World Health Organization case-control studies, which included almost 1800 women with breast cancer and 14,000 controls. Within the first 5 years of use, the

contraceptive was associated with a twofold risk of cancer, but overall the risk was not increased. Cervical and hepatic malignancy do not appear to be increased, and the risk of ovarian and endometrial cancers is decreased in women using this contraception ([Earl and David, 1994](#); [Kaunitz, 1996](#)). The risk of cervical carcinoma-in-situ may be increased ([Thomas and colleagues, 1995](#)). Weight gain is a real and predictable problem. There is an average gain of 5.4 pounds for the first year, 8.1 pounds after 2 years, and 13.8 pounds after 4 years of use ([World Health Organization, 1990](#)). In small studies, [Mainwaring and colleagues \(1995\)](#) and [Moore and associates \(1995\)](#) reported no weight gain in the first year of use. Headaches, breast tenderness, and depression have been reported to be associated with these injections.

In long-term users of depot medroxyprogesterone, loss of bone mineral density is a potential problem in women 18 to 39 years of age ([Scholes and colleagues, 1999](#)). This may be even a greater problem for teenagers because bone density is increased most rapidly from age 10 to 30 ([Cromer and colleagues, 1996](#); [Sulak and Kaunitz, 1999](#)). This is a particularly worrisome problem, but bone loss appears to be reversible after discontinuation of therapy ([Cundy and colleagues, 1994](#)). It is unknown if "add-back" estrogen therapy during depot contraception will reduce or reverse bone density loss during therapy.

Depot medroxyprogesterone is injected deeply into the upper outer quadrant of the buttock without massage to ensure that the drug is released slowly. The usual dose is 150 mg every 90 days. Within days, this results in plasma levels of approximately 1.5 to 3 ng/mL, which gradually decline to 0.2 ng/mL at 6 months and become undetectable by 7 to 9 months ([Ortiz and colleagues, 1977](#)). An additional contraceptive method should be used for at least 2 weeks after the initial injection. [Berenson and Wiemann \(1996\)](#) reported that 12 percent of adolescents who chose this method failed to obtain a second injection within 4 months of the initial injection.

Norethindrone ethanolate is injected in a similar manner in a dose of 200 mg, but it must be reinjected every 60 days ([World Health Organization, 1983](#)). Within a week of injection, plasma levels of norethindrone plateau at 10 to 17 ng/mL and remain at these values for about 3 to 4 weeks. After this time, the levels fall to approximately 4 ng/mL for 30 to 60 days ([Goebelsmann and colleagues, 1979](#)).

PROGESTIN IMPLANTS (NORPLANT SYSTEM). The *Norplant System* provides levonorgestrel in six silastic containers that are implanted subdermally. Each is 34 mm long, 2.4 mm in diameter, and contains 36 mg of levonorgestrel. The combined 216-mg dose results in an almost immediate plasma release of about 85 ug/day for the first 6 to 8 weeks, resulting in immediate contraceptive effectiveness. By 9 months after insertion, the release rate is about 50 ug/day, gradually decreasing to 25 to 30 ug/day by 60 months, when it should be removed ([Hatcher and colleagues, 1998](#)).

EFFECTIVENESS. During 18,530 woman-months of use, 19 pregnancies were reported in women using levonorgestrel implants; 11 of these were in years 6 to 8 ([Diaz and colleagues, 1987](#)). Data from the Population Council ([Sivin, 1988](#)), based on more than 12,000 woman-years of experience, indicates a failure rate in the first year of 0.04 per 100 woman-years. The rate was 0.2 in the second year, and rates of 0.9, 0.5, and 1.1 were reported in the third, fourth, and fifth years. Thus, this form of contraception is one of the most effective available. Importantly, after termination of use, normal fertility is promptly restored ([Sivin and colleagues, 1992](#)).

MODE OF ACTION. Up to a third of cycles may be ovulatory based on serum progesterone determinations of 3 ng/mL ([Brache and associates, 1990](#)). This estimate is likely overestimated by a factor of two; however, with progestin-induced changes in cervical mucus and endometrium, the contraceptive effect is extremely good. Despite early reports that contraceptive effectiveness was inversely proportional to body weight in excess of 70 kg, the development of a thinner silastic tube has partially eliminated this concern.

ADVANTAGES AND DISADVANTAGES. These are almost identical to those for oral progestins (described earlier), except for the effect on carbohydrate metabolism. [Konje and associates \(1992\)](#) reported that after 6 months of use, glucose and insulin values were altered even in nondiabetic women. They cautioned that these changes were not significant in normal women, but there were concerns in potential diabetics. It also appears that bone density loss does not occur with use of the Norplant System ([Cromer and associates, 1996](#); [Naessen and co-workers, 1995](#)). In a cross-sectional study of 103 users, [Alvarez-Sanchez and colleagues \(2000\)](#) demonstrated an 18 percent incidence of enlarged (> 25 mm) ovarian follicles compared with only 4 percent in a copper-intrauterine device control group. The longest time to resolution was 4 weeks.

Because of minor surgery involved, there are also problems associated with local infection. If the capsules are not inserted as directed, removal is more difficult. Finally, it should be remembered that barbiturates, carbamazepine, phenytoin and rifampin reduce the contraceptive effectiveness of Norplant (p. 1531). Some side effects of Norplant are listed in [Table 58-10](#).

CONTRAINDICATIONS. These are the same as those for oral progestins. Importantly, as emphasized by the [American Medical Association Board of Trustees \(1992\)](#), these agents are not to be used by governmental agencies to coerce women into using contraception in return for receipt of benefits.

LEGAL DIFFICULTIES. Despite the effectiveness, safety, and patient satisfaction with this excellent contraceptive, it has become the target of personal injury lawyers. They have found "a new area to litigate" based upon the alleged but totally unproven accusation that the silicone content of the rods is producing illness. The [New York Times on May 28, 1995](#), published a lead article entitled "Will the Lawyers Kill Off Norplant?" The story noted that in Dallas a woman stated she was "very happy with her Norplant but was having it out on the advice of her lawyer." She went on to say, "Once I get my money, can I get a second Norplant put in?" In our own clinics, Norplant insertions have decreased from approximately 150 to less than 5 per month since the litigation assault began, and requests for Norplant removals have soared.

According to the [American College of Obstetricians and Gynecologists \(1995\)](#), Wyeth-Ayerst Laboratories has announced that it will "offer health care providers legal defense and indemnification for lawsuits associated with the Norplant contraceptive implant." We agree with Dr. Wayne Barden, vice president of the Population Council, who was quoted in the [New York Times](#) article as saying, "I guess we could have expected it ... You'd think women would say, wait a minute—isn't this a little too much?" Despite this being "a little too much," it appears that in the United States personal injury lawyers have effectively reduced the use of this safe and highly effective contraceptive. Moreover, a 3-year, two-rod implant system (Norplant II) has been approved by the Food and Drug Administration, but it has not been marketed ([Berenson and colleagues, 1998](#)).

INJECTABLE MEDROXYPROGESTERONE ACETATE/ESTRADIOL CYPIONATE

A new contraceptive for use by monthly injection has been approved by the Food and Drug Administration. The agent contains 25 mg of medroxyprogesterone acetate plus 5 mg of estradiol cypionate and will be marketed under the name Lunelle or Cyclo-Provera ([Kaunitz, 1999a](#)).

MECHANISM OF ACTION. The drug inhibits ovulation and suppresses endometrial proliferation ([Aedo and co-workers, 1985](#)). Estradiol values reach a peak level by 3 to 4 days postinjection at values comparable to those associated with preovulatory surges in a normal ovulatory menstrual cycle. The values of estradiol remain at this level for approximately 10 to 14 days ([Oriowo and colleagues, 1980](#)). The subsequent decrease in estradiol values results in estrogen-induced withdrawal bleeding 10 to 20 days after the injection ([Oriowo and colleagues, 1980](#); [World Health Organization, Special Program on Research, 1989b](#)).

EFFECTIVENESS. Only six method failures in 70,000 woman-years of use have been reported ([Hall and co-workers, 1994](#)). This is an effectiveness similar to that seen following female sterilization procedures.

ADVANTAGES AND DISADVANTAGES. The frequency of injection is an obvious problem, but the drug likely will be marketed in a nonreusable sterile device that will allow self-injection and ease of use by medical and nursing staffs. After 3 months use, bleeding irregularities appear to be less common than with depot medroxyprogesterone acetate injections ([Kaunitz, 1999a](#)). Fully two thirds of long-term users have regular menses ([World Health Organization, 1989b](#)). Return to fertility after discontinuation is rapid, with up to 83 percent of women conceiving within 12 months of discontinuation ([Kaunitz, 1999a](#)). The rate of return to fertility was much more rapid than after discontinuing depot medroxyprogesterone acetate injections. The other effects of this new agent are similar to those for medroxyprogesterone injections for hypertension, headaches, dizziness, mastalgia, malaise, cervical changes, and weight gain ([Cuong and co-workers, 1996](#); [Sang and colleagues, 1995](#); [World Health Organization, 1988, 1993](#)).

METABOLIC EFFECTS. Procoagulant factors were not increased in women using this agent, and only slight decreases in factors VII and X activities were noted. Tissue plasminogen factor was increased while antithrombin III activity and protein C concentrations were slightly decreased ([Hall, 1998](#)). No instances of stroke, thromboembolic events, anaphylaxis or myocardial infarction have been reported ([Kaunitz, 1999a](#)). Lipid changes do not appear to be clinically important, but slight variations have been reported within days following injection and at 1 year of use ([Nelson, 2000](#); [Shulman, 2000](#)). Glucose response was increased slightly, and insulin response to glucose challenges was also increased slightly during use. Liver transaminases and bilirubin were also increased slightly while alkaline phosphatase values were decreased ([World Health Organization, 1997b](#)). No studies of bone density have as yet been reported.

PROPOSED CONTRAINDICATIONS. These are similar to those for combined oral contraceptives, which are listed in [Table 58-9 \(Kaunitz, 1999a\)](#).

MECHANICAL METHODS OF CONTRACEPTION

INTRAUTERINE CONTRACEPTIVE DEVICES

At one time in the United States, approximately 7 percent of sexually active women used an intrauterine device (IUD) for contraception. The two devices currently approved for use in the United States are shown in [Figure 58-4](#). The levonorgestrel-containing device ([LNg⁴-IUD⁵](#)) has not been approved for use. The percentages of unwanted pregnancies during the first year of perfect use associated with each IUD are 0.6 percent for the Copper T (Cu T), 1.5 percent for the Progestasert, and 0.1 percent for the LNg 20. Typical failure rates are 0.8 percent, 2.0 percent, and 0.1 percent respectively.

By 1986, the two most popular intrauterine devices used by American women had been withdrawn voluntarily from the market by their manufacturers. The Lippes Loop and Copper 7 (Cu 7) were withdrawn because of the financial burden of defense in liability cases. At that time, about half of the 2 million women in the United States wearing these devices were acceptable candidates for oral contraceptive therapy. Some of the remaining women continued to use the inert plastic devices, which could be left in place indefinitely. Many women, however, had to choose between alternative, albeit less effective, contraceptive measures and permanent sterilization. Fortunately, the Progestasert ([Fig. 58-4](#)) continued to be marketed in the United States in limited quantities but at a very high cost. By 1988, the Cu T model 380A ([Fig. 58-4](#)) became available, but it too is very expensive.

With new information on safety, the [IUD⁶](#) is once again gaining in popularity for several reasons. The most likely reason is that the Cu T and [LNg⁷ 20](#) are "use and forget" effective reversible methods of contraception that do not have to be replaced for 10 and 5 years, respectively. It is now established that the major actions of IUDs are not as abortifacients but as contraceptives. The risk of pelvic infections is markedly reduced with the current use of a monofilament string and newer techniques to ensure safer insertion. The risk of an associated ectopic pregnancy also has been clarified. Specifically, the contraceptive effect of the IUDs actually decreases the number of ectopic pregnancies ([World Health Organization, 1985, 1987](#)). If a pregnancy does occur, however, that pregnancy is more likely to be ectopic, especially in a woman using the Progestasert ([Mishell and Sulak, 1997](#)). Finally, the legal liability appears to be less since the Food and Drug Administration now classifies the Cu T and Progestasert as drugs. As such, the manufacturers must provide product information to be read by patients prior to insertion. This, plus signed consent forms which include a reasonable listing of risks and benefits, should reduce legal liability ([Mishell and Sulak, 1997](#)).

TYPES OF INTRAUTERINE DEVICES. In general, devices are one of two varieties. Those that are **chemically inert** are composed of a nonabsorbable material, most often polyethylene, and impregnated with barium sulfate for radiopacity. In those that are **chemically active**, there is continuous elution of copper or a progestational agent. At the present time only chemically active [IUD⁸](#)s are available.

PROGESTASERT. This is a T-shaped ethylene vinyl acetate co-polymer with a vertical stem containing 38 mg of progesterone and barium sulfate in a silicone base. The progesterone source supplies approximately 65 ug/day into the uterine cavity for 1 year. This does not alter plasma progesterone values. The device is 36 mm long and 32 mm wide, and has a single dark blue to black string attached to the base of the stem ([Fig. 58-4](#)). For insertion, the withdrawal technique must be used ([Fig. 58-5](#)).

LEVONORGESTREL DEVICE (LNg⁹-IUD¹⁰). This device is similar to the Progestasert, but contains levonorgestrel. It is currently in use in Europe and being tested in the United States. Its major advantage is the need to replace it only once every 5 years, compared with yearly for the Progestasert. This device releases levonorgestrel into the uterus at a relatively constant rate of 20 ug/day, which markedly reduces the systemic effects of the progestin. It is a T-shaped polyethylene structure that has its stem wrapped with a cylinder of polydimethylsiloxane/levonorgestrel mixture. A permeable membrane surrounds the mixture to regulate the rate of hormone release.

COPPER T 380A. This device is composed of polyethylene and barium sulfate. The stem is wound with 314 mm² of fine copper wire, and the arms each have 33-mm² copper bracelets, thus totalling 380 mm² of copper. Two strings extend from the base of the stem ([Fig. 58-4](#)). Originally, the strings were blue, but they now are an off-white color. **This device should not be "loaded" into its inserter tube more than 5 minutes before it is inserted.** The malleable arms tend to retain the "memory" of the inserter.

MECHANISMS OF ACTION. These mechanisms have not been defined precisely. Interference with successful implantation of the fertilized ovum, which at one time was believed to be the mode of action, is the least important action ([Mishell and Sulak, 1997](#)). The intense local inflammatory response that is induced, especially by copper-containing devices, in turn leads to lysosomal activation and other inflammatory actions that are spermicidal ([Alvarez and associates, 1988](#); [Ortiz and Croxatto, 1987](#)). In the unlikely event that fertilization does occur, the same inflammatory actions are directed against the blastocyst. The report by [Lippes and co-workers \(1978\)](#) that insertion of a Cu T or Cu 7 device up to 7 days after coitus effectively prevented pregnancy strongly supports the concept that copper-bearing devices can also compromise the blastocyst. For the chemically inert devices, contraceptive effectiveness generally increases with increased size and extent of contact with endometrium.

Another possible mechanism includes accelerated tubal motility likely induced by the intrauterine inflammatory response. Also, the endometrium is an extremely hostile site for implantation even if fertilization and successful tubal transport have occurred. The endometrium is atrophic in long-time Progestasert users.

The action of these devices may very well be outside the uterus ([Sivin, 1989](#)). There may be a major effect in preventing fertilization by spermicidal action or speeding ovum transport through the fallopian tube, or both ([Alvarez and co-workers, 1988](#); [Ortiz and Croxatto, 1987](#)). Finally, progestin-containing devices may interfere with sperm penetration through thickened cervical mucus.

EFFECTIVENESS. Intrauterine devices have 1-year and long-term continuation rates second only to implantable contraceptives (p. 1520). One-year continuation rates are equal to those of oral contraceptives. This almost certainly is due to their effectiveness and a once-only approach to contraception.

The effectiveness of the devices is similar to overall effectiveness of oral contraceptives. Even so, the typical first-year failure rate with a Progestasert is double that with the Cu T 380A (2.0 versus 0.8 percent). The Cu T 380A is one of the most effective contraceptive means available. Importantly, the unintended pregnancy rate decreases progressively after the first year of use ([Vessey and associates, 1983a](#)). This must in part be due to true method failures and not user failures. The [LNg¹¹-IUD¹²](#) appears to be even more effective than the Cu T 380A ([Rowe, 1992](#)) with perfect and typical user failure rates of 0.1 percent.

BENEFICIAL EFFECTS. Progesterone and the newer levonorgestrel-containing devices reduce menstrual blood loss and can even be used to treat menorrhagia. Moreover, the reduced menstrual blood loss is often associated with a reduction in dysmenorrhea. Despite the initial high cost of the device and insertion, the overall extended use of the Cu T 380A and the [LNg¹³-IUD¹⁴](#) make them both very cost effective. Women with contraindications to combination oral contraceptives and Norplant can often use these devices. Even the LNg-IUD can be used because it releases very small amounts of localized hormone. The LNg-IUD also is reported to reduce the incidence of pelvic infections and to be useful in women with uterine fibroids ([Toivonen and associates, 1991](#); [van den Hurk and O'Brien, 1999](#)). With discontinuation, fertility is not impaired ([Sivin and colleagues, 1992](#)).

ADVERSE EFFECTS. Numerous complications have been described with use of various intrauterine devices. For the most part, however, common side effects have not been serious, and the serious side effects have not been common. Moreover, with progressive use and advancing user age, unintended pregnancy, expulsion, and bleeding complications decrease in frequency.

UTERINE PERFORATION AND ABORTION. The earliest adverse effects are those associated with insertion. They include clinically apparent or silent *uterine perforation*, either while sounding the uterus or during insertion of the device, and *abortion of an unsuspected pregnancy*. The frequency of these complications depends on operator skill and the precautions taken to avoid interrupting a pregnancy. The incidence of perforations with the Cu T 380A is 0.6 per 1000 insertions, and for the Progestasert the incidence is 1.1 per 1000 insertions ([World Health Organization, 1987](#)). Although devices may migrate spontaneously into and through the uterine wall, most perforations occur, or at least begin, at the time of insertion.

UTERINE CRAMPING AND BLEEDING. Uterine *cramping* and some *bleeding* are likely to develop soon after insertion, and they persist for variable periods. Cramping can be minimized by administering a nonsteroidal anti-inflammatory agent approximately 1 hour prior to insertion. The occasional increase in cramping with menses also can be controlled in a similar manner.

MENORRHAGIA. Blood loss with menstruation is commonly doubled with the use of the Cu T 380A, and it may be so great as to cause iron-deficiency anemia. Most providers measure hemoglobin or hematocrit annually in women with IUD¹⁵s as well as any time they complain of heavy menstruation. This is a troubling side effect, and approximately 10 to 15 percent of women using the copper device have it removed for this problem ([Hatcher and associates, 1998](#)).

Progestasert, because of its localized progesterone action, is associated with a low incidence of menorrhagia and anemia. For example, normal menstruation results in blood loss of about 35 mL. Mean blood loss with most copper-containing devices is approximately 50 to 60 mL per cycle, but can be more ([Guillebaud and colleagues, 1979](#)). Mean blood loss with the Progestasert is about 25 mL per cycle. Blood loss with the LNG¹⁶-IUD¹⁷ may be even less than with the Progestasert.

INFECTION. Pelvic infections, including septic abortion, have developed with a variety of intrauterine devices. *Tubo-ovarian abscesses*, which may be unilateral, have been described. With suspected infection, the device should be removed, and the woman treated with effective antibiotics. Deaths from sepsis have been reported with these devices. Because of the risk of severe pelvic infections with sterility, IUD¹⁸ use is usually discouraged for women under the age of 25 or those of low parity. According to [Vessey and associates \(1983a\)](#), there is not prolonged impairment of fertility after removing the devices from parous women.

[Daling \(1985\)](#) and [Cramer \(1985\)](#) and their associates reported that IUD¹⁹s are associated with increased infertility due to tubal factors. These effects were negligible with copper-bearing devices, but more apparent in nulliparous women, especially if they had multiple sexual partners and used the now-discontinued Dalkon shield. Interestingly, [Lee and Rubin \(1988\)](#) reported that married women and those with only one sexual partner had no higher risk of developing pelvic infection than controls **after** the first 4 months of use.

Following insertion of an IUD²⁰, bacteria can be recovered from the uterine cavity for several days, but at appreciably lower rates after the first 24 hours ([Mishell and colleagues, 1966](#)). There is a small increased risk of pelvic infection for up to the first 20 days following insertion ([Farley and associates, 1992](#)). There currently is no consensus whether antibiotic administration at the time of insertion reduces the incidence of postinsertion infections ([Ladipo, 1991](#); [Sinei, 1990](#); [Walsh, 1998](#), and their associates). Thus, the major risk of infection is due to insertion and does not increase with long-term use. In fact, long-term use of copper- and hormonal-containing devices results in pelvic infection rates comparable to those of oral contraceptive users. Any infection after 45 to 60 days should be considered sexually transmitted and appropriately treated ([Lee and associates, 1983](#)). The newer copper- and progestin-releasing devices also may reduce the incidence of pelvic infection ([Toivonen and co-workers, 1991](#)).

Women with intrauterine devices may be at greater risk for HIV²¹ infection than women using other forms of contraception ([Musicco and associates, 1996](#)). IUD²²s should not be used in HIV-positive women ([Hatcher and colleagues, 1998](#)).

Actinomyces-like structures identified in Papanicolaou smears and the prolonged use of an IUD²³ have been linked. In his scholarly review, [Fiorino \(1996\)](#) cited an incidence of 7 percent of *Actinomyces* seen on cytology smears in women with these devices, compared with less than 1 percent of nonusers. The clinical importance of this finding is not clear, but it is worrisome. In most studies, an increased prevalence of *Actinomyces israelii* or actinomyces-like organisms was apparent only after several years of use. Moreover, women who developed a pelvic abscess caused by this organism had used the device for a mean of 8 years before symptoms developed. [Keebler and co-workers \(1983\)](#) showed that once the smear became positive for actinomyces, all subsequent smears remained positive until the device was removed.

In the absence of symptoms, the incidental finding of actinomyces by cytology is problematic. Penicillin therapy is not effective; therefore, some clinicians chose to remove the device, although there is no evidence that this will prevent infection ([Fiorino, 1996](#)). Most agree, however, that if signs or symptoms of infection develop in women who harbor actinomyces, the device should be removed and antibiotic therapy instituted.

PREGNANCY WITH A DEVICE IN UTERO. As emphasized in [Chapter 10 \(p. 227\)](#), it is important to identify all pregnant women who might be using an IUD²⁴. A device within the pregnant uterus may be dangerous for the woman and her fetus. A device residing beyond the uterus may be dangerous for the woman. Appropriate steps should be taken at delivery to identify and ensure removal of the device.

When pregnancy is recognized and the tail of the device is visible through the cervix, it should be removed. This will help reduce subsequent complications such as late abortion, sepsis, and preterm birth. [Tatum and co-workers \(1976\)](#) observed the abortion rate to be 54 percent with the device left in situ compared with 25 percent if promptly removed. Moreover, with the device remaining in situ, the frequency of low birthweight, chiefly from preterm delivery, was 20 percent, compared with about 5 percent if the device was removed early. [Vessey and associates \(1979\)](#) confirmed these observations. If the tail is not visible, attempts to locate and remove the device may result in abortion. Some practitioners have successfully used sonographically assisted removal of devices without visible strings.

Second-trimester abortion with an IUD²⁵ in place is more likely to be septic ([Lewit, 1970](#); [Vessey and associates, 1974](#)). Sepsis is at times fulminant and often fatal, and because of these risks, the woman should be offered the option of pregnancy termination ([American College of Obstetricians and Gynecologists, 1992](#)). Women pregnant with a device in utero who demonstrate any evidence of uterine infection must have intensive antibiotic therapy and prompt uterine evacuation.

Fetal malformations have not been reported to be increased with pregnancies complicated by the presence of any intrauterine device.

ECTOPIC PREGNANCIES. Although most intrauterine pregnancies are prevented, the device provides less protection against extrauterine nidation. With a contraceptive failure, the risk for an ectopic pregnancy increases significantly and may be increased even more in women using Progestasert ([Chap. 34, p. 884](#)). Because the device does not prevent extrauterine pregnancy reliably, women already at high risk for an ectopic pregnancy—those with previous salpingitis, ectopic pregnancy, or tubal surgery—are poor candidates for an IUD²⁶.

CONTRAINDICATIONS. Contraindications to the use of the Cu T 380A and Progestasert are listed in [Table 58-11](#).

PROCEDURES FOR INSERTION. The Food and Drug Administration requires that before an intrauterine device is inserted, the woman must be given a brochure detailing the side effects and apparent risks from its use. Most devices have a special inserter, usually a sterile graduated plastic tube into which the device is withdrawn just before insertion ([Fig. 58-5](#)). Timing of insertion influences the ease of placement as well as the pregnancy and expulsion rates. Insertion near the end of normal menstruation, when the cervix is usually softer and the canal somewhat more dilated, may facilitate insertion and at the same time exclude early pregnancy. Insertion, however, need not be limited to this time. For the woman who is sure she is not pregnant and does not want to be pregnant, insertion may be carried out anytime during the ovulation cycle.

Insertion at the time of delivery or very soon thereafter is followed by an unsatisfactorily high expulsion rate. The recommendation has been made, therefore, to withhold insertion for at least 8 weeks to reduce expulsion as well as to minimize the risk of perforation. In our extensive experiences, however, earlier insertion has not led to perforation or expulsion rates significantly higher than for insertion remote from pregnancy. In the absence of infection, the device may be inserted immediately after early abortion.

A satisfactory technique for insertion and a plan for follow-up is as follows:

1. Determine if there are contraindications, counsel the woman regarding various problems associated with device use, and obtain consent.
2. Administer preinsertion aspirin or codeine to allay cramps.
3. Perform a pelvic examination to identify the position and size of the uterus and adnexa. If abnormalities are found, a device is often contraindicated.
4. Visualize the cervix and grasp it with a tenaculum. Use sterile instruments and a sterile intrauterine device. Wipe the cervix and the vaginal walls with an antiseptic solution. The cervical canal and uterine cavity are first straightened by applying gentle traction on the tenaculum, and the uterus is sounded to identify the direction and depth of the uterine cavity. The movable flange on the barrel of the inserter should be adjusted to the depth to which the device should be inserted. As shown in [Figure 58-5](#), the inserter, with the device contained within its most distal portion, is then gently inserted to the fundus. After rotating the inserter so that the device is positioned high in the transverse plane of the uterus, the inserter is removed while the device is held in the fundus by the plastic rod within the inserter. **Thus, the device is not pushed out of the tube, but rather it is held in place by the rod while the inserter tube is withdrawn.**
5. Cut the marker tail 2 cm from the external os, remove the tenaculum, observe for bleeding from the tenaculum puncture sites, and if there is no bleeding, remove

the speculum.

6. Advise the woman to report promptly any apparent adverse effects.

EXPULSION. Loss of the device from the uterus is most common during the first month after insertion. The woman should be instructed to palpate the strings protruding from the cervix by either sitting on the edge of a chair or squatting down and then advancing the middle finger into the vagina until the cervix is reached. The woman should be checked in 1 month, usually after menses, for appropriate placement by identifying the tail protruding from the cervix. Barrier contraception may be desirable during this time, especially if a device has been expelled previously.

LOCATING A LOST DEVICE. When the tail of a device cannot be visualized, the device may have been expelled, or it may have perforated the uterus. In either event, pregnancy is possible. Conversely, the tail simply may be in the uterine cavity along with a normally positioned device. Often, gentle probing of the uterine cavity with a Randall stone clamp or a rod with a terminal hook will retrieve the string. **Never assume that the device has been expelled unless it was seen.**

When the tail is not visible and the device is not felt by gentle probing of the uterine cavity, sonography is done to ascertain if the device is within the uterine cavity. If these findings are negative or inconclusive, then a plain x-ray of the abdomen and pelvis is taken with a sound inserted into the uterine cavity. Instillation of radiocontrast for hystero-graphy may be done, and hysteroscopy is yet another alternative. Obviously none of these maneuvers except sonography should be performed during early pregnancy.

An open device of inert material, such as the Lippes Loop, located outside the uterus may or may not do harm. Perforations of large and small bowel and bowel fistulas, with attendant morbidity, have been reported remote from the time of insertion. An extrauterine copper-bearing device induces an intense local inflammatory reaction and adherence to the inflamed structure. Chemically inert devices usually are removed easily from the peritoneal cavity by laparoscopy or posterior colpotomy. Copper-bearing devices are more firmly adherent and laparotomy may be necessary.

A device may penetrate the uterine wall in varying degrees. At times, part of the device may extend into the peritoneal cavity while the remainder is firmly fixed in the myometrium. Devices also can penetrate into the cervix and actually protrude into the vagina.

REPLACEMENT. Chemically inert devices may be left in the uterus indefinitely. In some cases, the polyethylene compound becomes encrusted with calcium salts, and endometrial erosion causes bleeding that prompts replacement. Copper-bearing devices have to be replaced periodically. The Copper T 380 A is approved for 10 years of continuous use. The Progestasert device should be replaced annually, and the [LNg²⁷-IUD²⁸](#) has been used effectively for 5 years.

BARRIER METHODS

For many years, condoms, vaginal spermicidal agents, and vaginal diaphragms have been used for contraception with variable success ([Table 58-2](#)).

MALE CONDOM. These products provide effective contraception, and their failure rate with experienced and strongly motivated couples has been as low as 3 or 4 per 100 couple-years of exposure ([Vessey and co-workers, 1982](#)). Generally, and during the first year of use especially, the failure rate is much higher ([Table 58-2](#)). [Trussell and colleagues \(1990\)](#) also reported that women older than 30 years of age had fewer unintended pregnancies than those younger than 25.

When used properly, condoms provide considerable but not absolute protection against a broad range of sexually transmitted diseases, including [HIV²⁹](#) infection, gonorrhea, syphilis, herpes, chlamydia, and trichomoniasis. They also possibly prevent and ameliorate premalignant changes in the cervix ([Population Reports, 1982](#)). Because the Centers for Disease Control and Prevention recommend condoms for couples at risk for HIV infection, including those with multiple sex partners, their use has escalated exponentially since the mid-1980s.

The contraceptive effectiveness of the male condom is enhanced appreciably by the use of a condom with a reservoir tip and with spermicidal lubricant added to the condom. The contraceptive and antibacterial and antiviral effectiveness is improved even more with the addition of an intravaginal spermicidal agent. Such vaginal agents as well as those used only for lubrication should be water-based products. Oil-based products will destroy latex condoms and diaphragms ([Waldron, 1989](#)).

LATEX SENSITIVITY. Some individuals are extremely sensitive to latex. Because latex provides protection against sexually transmitted diseases, and natural membrane condoms do not, this created a dilemma until recently. A nonallergenic condom has been developed of synthetic thermoplastic elastomer usually used in surgical gloves ([Mason, 1992](#)). A polyurethane condom is also currently available in the United States ([Table 58-12](#)). Both products are effective against sexually transmitted diseases, including [HIV³⁰](#) ([Waldron, 1991](#)). Unfortunately, the polyurethane condom has a significantly higher breakage rate than latex condoms, 7.2 and 1.1 percent, respectively ([Frezieres and colleagues, 1998](#)).

FEMALE CONDOM (VAGINAL POUCH). The Food and Drug Administration refers to female condoms as vaginal pouches. Before approval for marketing, a vaginal pouch must be proven to prevent pregnancy and sexually transmitted diseases, including [HIV³¹](#). Only one device is available, and it is marketed as the *Reality* condom. It is a polyurethane sheath with one flexible polyurethane ring at each end. The open ring remains outside the vagina, and the closed internal ring is fitted under the symphysis like a diaphragm ([Fig. 58-6](#)). In vitro tests have shown the female condom to be impermeable to human immunodeficiency virus, cytomegalovirus, and hepatitis B virus. It has a 0.6 percent breakage rate. The slippage and displacement rate is about 3 percent compared with an 8 percent rate for male condoms. Overall, acceptability has been about 60 percent for women and 80 percent for men. Unfortunately, the pregnancy rate is higher than with the male condom ([Table 58-2](#)).

SPERMICIDAL CONTRACEPTIVES. These contraceptives are marketed variously as creams, jellies, suppositories, film, and foam in aerosol containers ([Fig. 58-7](#)). They are used widely in this country, especially by women who find oral contraceptives or an [IUD³²](#) unacceptable. They are useful especially for women who need temporary protection, for example, during the first week after starting oral contraceptives or while nursing.

Most agents can be purchased without a prescription. Typically, they work by providing a physical barrier to sperm penetration as well as a chemical spermicidal action. The active spermicidal ingredient is nonoxynol-9 or octoxynol-9. **To be highly effective, the spermicides must be deposited high in the vagina in contact with the cervix shortly before intercourse.** Their duration of maximal spermicidal effectiveness is usually no more than 1 hour. Thereafter they must be reinserted before repeat intercourse. Douching should be avoided for at least 6 hours after intercourse.

High pregnancy rates are primarily attributable to inconsistent use rather than to method failure. If inserted regularly and correctly, foam preparations probably result in 5 to 12 pregnancies per 100 woman-years of use ([Trussell and associates, 1990](#)). Spermicides in current use appear to provide at least partial protection against some sexually transmitted diseases, including gonorrhea and probably papillomavirus and [HIV³³](#) ([Feldblum and Fortney, 1988](#)).

LEGAL DIFFICULTIES. Although a preliminary study suggested that vaginal spermicides might be associated with an increased frequency of fetal malformations, well-designed studies by [Mills and co-workers \(1982\)](#) and [Shapiro and associates \(1982\)](#) found no such association. In fact, the [Food and Drug Administration \(1986\)](#) concluded that evidence *did not* support an association between spermicide use and congenital malformations. Despite this scientific evidence, a court decision in *Wells v Ortho Pharmaceutical* was rendered in favor of the plaintiff in a suit alleging that congenital malformations were caused by maternal spermicide exposure. The decision was upheld by an appellate court. Subsequently, [Louik and colleagues \(1987\)](#) reported results from their case-controlled surveillance system and found no association with spermicide use and Down syndrome, hypospadias, limb-reduction defects, neoplasms, or neural-tube defects. [Strobino and colleagues \(1988\)](#) also did not identify increased congenital malformations in a cohort study. Thus, evidence indicates that spermicide use is not teratogenic ([Briggs and colleagues, 1998](#)).

DIAPHRAGM PLUS SPERMICIDE. The vaginal diaphragm, consisting of circular rubber dome of various diameters supported by a circumferentially placed metal spring, can be very effective when used in combination with spermicidal jelly or cream. The spermicide is applied to the superior surface both along the rim and centrally. The device is then placed in the vagina so that the cervix, vaginal fornices, and anterior vaginal wall are partitioned effectively from the remainder of the vagina and the penis. At the same time, the centrally placed spermicidal agent is held against the cervix by the diaphragm. When appropriately positioned, the rim is lodged superiorly deep in the posterior vaginal fornix, and inferiorly the rim lies in close proximity to the inner surface of the symphysis immediately below the urethra ([Fig. 58-8](#)). If the diaphragm is too small, it will not remain in place. If too large, it will be uncomfortable when it is forced into position. A cystocele or uterine prolapse is very likely to result in instability and therefore expulsion. Because the variables of size and spring flexibility must be specified, the diaphragm is available only by prescription.

The diaphragm and spermicidal agent can be inserted hours before intercourse, but if more than 2 hours elapse, additional spermicide should be placed in the upper

vagina for maximum protection and be reapplied before each coital episode. The diaphragm should not be removed for at least 6 hours after intercourse. Because toxic shock syndrome has been described following its use, it may be worthwhile to remove the diaphragm at the end of 6 hours, or at least the next morning, to minimize this uncommon event ([Alcid and associates, 1982](#)).

The diaphragm requires a high level of motivation for proper use that, when expended, is accompanied by a low pregnancy rate. [Vessey and colleagues \(1982\)](#) reported a pregnancy rate of only 1.9 to 2.4 per 100 woman-years for established users. [Bounds and associates \(1995\)](#), in a small study, reported a much higher failure rate of 12.3 per 100 women-years. The unintended pregnancy rate is lower in women past 35 than in those younger than 30. Finally, diaphragm use results in a decreased incidence in sexually transmitted diseases compared with condom use ([Rosenberg and colleagues, 1992](#)). There is a slight but real increase in urinary infections associated with diaphragm use ([Hatcher and associates, 1998](#)).

CONTRACEPTIVE SPONGE. This device is no longer marketed.

CERVICAL CAP. The *Prentif* cavity-rim cervical cap was approved for use by the [Food and Drug Administration in 1988](#). The flexible, cuplike device, made of natural rubber, is fitted around the base of the cervix. It can be self-inserted and allowed to remain in place for no more than 48 hours. It should be used with a spermicide applied once at insertion. According to trials conducted by the National Institutes of Health, the cap is comparable in effectiveness to the diaphragm. Unfortunately, the cost is high, and the fitting is critical for the device to be successful. Moreover, user misplacement of the cap makes it a less effective method overall than the diaphragm and a spermicidal agent.

PERIODIC (RHYTHMIC) ABSTINENCE

Ideally, sexual abstinence during and around the time of ovulation should prevent pregnancy; unfortunately, this is not always the case. For example, pregnancy rates with various methods of periodic abstinence—rhythm, natural family planning, or fertility awareness methods—have been estimated from 5 to 40 per 100 woman-years ([Population Reports, 1981](#)). In other words, this is an unwanted pregnancy rate of 25 percent during the first year of use ([Table 58-2](#)).

The human ovum is probably susceptible to successful fertilization for only about 12 to 24 hours after ovulation. Motile sperm, however, have been identified in cervical mucus as many as 7 days after coitus or artificial insemination, and in oviducts of women undergoing laparotomy as long as 85 hours after coitus ([Ahlgren, 1975](#)). It is unlikely, however, that sperm retain the capability for successful fertilization for this long a period.

CALENDAR RHYTHM METHOD. Ovulation most often occurs about 14 days before the onset of the next menstrual period, but unfortunately, not necessarily 14 days after the onset of the last menstrual period. Therefore, the *calendar rhythm method* is not reliable. In 1982, the International Planned Parenthood Federation concluded that "couples electing to use periodic abstinence should, however, be clearly informed that the method is not considered an effective method of family planning."

TEMPERATURE RHYTHM METHOD. The temperature rhythm method relies on *slight* changes—sustained 0.4 degree Fahrenheit increase—in the morning basal body temperature that usually occur just before ovulation. This method is much more likely to be successful if, during each menstrual cycle, intercourse is avoided until well after the ovulatory temperature rise. For this method to be most effective, the woman must abstain from intercourse from the first day of menses through the third day after the increase in temperature. For obvious reasons, this is not a popular method of contraception! With excellent compliance, however, unwanted pregnancies occur at about 2 percent during the first year of use ([Table 58-2](#)).

CERVICAL MUCUS RHYTHM METHOD. The *cervical mucus rhythm method*, or so-called *Billings method*, depends on awareness of vaginal "dryness" and "wetness" as the consequence of changes in the amount and kind of cervical mucus formed at different times in the menstrual cycle. Abstinence is required from the beginning of menses until 4 days after slippery mucus is identified. This method has not achieved popularity. A small, hand-held device that detects small variations in electrolyte concentrations in vaginal or oral secretions is also claimed to be capable of predicting ovulation 5 to 7 days in advance. [Roumen and Dieben \(1988\)](#) found that this device was not accurate in predicting the day of ovulation. When the cervical mucus method is used accurately, the first year failure rate is approximately 3 percent ([Table 58-2](#)).

SYMPTOTHERMAL METHOD. The symptothermal method combines the use of changes in cervical mucus (onset of fertile period), changes in basal body temperature (end of fertile period), and calculations to estimate the time of ovulation. This is a more complex system to learn and apply, and it does not appreciably improve reliability ([Table 58-2](#)). The use of home kits to detect luteal hormone increases which appear in the urine on the day prior to ovulation may improve the accuracy of periodic abstinence methods ([Hatcher and associates, 1998](#)).

For the interested reader, the December 1991 supplement to the *American Journal of Obstetrics and Gynecology* was devoted to the subject of natural family planning. It included 27 papers on this subject, as well as a final discussion and recommendations ([Queenan and associates, 1991](#)).

CONTRACEPTIVE CHOICES FOR ADOLESCENTS

A discussion of the biological antecedents of teenage pregnancy has been presented in [Chapter 4](#). Briefly stated, menarche has decreased from approximately age 17 in the mid-1800s to near 12 years of age in the year 2001. Unfortunately, this means that reproductive function is established sooner than the psychological understanding of the consequences of sexual activity. This far too often results in intermittent spontaneous sexual encounters and unrealistic perception of the risks for pregnancy and sexually transmitted diseases ([Cromer and associates, 1996](#); [Sulak and Haney, 1993](#)). Contraception is most often sought more than a year after sexual activity has begun ([Mosher and McNally, 1991](#)).

COMBINED ORAL CONTRACEPTIVES. As a method, these agents are the best choice for this age group because they provide effective contraception, increased bone density, and can be used to improve acne and regulate irregular menses. The obvious disadvantage is the daily requirement of taking a pill.

LONG-ACTING METHODS OF CONTRACEPTION. The **Norplant System** is an obvious choice because it provides effective contraception for 5 years with a "use and forget" system. The implants do not result in bone loss at a critical time when bone mass should be increasing ([Sulak and Kaunitz, 1999](#)). The disadvantages for an adolescent woman include menstrual irregularities and an insertion site inside the upper arm.

Injectable depot medroxyprogesterone is an effective contraceptive that also may be considered a "use and forget" method for 3 months. The disadvantages include the injections every 3 months, menstrual irregularities, and loss of bone mass ([Sulak and Kaunitz, 1999](#)).

The newly approved injectable medroxyprogesterone acetate plus estradiol cypionate also provides an effective contraception with better control of menses and, **it is hoped**, little or no bone mass loss. This compound, however, is not a true "use and forget" method because monthly injections are required.

Barrier techniques despite their obvious advantage of providing some protection against sexually transmitted diseases are not good choices for adolescents. These methods obviously require preplanning and motivation for their proper use. Such methods, especially vaginal spermicides and male condoms, should be considered primarily as backup contraceptives and protective methods directed against sexually transmitted diseases.

CONTRACEPTIVE CHOICES FOR WOMEN PAST 35

Although fertility decreases beginning at age 35 to 40 years, these women are still at risk for unwanted pregnancy and for sexually transmitted diseases. [Henshaw \(1998\)](#) reported that half of all pregnancies in women in their 40s are unintended, and that 65 percent of this half are terminated.

COMBINED ORAL CONTRACEPTIVES. These agents, especially the newer, low-dose estrogen compounds, when used by nonsmokers without systemic disease, are highly effective, well tolerated, provide many health benefits, and are associated with minimal risk ([Beck, 1995](#); [Speroff and Sulak, 1995](#)). As discussed, these agents can be used until the menopause.

INJECTABLE DEPOT MEDROXYPROGESTERONE. This is a highly effective hormonal contraceptive, and it can also be used by some women who cannot for medical reasons take combination oral contraceptives ([Speroff and Sulak, 1995](#)).

INJECTABLE MEDROXYPROGESTERONE PLUS ESTRADIOL CYPIONATE. This product at first glance appears to be an excellent product for women in this age group except for the requirement of monthly injections. It may prove to be superior to implants and depot medroxyprogesterone injections if abnormal bleeding is less

troublesome. Certainly, abnormal uterine bleeding in older women might be the result of a genital malignancy ([Sulak and Haney, 1993](#)).

PROGESTIN IMPLANTS (NORPLANT SYSTEM). These are exceedingly effective, well tolerated, and should be considered for women past 35 ([Speroff and Sulak, 1995](#)). The only apparent disadvantage for use in older women is the possible adverse effects of levonorgestrel on glucose tolerance and lipoproteins.

INTRAUTERINE DEVICES. This method is a logical choice for an older woman who has completed her family and is in a monogamous relationship.

BARRIER TECHNIQUES AND SPERMICIDAL AGENTS. These methods can be used either as primary or backup contraception. Their effectiveness improves with advancing age after 40, likely because fertility also decreases appreciably after age 40. This method also provides additional protection against sexually transmitted diseases ([Speroff and Sulak, 1995](#); [Sulak, 1996](#)).

POSTCOITAL CONTRACEPTION

ESTROGENS AND PROGESTINS. The first *morning-after pill* was stilbestrol which, according to [Kuchara \(1971\)](#), prevented pregnancies in 1000 women who had inadequate contraception at the time of intercourse. Stilbestrol is no longer recommended, but pregnancy prevention is reported with other hormonal regimens as well as with insertion of copper-containing IUD³⁴s. A number of oral contraceptive regimens—known as the *Yuzpe method*—were approved in 1997 by the Food and Drug Administration for use as postcoital emergency contraception ([Table 58-13](#)). This was followed in 1998 by FDA approval of the first emergency contraceptive kit. The *Preven Emergency Contraceptive Kit* contains a pregnancy test and four oral contraceptive tablets each containing 50 ug of ethinyl estradiol and 0.25 mg of levonorgestrel. Two tablets are taken within 72 hours of intercourse followed 12 hours later by the second dose. Best results are obtained if the steroidal agents are taken within 72 hours of intercourse. All oral hormone regimens shown in [Table 58-13](#) follow the same dosage schedule.

Access to emergency contraception is not universal. [Trussell and colleagues \(2000\)](#) found that only 75 percent of attempts to access care through the Emergency Contraception Hotline were successful. Physicians can register to be included as a resource and patients can call for referrals on the Hotline at 1-888-NOT-2-LATE (888.668.2528). The Emergency Contraception Website is [not-2-late.com](#).

MECHANISM OF ACTION. The major mechanism is inhibition or delay of ovulation ([Food and Drug Administration, 1997](#)). Other mechanisms include alteration of the endometrium, sperm penetration, and tubal motility. **Established pregnancies are not harmed.**

Combined estrogen and progestin regimens are highly effective and have been reported to decrease the risk of pregnancy by 75 percent ([Trussell and associates, 1996, 1998b](#)). Thus, if 100 women had unprotected intercourse during the second to third week of their menstrual cycle, eight would be expected to conceive. With appropriate use of one of the regimens shown in [Table 58-13](#), only two would actually conceive.

Due to the estrogen in these compounds, nausea and vomiting remain major problems. [Trussell and associates \(1998a\)](#) reported nausea in 50 percent of women and vomiting in 20 percent. For this reason, we routinely prescribed an oral antiemetic at least 1 hour before each dose. [Raymond and colleagues \(2000\)](#) conducted a randomized trial and found that 1-hour pretreatment with 50-mg meclizine given orally decreased nausea from 64 to 47 percent compared with placebo. If vomiting occurs within 2 hours of a dose, the dose must be repeated.

PROGESTINS ONLY. The use of progestin-only pills results in markedly less nausea and vomiting. According to the [Task Force on Postovulatory Methods of Fertility Regulation \(1998\)](#), progestins are more effective than combination estrogen and progestin pills.

OVRETTE METHOD. The use of this agent, consisting of 20 pills within 72 hours of unprotected intercourse followed in 12 hours by a second dose of 20 pills, has proven to be effective and is less likely to cause nausea and vomiting. Each dose of 20 pills contains 0.75 mg of levonorgestrel.

PLAN B METHOD. In 1998, the Food and Drug Administration approved a new progestin-only regimen, marketed as Plan B, which consists of two tablets each containing 0.75-mg levonorgestrel ([American College of Obstetricians and Gynecologists, 1999a](#)). The first dose is taken within 72 hours of unprotected coitus and the second dose 12 hours later. This new regimen resulted in a crude pregnancy rate of 1.1 percent versus 3.2 percent in a similar group of women treated with the Yuzpe regimen.

COPPER-CONTAINING INTRAUTERINE DEVICES. [Fasoli and co-workers \(1989\)](#) summarized nine studies that included results from 879 women who accepted some type of copper-containing IUD³⁵ as a sole method of postcoital contraception. Only one pregnancy was reported, and it aborted spontaneously. More recently, [Trussell and Stewart \(1998\)](#) reported that when the IUD was inserted up to 5 days after unprotected coitus, the failure rate was 1 percent. A secondary advantage is that an effective 10-year method of contraception is already in place.

MIFEPRISTONE (RU 486) AND EPOSTANE. These methods are discussed in [Chapter 33 \(p. 874\)](#). They should be ideal for postcoital contraception by their action to block progesterone production (epostane) or its action (mifepristone). Implantation would be prevented by either mechanism to produce so-called *menstrual induction*. [Glazier and colleagues \(1991, 1992\)](#) reported that a single, 600-mg oral dose of mifepristone prevented pregnancy in 402 women at risk compared with four pregnancies in 398 women given two doses of 100 ug of ethinyl estradiol and 1 mg of norgestrel 12 hours apart.

Progestin and combination estrogen and progestin agents must be used within 72 hours of unprotected intercourse to be effective. A single, 600-mg dose of mifepristone is effective up to 17 days after intercourse ([Weiss, 1993](#)). [Grimes and Cook \(1992\)](#) propose that mifepristone for postcoital contraception will lower the induced abortion rate.

METHOTREXATE AND MISOPROSTOL. [Hausknecht \(1995\)](#) reported that intramuscular methotrexate, 50 mg/m², plus vaginally administered misoprostol, 800 mg, 5 to 7 days later, was highly effective in inducing abortion up to 63 days menstrual age. The methotrexate dose is the same used to treat ectopic pregnancies; misoprostol is commonly used for cervical ripening and induction ([Chap. 20, p. 472](#)). Of the 178 women enrolled in the study, 96 percent had a successful medical abortion. If postcoital contraception fails, this regimen is a logical next choice if an abortion is chosen.

FAILURE OF POSTCOITAL CONTRACEPTION. Any postcoital contraceptive method is associated with failures. This can likely be reduced by employing a barrier technique until the next menses to prevent fertilization after use of the postcoital method. It must be remembered that estrogen administration prior to ovulation may induce ovulation. Finally, if menses are delayed for more than 3 weeks past their expected onset, pregnancy is likely.

CONTRACEPTIVE CHOICES FOR WOMEN WITH MEDICAL CONDITIONS

Pregnancies in women with medical complications often result in dangers that far exceed those seen with most forms of contraception. The choice of the most effective and safest method of contraception, however, is dependent on the physician's understanding of the basic pathophysiology of the disease and how this is modified by pregnancy. Only with such knowledge can the appropriate contraceptive or recommendation for sterilization be made. For these reasons, such recommendations are made throughout this book as individual diseases are discussed.

LACTATION

Breast feeding is important to infant health and to child-spacing. For mothers who are nursing, ovulation during the first 10 weeks after delivery is unlikely ([Perez, 1981](#)). Nursing is not a reliable method of family planning, however, for women whose infants are on a 3- to 4-hour, daytime-only feeding schedule and are receiving other food. **Waiting for first menses involves a risk of pregnancy because ovulation may antedate menstruation.** Certainly, after the first menses, contraception is essential unless the woman desires another pregnancy. Estrogen-progestin contraceptives may reduce both the rate and the duration of milk production. The benefits from prevention of pregnancy by the use of combined oral contraceptives would appear to outweigh the risks in selected patients, but progestin-only oral contraceptives appear to be the best choice in most cases (p. 1531). In a retrospective cohort study, [Kjos and colleagues \(1998\)](#) reported that for women with gestational diabetes, use of a progestin-only oral contraceptive increased the risk of insulin-dependent diabetes threefold.

Intrauterine devices have been recommended for the lactating, but potentially ovulating, sexually active woman. An increased rate of uterine perforation has been identified in lactating women with an IUD³⁶, perhaps as the consequence of vigorous myometrial contractions and involution brought about by the release of oxytocin in response to suckling ([Heartwell and Schlesselman, 1983](#)). The risk is not so great, however, that intrauterine devices should not be used.

TABLE 58-1. Voluntary Risks in Perspective.

Activity	Chance of Death (per Year)
Risks for Men and Women of All Ages	
Motorcycling	1 in 1000
Automobile driving	1 in 5900
Power boating	1 in 5900
Playing football	1 in 25,000
Canoeing	1 in 100,000
Risks for Women Aged 15-44 Years	
Using tampons	1 in 350,000
Having sexual intercourse (PID)	1 in 50,000
Risks for Women Preventing Pregnancy	
Using oral contraceptives	
Nonsmoker	1 in 67,000
Age < 35	1 in 200,000
Age 35-44	1 in 29,000
Heavy smoker (25 or more cigarettes per day)	1 in 1700
Age < 35	1 in 5300
Age 35-44	1 in 700
Using IUDs (per year)	1 in 10 million
Using diaphragm, condom, or spermicides	None
Using fertility awareness methods	None
Undergoing sterilization:	
Laparoscopic tubal ligation	1 in 38,500
Hysterectomy	1 in 1,600
Vasectomy	1 in 1,000,000
Risk per Pregnancy from Continuing Pregnancy	1 in 10,000
Risk from Terminating Pregnancy	
Legal abortion	
Before 9 weeks	1 in 263,000
Between 9-12 weeks	1 in 100,000
Between 13-15 weeks	1 in 35,000
After 15 weeks	1 in 10,000

IUDs = intrauterine devices; PID = pelvic inflammatory disease.

TABLE 58-2. Failure and Continuation Rates at 1 Year for Various Methods of Birth Control.

Method	Percent of Women with Accidental Pregnancy within the First Year		Percent of Women Continuing Use at 1 Year ^c
	Typical Use ^a	Perfect Use ^b	
Chance ^d	85	85	
Spermicides ^e	26	6	40
Periodic abstinence	25		63
Calendar		9	
Ovulation method		3	
Symptothermal ^f		2	
Postovulation		1	
Cervical cap ^g			
Parous women	40	26	42
Nulliparous women	20	9	56
Diaphragm ^g	20	6	56
Withdrawal	19	4	
Condom ^h			
Female (Reality)	21	5	56
Male	14	3	61
Pill	5		71
Progestin only		0.5	
Combined		0.1	
Emergency contraception	Reduces risk by at least 75 percent ⁱ		
Intrauterine device (IUD)			
Progestasert	2.0	1.5	81
Copper T 380A	0.8	0.6	78
Depo-Provera	0.3	0.3	70
Norplant and Norplant-II	0.05	0.05	88
Lactation	Highly effective, temporary ^j		
Female sterilization	0.4	0.4	100
Male sterilization	0.15	0.10	100

^a Among typical couples who initiate use of a method (not necessarily for the first time), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason.

^b Among couples who initiate use of a method (not necessarily for the first time) and who use it *perfectly* (both consistently and correctly), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason.

^c Among couples attempting to avoid pregnancy, the percentage who continue to use a method for 1 year.

^d The percentages becoming pregnant in the typical use and perfect use columns are based on data from populations where contraception is not used and from women who cease using contraception in order to become pregnant. Among such populations, about 89% become pregnant within 1 year. This estimate was lowered slightly (to 85%) to represent the percentage who would become pregnant within 1 year among women now relying on reversible methods of contraception if they abandoned contraception altogether.

^e Foams, creams, gels, vaginal suppositories, and vaginal film.

^f Cervical mucus (ovulation) method supplemented by calendar in the preovulatory and basal body temperature in the postovulatory phases.

^g With spermicidal cream or jelly.

^h Without spermicides.

ⁱ For treatment schedules, see Table 58-13.

^j To maintain effective protection against pregnancy, another method of contraception must be used as soon as menstruation resumes, the frequency or duration of breast feeding is reduced, bottle feeding is introduced, or the baby reaches 6 months of age.

Modified with permission from Hatcher and colleagues (1998).

	Ortho-Cept, Desogen	30	Desogestrel 0.15	
	Mircette ^b	20	Desogestrel 0.15	
Triphasic	Ortho Tri-Cyclen	35/35/35	Norgestimate 0.18/0.215/0.25	
Medium Androgenic Activity of Progestin Component				
Monophasic	Norlestrin 1/50	50	Norethindrone acetate 1.0	
	Ovcon 50, Genora 1/50, Norethin 1/50M	50	Norethindrone 1.0	
	Demulen	50	Ethinodiol diacetate 1.0	
	Demulen 1/35	35	Ethinodiol diacetate 1.0	
	Ortho-Novum 1/35, Norinyl 1 + 35, Genora 1/35, Norethin 1/35E, Norcept-E 1/35, Nelova 1/35, NEE 1/35	35	Norethindrone 1.0	
	Loestrin 1/20	20	Norethindrone acetate 1.0	
	Alesse	20	Levonorgestrel 0.1	
	Biphasic	Ortho-Novum 10/11, NEE 10/11, Jenest-28	35/35	Norethindrone 0.5/1.0
		Ortho-Novum 7/7/7	35/35/35	Norethindrone 0.5/0.75/1.0
	Triphasic	Tri-Norinyl	35/35/35	Norethindrone 0.5/1.0/0.5
Triphasil, Tri-Levlen		30/40/30	Levonorgestrel 0.5/0.075/0.125	
Estrostep		20/30/35	Norethindrone acetate 1.0	
High Androgenic Activity of Progestin Component				
Monophasic	Ovral	50	Norgestrel 0.5	
	Norlestrin 2.5/50	50	Norethindrone acetate 2.5	
	Loestrin 1.5/30	30	Norethindrone acetate 1.5	
	Lo-Ovral	30	Norgestrel 0.3	
	Nordette	30	Levonorgestrel 0.15	
	Levlen	30	Levonorgestrel 0.15	
Progestin Only				
Monophasic	Micronor	None	Norethindrone 0.35	
	Nor-QD	None	Norethindrone 0.35	
	Ovrette	None	Norgestrel 0.075	

EE = ethinyl estradiol.

^a All these compounds have a favorable high-density lipoprotein (HDL)/low-density lipoprotein (LDL) cholesterol ratio, but the compounds containing desogestrel appear to have a more favorable effect by virtue of not decreasing the HDL₂-cholesterol fraction (Godsland and Wynn, 1984; Krauss, 1988).

^b On days 22 and 23 an inert tablet is taken and on days 24-28 a tablet containing 10 μ g of ethinyl estradiol is taken.

Modified by Mishell and colleagues (1997), with permission.

TABLE 58-6. Drugs Known and Suspected to Decrease Contraceptive Effectiveness of Combination Oral Contraceptives and Recommended Management.

Drugs	Recommended Management
Barbiturates	Use back-up or higher dose contraceptive
Carbamazepine ^a	Use back-up or higher dose contraceptive
Felbamate	Use back-up or higher dose contraceptive
Griseofulvin	Use back-up or higher dose contraceptive
Ketoconazole/Itraconazole	Use back-up or higher dose contraceptive
Phenytoin	Use back-up or higher dose contraceptive; monitor phenytoin concentration because of possible enhancement of phenytoin effect
Primidone	Use alternative contraceptive
Rifampin	Use back-up or higher dose contraceptive
Topiramate	Use back-up or higher dose contraceptive

^a Possible decreased contraceptive effect.

TABLE 58-8. Unit Costs for Contraceptive Drugs, Methods, and Associated Services.

Method	Unit Cost in US Dollars	
	Managed Payment Model	Public Payer Model
Tubal ligation ^a	2465	1190
Vasectomy ^a	755	353
Oral contraceptives		
Drug	21/cycle	17/cycle
Office visit ^a	38	16
Implant		
Drug ^a	365	365
Insertion ^a	333	48
Removal	100	80
Injectable contraceptive		
Drug	30/quarter	30/quarter
Office visit	38/quarter	17/quarter
Progestrone-T IUD		
Device	82	82
Insertion	207	62
Removal	70	11
Copper-T IUD		
Device ^a	184	109
Insertion ^a	207	62
Removal	70	11
Diaphragm ^b		
Device (1st and 3rd year)	18	15
Office visit (device fitting)	38	16
Spermicidal jelly ^c	12	8
Male condom ^b	1	0.33
Female condom ^b	4	1.25
Spermicides ^{b, c}	12	9
Cervical cap ^b		
Device (1st and 3rd year)	31	19
Office visit (device fitting)	38	16
Spermicidal jelly ^c	12	9
Withdrawal	0	0
Periodic abstinence	0	0
No method	0	0

IUD = intrauterine device.

^a First year only.

^b Method costs were calculated on 83 acts of intercourse per year. Diaphragm and cap users were assumed to replace their devices during the third year.

^c Used for 10 acts of intercourse.

Adapted with permission from Trussell and colleagues (1995) and Association of Professors of Gynecology and Obstetrics (1999).

TABLE 58-9. Contraindications and a Warning About the Use of Combination Oral Contraceptives.

Oral contraceptives should not be used in women with any of the following conditions:

Thrombophlebitis or thromboembolic disorders

A past history of deep-vein thrombophlebitis or thromboembolic disorders

Cerebrovascular or coronary-artery disease

Known or suspected breast carcinoma

Endometrial carcinoma or other known or suspected

estrogen-dependent neoplasia

Undiagnosed abnormal genital bleeding

Cholestatic jaundice of pregnancy or jaundice with prior pill use

Hepatic adenomas or carcinomas

Known or suspected pregnancy.

Warnings:

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

TABLE 58-11. Contraindications to Use of an Intrauterine Device.

Copper T 380A

Pregnancy or suspicion of pregnancy
Abnormalities of the uterus resulting in distortion of the uterine cavity
Acute pelvic inflammatory disease (PID) or a history of PID
Postpartum endometritis or infected abortion in the past 3 months.
Known or suspected uterine or cervical malignancy, including unresolved abnormal Pap smear
Genital bleeding of unknown etiology
Untreated acute cervicitis or vaginitis, including bacterial vaginosis, until infection is controlled
Wilson disease
Allergy to copper
Patient or her partner has multiple sex partners
Conditions associated with increased susceptibility to infections with microorganisms including, but not limited to leukemia, acquired immunodeficiency syndrome (AIDS), and intravenous drug abuse
Genital actinomycosis
A previously inserted intrauterine device (IUD) that has not been removed.

Progestasert

Pregnancy or suspected pregnancy
History of ectopic pregnancy or a condition that predisposes to ectopic pregnancy
Presence or history of PID or factors that predispose to PID
Patient or her partner has multiple sex partners
Presence or history of one or more sexually transmitted infections, including but not limited to gonorrhea or chlamydial infections
Postpartum endometritis or infected abortion
Incomplete involution of uterus following abortion or childbirth
A previously inserted IUD still in place
History of pelvic surgery that may be associated with an increased risk of ectopic pregnancy, eg, surgery of the fallopian tubes or surgery for pelvic adhesions or endometriosis
Abnormalities of the uterus resulting in distortion of the uterine cavity or uteri that measure < 6 cm or > 10 cm by sounding
Known or suspected uterine or cervical malignancy including an unresolved, abnormal Pap smear
Genital bleeding of unknown etiology
Vaginitis or cervicitis unless and until infection has been eradicated and has been shown to be nongonococcal and nonchlamydial
Genital actinomycosis
Conditions or treatments associated with increased susceptibility to infections with microorganisms including but not limited to leukemia, diabetes, a history of endocarditis or certain types of heart disease that are associated with an increased risk of endocarditis, AIDS, and conditions requiring chronic corticosteroid therapy
Intravenous drug abuse.

Contraindications from ParaGard Prescribing Information, Raritan, NJ: Ortho-McNeil Pharmaceutical Corporation, January 1996; and Progestasert System Prescribing Information, Palo Alto, CA: ALZA Pharmaceuticals, June 1994.

TABLE 58-13. Oral Contraceptives Used for Emergency Contraception in the United States.

Brand	Manufacturer	Pills per Dose^a and Color	Ethinyl Estradiol (µg per dose)	Levonorgestrel (mg per dose)^b
Preven ^c	Gynetics	2 blue	100	0.50
Ovral ^a	Wyeth-Ayerst	2 white	100	0.50
Alesse ^d	Wyeth-Ayerst	5 pink	100	0.50
Levlite ^d	Berlex	5 pink	100	0.50
Nordette ^d	Wyeth-Ayerst	4 light-orange	120	0.60
Levlen ^d	Berlex	4 light-orange	120	0.60
Levora ^d	Watson	4 white	120	0.60
Lo/Ovral ^d	Wyeth-Ayerst	4 white	120	0.60
Plan B	Wyeth-Ayerst	1 white	0	0.75
Triphasil ^d	Wyeth-Ayerst	4 yellow	120	0.50
Tri-Levlen ^d	Berlex	4 yellow	120	0.50
Trivora ^d	Watson	4 pink	120	0.50
Ovrette	Wyeth-Ayerst	20 yellow	0	0.75

^a The treatment schedule is one dose within 72 hours after unprotected intercourse, and another dose 12 hours later.

^b The progestin in Ovral, Lo/Ovral, and Ovrette is norgestrel, which contains two isomers, only one of which (levonorgestrel) is bioactive; the amount of norgestrel in each tablet is twice the amount of levonorgestrel.

^c Preven is the only dedicated product specifically marketed for emergency contraception.

^d Declared safe and effective for use as emergency contraception by the Food and Drug Administration.

Modified from Hatcher and colleagues (1998), with permission.

59. Sterilization

Surgical sterilization is the most popular form of contraception among couples of reproductive age ([Fig. 59-1](#)). According to the [Association for Voluntary Surgical Contraception \(1989\)](#), 66 percent of 976,000 sterilization procedures performed in the United States in 1987 were in women.

With approximately 700,000 women a year currently choosing voluntary sterilization, it is obvious that this is a procedure that women not only want, but demand. Despite this clear mandate, there are still an excessive number of federal rules and regulations that mainly serve to discourage voluntary sterilization among financially underprivileged women. This is done by threatening to sever federal funding to the organizations that provide service. These restrictive practices will likely appear as ridiculous to future generations as will the men (certainly not women) who devised and promulgated them.

FEMALE STERILIZATION

From a medical standpoint, sterilization can be performed at any time and often is done at cesarean delivery. For women who deliver vaginally, the early puerperium is a particularly convenient time. The oviducts are accessible at the umbilicus directly beneath the abdominal wall for several days after delivery. Thus, the operation is technically simple, and hospitalization need not be prolonged. All these factors collectively make this a less dangerous procedure than an interval sterilization.

Some prefer to perform sterilization in the immediate puerperium ([Bucklin and Smith, 1999](#)). This has some disadvantages, and some clinicians prefer to wait for 12 to 24 hours. For example, at Parkland Hospital, puerperal tubal ligation is performed in the obstetrical surgical suite the morning after delivery to minimize hospital stay. The likelihood of postpartum hemorrhage in multiparous women subsides remarkably 12 hours after delivery. In addition, the status of the newborn can be ascertained much more precisely several hours after birth.

PUERPERAL TUBAL STERILIZATION

The first tubal sterilization reported in the United States 120 years ago consisted of ligating the oviducts with a silk ligature about 1 inch from their uterine attachment following a second cesarean delivery ([Lungren, 1881](#)). Literally, the woman had her tubes tied. Subsequently, it became apparent that an unacceptably high failure rate followed ligation without tubal resection. A variety of techniques are now employed to disrupt tubal patency.

IRVING PROCEDURE. This procedure is least likely to fail. The procedure involves severing the oviduct and separating it from the mesosalpinx sufficiently to create a medial segment of tube ([Fig. 59-1A](#)). The distal stump of the proximal tubal segment is buried within a tunnel in the myometrium posteriorly, and the proximal end of the distal tubal segment is buried within the mesosalpinx. The procedure requires considerable exposure.

POMEROY PROCEDURE. This is the simplest, reasonably effective method of dividing the tube ([Fig. 59-1B](#)). It generally has been considered important that plain catgut be used to ligate the knuckle of tube, because the rationale of this procedure is based on prompt absorption of the ligature and subsequent separation of the severed tubal ends.

PARKLAND PROCEDURE. The Parkland procedure, shown in [Figure 59-1C](#), was developed in the 1960s and was designed to avoid the initial intimate approximation of the cut ends of the oviduct inherent with the Pomeroy procedure. A small infraumbilical abdominal wall incision is made. The oviduct is identified by grasping the midportion with a Babcock clamp and confirming by direct identification of distal fimbriae. This prevents confusing the round ligament with the midportion of the oviduct. **Whenever the oviduct is inadvertently dropped, it is mandatory to repeat completely the identification procedure just described.**

An avascular site ([Fig. 59-2A](#)) in the mesosalpinx adjacent to the oviduct is then perforated with a small hemostat, and the jaws are opened to separate the oviduct from the adjacent mesosalpinx for about 2.5 cm. The freed oviduct is ligated proximally and distally with 0 chromic suture, and the intervening segment of about 2 cm is excised and inspected for hemostasis ([Fig. 59-2B](#)). Both resected segments are labeled and submitted for histological confirmation. The failure rate has been approximately 1 in 400 procedures.

MADLENER PROCEDURE. This procedure is similar to the Pomeroy operation, except that a knuckle of tube is crushed and ligated with nonabsorbable suture but not resected ([Fig. 59-1D](#)). **This procedure is mentioned only to discourage its use because of a failure rate of about 7 percent.**

FIMBRIECTOMY. Removal of all of the distal tube to effect sterilization was recommended by [Kroener \(1969\)](#) and others. Kroener doubly ligated the oviduct with silk suture and then excised the fimbriated end ([Fig. 59-1E](#)). Although he reported no failures, others have, and in some instances, the rate has been as high as 3 percent ([Metz, 1977](#); [Taylor, 1972](#)). Failures are usually due to a small amount of fimbrial tissue being left, or from recanalization of the proximal portion of the tube.

NONPUERPERAL (INTERVAL) TUBAL STERILIZATION

The techniques of nonpuerperal tubal sterilization, including modifications that have been recommended to accomplish sterilization through tubal occlusion, are almost bewildering in number. Basically, they consist of:

1. Ligation and resection at laparotomy, as described earlier for puerperal sterilization.
2. The permanent application of a variety of rings or clips to the fallopian tubes, usually by laparoscopy.
3. Electrocoagulation of a segment of the oviducts, again usually through a laparoscope.

LAPAROTOMY. Once the uterus has involuted completely and returned to the true pelvis postpartum, exposure is enhanced if the uterus and adnexa are pushed out of the true pelvis to beneath the abdominal wall using a manipulator inserted into the uterus. Using this technique, "minilaparotomies" can be performed through a 3-cm incision made suprapubically, and tubal sterilization can be effected.

COLPOTOMY. *Vaginal tubal sterilization* can usually be performed as an interval procedure once the uterus has involuted and pregnancy-induced hyperemia has subsided. The peritoneal cavity is entered through the posterior vaginal fornix—colpotomy or culdotomy—the oviducts are grasped, and either a Parkland or Pomeroy-type resection or fimbriectomy is performed. This approach has a higher infection rate and often a higher failure rate.

LAPAROSCOPY. An article in *Life* magazine on July 28, 1972 referred to the laparoscopic technique as "Band-Aid" surgery ([Fig. 59-3](#)). Laparoscopic tubal ligation is the leading method of family planning for women desiring sterilization ([Filshie, 1999](#)). The woman is usually cared for in an ambulatory surgical setting. Anesthesia, usually general with tracheal intubation, is induced. After producing a pneumoperitoneum with carbon dioxide, the sterilization procedure is accomplished. Most often the woman can be discharged several hours later. The actual disruption of tubal continuity has been accomplished using loops, clips, and electrocauterization with and without transection of the tube. Because electrocauterization destroys a large segment of tube, surgical reversal, most often, is not possible, and this procedure is not generally recommended for women under 25, or those of low parity.

HAZARDS FROM TUBAL STERILIZATION

Principal hazards are anesthetic complications, inadvertent injury of adjacent structures, the rare occurrence of pulmonary embolism, and failure to produce sterility with subsequent development of an ectopic pregnancy ([Chap. 34](#)).

Because of improved safety with anesthetic and laparoscopic techniques, the case-fatality rates for tubal sterilization have diminished appreciably over the past 2 decades. For example, from 1977 to 1981, [Peterson and co-workers \(1983\)](#) estimated the case-fatality frequency to be 8 per 100,000 procedures. More recently, [Hatcher and colleagues \(1998\)](#) reported mortality rates of approximately 1.5 per 100,000 for laparoscopic sterilizations. This compares favorably with maternal mortality rates of approximately 8 per 100,000 live births ([Chap. 1, p. 6](#)).

[DeStefano and co-workers \(1983\)](#) identified intraoperative or postoperative complications in 1.7 percent of a large number of women who underwent nonpuerperal laparoscopic tubal electrocoagulation for sterilization. Factors identified to increase morbidity were previous abdominal or pelvic surgery, a history of previous pelvic infection, obesity, diabetes, and general anesthesia.

TUBAL STERILIZATION FAILURES. No method of tubal sterilization is without failure. Either uterine or ectopic pregnancies may result from such failures.

INTERVAL TUBAL FAILURE. The reasons for interval tubal failures are not always apparent, but some reasons are:

1. Surgical errors likely account for 30 to 50 percent of cases.
2. The patient was already pregnant at the time of the surgery, a so-called luteal phase pregnancy.
3. An occlusion method failure may be due to fistula formation, which may follow electrocautery procedures. Faulty clips may not be occlusive enough, or the fallopian tube may spontaneously undergo reanastomosis.
4. Equipment failure, such as a defective electric current for the electrocautery, also may be a causative factor.

PUERPERAL STERILIZATION FAILURE. Although an increased failure rate for sterilization at the time of cesarean delivery has been reported by some, with the technique for tubal sterilization used at Parkland Hospital ([Figs. 59-1C](#) and [59-2](#)), we have identified no difference. Two major reasons account for the failure of puerperal sterilizations. These are:

1. Surgical errors, which include transection of the round ligament instead of the oviduct or partial transection of the oviduct.
2. Formation of a fistula tract between the severed tubal stumps, or spontaneous reanastomosis.

[Soderstrom \(1985\)](#) concluded that most sterilization failures were not preventable. A similar conclusion was reached by the [American College of Obstetricians and Gynecologists \(1996\)](#), which stated, "pregnancies after sterilization may occur without any technical errors."

METHOD-ASSOCIATED STERILIZATION FAILURES. It is apparent that certain sterilization methods are associated with lower failure rates than others. For example, from review of the data listed in [Table 59-1](#), puerperal sterilization and interval unipolar coagulation appear to have the lowest failure rates. When less than three tubal sites are coagulated, the 5-year cumulative probability of pregnancy is about 12 per 1000 procedures. This compares with only 3 per 1000 if three or more sites are coagulated ([Peterson and associates, 1999](#)). Finally, the lifetime increased cumulative failure rates over time are supportive that failures after 1 year are not likely due to technical errors.

ECTOPIC PREGNANCY. Approximately half of the pregnancies that occur after a failed electrocoagulation procedure are ectopic, compared with 10 percent following failure of a ring, clip, or tubal resection method ([Hatcher and colleagues, 1990](#)). These must be compared with an ectopic pregnancy rate in nonsterilized women of about 1 percent ([Chap. 34, p. 885](#)). **Any symptoms of pregnancy in a woman after tubal sterilization must be investigated, and an ectopic pregnancy must be excluded.**

POSTTUBAL LIGATION SYNDROME. This syndrome is variably characterized by pelvic discomfort, ovarian cyst formation, and especially menorrhagia. It remains to be established that tubal ligation induces any of these changes. [Kasonde and Bonnar \(1976\)](#) measured menstrual blood loss before and for 6 to 12 months after tubal sterilization. They found no significant changes in menstrual blood loss. They also reported that women who presented with menorrhagia soon after sterilization usually had the problem beforehand, or they had been using oral contraceptives, which reduced blood loss. [DeStefano and co-workers \(1983\)](#) followed nearly 2500 women for 2 years after tubal sterilization and reported that, except for menstrual pain, there was no increase in the prevalence of adverse menstrual function. In fact, half or more of women with adverse menstrual function before sterilization had an improvement over 2 years following sterilization. [DeStefano and colleagues \(1985\)](#) and [Shy and associates \(1992\)](#) included a control group of women whose partners had undergone vasectomy. They reported that abnormal menstrual bleeding seldom developed unless it was reported before sterilization. Interestingly, women with menstrual irregularities before sterilization were less likely than controls to revert spontaneously to normal cyclic menses later. [Vessey and associates \(1983\)](#) compared the frequency of gynecological and psychological disorders among women who had undergone tubal sterilization with those in women whose husbands had undergone vasectomy, and found little difference between the two groups.

Recent observations reported by [Peterson and colleagues \(2000\)](#) for the U.S. Collaborative Review of Sterilization Working Group are important. They showed that tubal sterilization is not followed by increased risks for menstrual abnormalities. This was concluded after study of 9514 women who had undergone tubal sterilization and who were compared with a cohort of 573 women whose partners had undergone vasectomy. Neither increased volume of menstrual flow nor intermenstrual bleeding were different in the two groups. In fact, women who had tubal sterilization were more likely to report decreased duration of bleeding, amount of bleeding, and dysmenorrhea.

Some women who had undergone tubal sterilization were reported by [Hargrove and Abraham \(1981\)](#) to have high serum estradiol and low serum progesterone levels compared with controls. Other investigators have failed to identify luteal phase dysfunction after tubal sterilization, except possibly after techniques that can cause obstruction of the utero-ovarian artery ([Alvarez-Sanchez and colleagues, 1981](#); [Donnez and associates, 1981](#)).

Although complete transection of the oviduct is mandatory, it is desirable at the same time to preserve blood supply through the adjacent mesosalpinx. This likely minimizes the possibility of "postligation" abnormalities attributed by some to tubal sterilization. Interestingly, [El-Minawi and associates \(1983\)](#), by means of venography, commonly identified uterovaginal and ovarian varicosities after the Pomeroy and some other procedures, but not following the Parkland technique.

RESTORATION OF FERTILITY

No woman should undergo tubal sterilization believing that her fertility can be restored by either surgery or assisted reproductive techniques that include in-vitro fertilization and ovum transfer. These procedures are costly, difficult, and uncertain. Success rates vary greatly depending upon the age of the woman and the technology utilized.

HYSTERECTOMY

For the woman who desires no more children, hysterectomy has many theoretical advantages. In the absence of uterine or other pelvic disease, however, hysterectomy for sterilization at the time of cesarean delivery, early in the puerperium, or even remote from pregnancy is difficult to justify. Mortality rates for hysterectomy for benign diseases vary from 5 to 25 per 100,000 in women aged 35 to 44 ([Wingo and colleagues, 1985](#)). With cesarean hysterectomy, blood loss is greater than with cesarean plus tubal sterilization, and urinary tract injury is appreciable ([Gilstrap and colleagues, 2001](#)).

HYSTEROSCOPY

Sterilization utilizing hysteroscopy to visualize the tubal ostia and somehow obliterate them is a worthy goal and has received considerable attention. To date, the failure rate and other problems limit the clinical utility of this approach ([Zatuchni and colleagues, 1983](#)).

MALE STERILIZATION

It is estimated that more than 400,000 men annually undergo vasectomy in the United States. Through a small incision in the scrotum, the lumen of the vas deferens is disrupted to block the passage of sperm from the testes ([Fig. 59-4](#)). The procedure is usually performed within 20 minutes using local analgesia. Techniques generally are either traditional or no-scalpel vasectomy ([Clenney and Higgins, 1999](#)). According to [Hendrix and colleagues \(1999\)](#) in their review, compared with vasectomy, female tubal sterilization has a 20-fold increased complication rate, 10- to 37-fold failure, and a 3-fold higher cost. In Dallas in 2000, total charges for a vasectomy were \$700 compared with \$5500 for an outpatient laparoscopic tubal ligation.

A disadvantage of vasectomy is that sterility is not immediate. Complete expulsion of sperm stored in the reproductive tract beyond the interrupted vas deferens takes about 3 months or 20 ejaculations ([American College of Obstetricians and Gynecologists, 1996](#)). Semen should be checked until two consecutive sperm counts are zero. During this period, another form of contraception must be used. The failure rate for vasectomy is much less than 1 percent, but is dependent on several factors. These include failure from unprotected intercourse too soon after ligation, failure to occlude the vas deferens, or recanalization. [Hendrix and colleagues \(1999\)](#) reported that female tubal sterilization is 10 to 37 times more likely to fail than vasectomy.

Restoration of fertility after a successful vasectomy does not always succeed. A review of several reports suggests that odds for success are about 50 percent, with somewhat higher rates following microsurgical reanastomosis. As with women, the risks of regret after sterilization appear to relate primarily to immaturity at the time of sterilization ([Howard, 1982](#)). Three factors that appear to be important in restoration of fertility after previous vasectomy are:

1. The application of meticulous microsurgical techniques for reanastomosis.
2. The length of time after vasectomy.
3. The presence of sperm granulomas.

CARDIOVASCULAR DISEASE

Antibodies directed at spermatozoa can be identified frequently after vasectomy. Concern was raised over the possibility that the immune response might cause harmful systemic changes. Carefully made observations on a very large number of men who had undergone vasectomy several years before have not identified an increase in cardiovascular disease, circulating immune complexes, or damage to retinal blood vessels ([Giovannucci and colleagues, 1992](#); [Goldacre and co-workers, 1983](#)). More recently, [Manson and associates \(1999\)](#) provided data from the U.S. Physicians' Health Study that included a 15-year follow-up of 1159 physicians who had undergone vasectomy. Compared with controls, there was no difference in occurrence of myocardial infarction or stroke.

PROSTATIC AND TESTICULAR CARCINOMA

There is no convincing evidence of an increased incidence of testicular cancer following vasectomy ([Giovannucci and colleagues 1992](#)). Although [Giovannucci and associates \(1993a, 1993b\)](#) reported a weak positive correlation between vasectomy and prostatic carcinoma, [Hayes and co-workers \(1993\)](#) did not. The consensus report from the [1993 National Institutes of Health Conference on Vasectomy and Prostate Cancer](#) concluded that data were insufficient to alter recommendations for the procedure. A subsequent study by [Lesko and colleagues \(1999\)](#) of 1216 vasectomized men and 1400 controls indicated an almost twofold risk of prostatic cancer in men less than 55 years old but no increased risk thereafter.
