WILLIAMS OBSTETRICS - 21st Ed. (2001)

FRONT MATTER

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Dedication

It is with sadness and pride that we dedicate this 21st Edition of Williams Obstetrics to Dr. Paul C. MacDonald. The sadness is because of his death on November 25, 1997. The pride comes from our association with him and his career which culminated at the time of his death as Professor of Obstetrics & Gynecology at The University of Texas Southwestern Medical Center at Dallas as well as the Cecil H. and Ida Green Distinguished Chair in Reproductive Biology and Director of the Cecil H. and Ida Green Center for Reproductive Biology Sciences.

After his residency training at Parkland Hospital, Paul MacDonald was a member of an elite group of young obstetrician-gynecologists who studied steroid biochemistry with Dr. Seymour Lieberman at Columbia University. After his return to Dallas, Dr. MacDonald rapidly earned a reputation as an astute clinician, a gifted teacher, and a brilliant investigator. His distinguished career was spent wedding the basic sciences with obstetrics, gynecology, and human reproduction. His earliest scientific discoveries included elucidation of the origin and metabolism of gonadal and adrenal steroid hormones in children, women, and men. While he served as Chairman of Obstetrics & Gynecology at UT Southwestern from 1970 to 1977, he developed a close relationship with the well-known philanthropists, Mr. and Mrs. Cecil H. Green. Mr. Green, a co-founder of Texas Instruments, endowed the Cecil H. and Ida Green Center for Reproductive Sciences headed by Dr. MacDonald as the Green Distinguished Chair in Reproductive Biology. The accomplishments of Dr. MacDonald and his team of clinicians and scientists included biochemical and molecular foundations of the initiation of human parturition; pathophysiology of pregnancy-induced hypertension; physiology and pathophysiology of endometrium; extraglandular estrogen formation in postmenopausal women and its relationship to obesity, age, and endometrial cancer; dehydroepiandrosterone sulfate as the precursor of placental estrogen in human pregnancy; and human fetal lung development and the respiratory distress syndrome of newborns.

For over 25 years, there were many clinician-scientists and postdoctoral fellows who trained with Dr. MacDonald and who subsequently served as division chiefs, departmental chairs, and deans of medical schools. He held numerous distinguished appointments including study sections, peer-review committees, and task forces for the National Institutes of Health and the March of Dimes. He was elected to the Institute of Medicine in 1987 and to the American Academy of Arts and Sciences in 1997. One particularly cherished honor was the Paul C. MacDonald Professorship in Obstetrics & Gynecology established by his trainees in conjunction with other national academics as well as community obstetricians-gynecologists. Shortly following his death, these same individuals tripled the endowment to that of the Paul C. MacDonald Distinguished Chair in Obstetrics & Gynecology.

A tireless worker, Dr. MacDonald always found time to offer help and to stimulate young clinicians and scientists. He demanded perfection of himself as well as those with whom he worked, but he always gave full credit to the entire team for their successes. He will be fondly remembered for his provocative insights into human reproduction and for his remarkable humanity.

Preface

As *Williams Obstetrics* nears its 100th year of active service, we are again reminded of this excerpt from the preface in the First Edition:

In the following pages I have attempted to set forth with thoroughness the scientific basis for the practical application of the obstetrical art.... At the same time I have endeavored to present the more practical aspects of obstetrics in such a manner as to be of direct service to the obstetrician at the bedside.

JOHN WHITRIDGE WILLIAMS (1903)

This philosophy did not change in nineteen editions of this text that followed during the 20th century. The evolution of obstetrics as a clinical specialty was largely accomplished through the first half of the 1900s. Beginning then, academic leaders in our specialty demanded scientific verification of principles that underlie obstetrical practice. Thus, through the leadership of a relatively small number of "giants" in our field, scientific underpinnings of obstetrics began to assume a role of primary importance after the mid-20th century. Extensive research into maternal and fetal physiology, as well as endocrinology, infectious diseases, ultrasonography, and genetics paved the way for the birth of the subspecialty of Maternal-Fetal Medicine in the 1970s. Subsequently, genomic research and development of molecular techniques allowed opening of vistas in obstetrical research that likely will keep us busy much of the 21st century.

In addition to research to provide scientific proof of clinical practices, the demand for evidence-based medicine and documentation of clinical outcomes has been a major driving force in clinical medicine for the past two decades. Although there is no doubt that medicine remains an art, it is also a science, and many of these changes were long overdue.

For all of these reasons, our mandate to chronicle scientific and medical advances in this textbook, along with their clinical application to the care of mother and fetus, has assumed monumental proportions. With all of these caveats, is it possible for a single obstetrical textbook to be "everything to all"? Although the obvious answer may appear to be *no*, we have endeavored to provide to the practitioner of obstetrics and of maternal-fetal medicine scientific and clinical data that underlie recommendations for clinical practice. To help achieve this goal, we have sought new talent. Two new editors from the University of Alabama at Birmingham bring with them special expertise in the field of evidence-based clinical medicine and state-of-the-art application of clinical and molecular genetics as they pertain to obstetrics. Because of our participation in the Maternal-Fetal Medicine Units Network, we also draw heavily from the experiences of this multi-center collaborative to elucidate important problems that plague the mother and fetus. Careful consideration of the discoveries high-lighted each year at the annual meetings of the Society for Maternal-Fetal Medicine and Society for Gynecologic Investigation also provides contemporaneous data. Finally, and as before, we continue to emphasize clinical practice recommendations that are promulgated by national organizations to include the American College of Obstetricians and Gynecologists, the National Institutes of Health, and the Centers for Disease Control and Prevention.

The 21st edition of *Williams Obstetrics* has been extensively revised and an attempt made to include a synopsis of the burgeoning literature relevant to all aspects of our specialty. To accomplish this, more than 4000 new references have been cited along with an addition of over 250 new figures and tables. As we have done for the past seven editions, we cite frequently our clinical experiences from the Obstetrical Service at Parkland Hospital. To our sometimes vocal critics, we again emphasize that these clinical management schemata are not the only acceptable ones that may be employed to obtain excellent clinical outcomes. Certainly these management guidelines have served us well in caring for over 400,000 indigent pregnant women. We have also cited time-honored clinical practices used contemporaneously at the University of Texas at Houston as well as the University of Alabama at Birmingham, and we again emphasize that these may be only one of several acceptable

methods of management.

We are fortunate to have a large number of vitally important people who have helped us complete this work. At The University of Texas Southwestern, we are especially indebted to Dr. Linette Casey for her expertise in basic physiology and endocrinology of human reproduction, placental development and function, fetal development, and the science of parturition. Drs. George Wendel and Jeanne Sheffield provided valuable insight into infections and sexually transmitted diseases, Dr. Barry Schwarz for contraceptive and sterilization techniques, and Dr. David Miller for trophoblastic disease. Drs. Diane Twickler, Rigoberto Santos, and Jodi Dashe generously supplied ultrasonographs as well as other types of maternal and fetal imaging. Drs. Shiv Sharma and Donald Wallace provided input into the subject of obstetrical anesthesia. Finally, Dr. Don McIntire was essential for provision of demographic and prevalence statistics cited throughout many chapters. Importantly, much of the stimulus to determine why, when, and how tenets evolve in obstetrics was provided by our Maternal-Fetal Medicine fellows who were unrelenting! These include Drs. Nicole Yost, Jeanne Sheffield, Gerda Zeeman, and Julie Lo. Finally, the massive amount of work done by our residents, nurses, and other personnel in obstetrics and gynecology should not be underappreciated. Their dedication to the care of women, and in most cases indigent women, continues to be inspiring.

It is easy to overlook administrative duties when so much time is devoted to the creation of a textbook. To this end, many of the administrative duties at the University of Texas Southwestern Medical Center and Parkland Hospital were carried out by Dr. Barry Schwarz as Vice-Chair of Obstetrics & Gynecology and Dr. Steve Bloom as Associate Director of Obstetrics at Parkland Hospital.

Meticulous coordination of this multi-institutional manuscript that comprised over 4500 pages was provided by Marsha Congleton and Connie Utterback. Much of the day-to-day production was provided by Beverly King, Minnie Tregaskis, Melinda Epstein, Cynthia Allen, Barbara Smith, Leticia Varela, Lynne McDonnell, Julie Thompson, Jeanette Cogburn, Dina Trujillano, and Ellen Watkins in Dallas; Carol Durham and Grace Lopez at the University of Texas at Houston; and Belinda Rials and Rhonda Scott at the University of Alabama at Birmingham. As she had in the previous two editions, Nancy Marshburn lent her considerable artistic experience to the development of new and revised figures.

After almost 100 years, *Williams Obstetrics* has a new publisher. In the very short time we have known and worked with them, Andrea Seils, Susan Noujaim, Karen Davis, and Marty Wonsiewicz of McGraw-Hill have proven to be excellent colleagues as well as good friends. Happily, joining the new McGraw-Hill team from Appleton & Lange is John Williams, who has ably served as production editor the last three volumes. To all of these people, as well as to many, many more not cited, we as always are grateful.

Finally, our families have made contributions to this text in a number of ways, perhaps the most apparent being less time that we could spend with them. Thus, to Deann Gant, Marjorie Leveno, JoEllen Gilstrap, and Dr. Dwight Rouse, we offer our thanks for their unwavering support.

SECTION I - HUMAN PREGNANCY

1. Obstetrics in Broad Perspective

Publication of this 21st edition of *Williams Obstetrics* is conspicuously coincidental with the beginning of the 21st century. Indeed, the first 20 editions of this textbook have encompassed the 20th century and chronicled dramatic advances in obstetrics. As shown in [Table 1-1](#), healthier mothers and babies ranks as one of the 10 great public health achievements in the United States between 1900 and 1999. At the beginning of the century, almost 1 in every 100 women giving birth in this country died of pregnancy-related complications, and nearly 1 of 10 infants died before age 1 year ([Centers for Disease Control, 1999b](#)). As shown in [Figures 1-1](#) and [1-2](#), by the end of the 20th century, infant mortality had declined more than 90 percent to 7.2 per 1000 live births in 1997, and the maternal mortality rate declined almost 99 percent to 7.7 deaths per 100,000 live births in 1997.

This chapter provides a synopsis of the current state of maternal and newborn health in the United States. Following this is a perspective on the forces affecting obstetrics as we begin what we hope will become another successful century of *Williams Obstetrics*.

VITAL STATISTICS

The vital statistics of the United States are collected and published through a decentralized, cooperative system ([Tolson and colleagues, 1991](#)). Responsibility for the registration of births, deaths, fetal deaths, marriages, divorces, annulments, and induced terminations of pregnancy is vested in the individual states and certain separate governmental entities. The system comprises 57 registration areas: each state, the District of Columbia, New York City, American Samoa, Guam, the Northern Mariana Islands, Puerto Rico, and the Virgin Islands.

The first standard certificates for the registration of live births and deaths were developed in 1900. An act of Congress in 1902 established the Bureau of the Census to develop a system for the annual collection of vital statistics. The overall objective was to develop and maintain a system for registration that is uniform in such matters as forms, procedures, and statistical methodology. The Bureau retained the authority for producing national vital statistics until 1946, when the function was transferred to the United States Public Health Service. It is presently assigned to the Division of Vital Statistics of the National Center for Health Statistics. The standard certificate of live birth was substantially revised in 1989 to include much more information on medical and lifestyle risk factors and also obstetrical care practices. Currently, more than 99 percent of births in the United States are registered ([Ventura and colleagues, 2000](#)). According to Dr. Stephanie Ventura of the National Center for Health Statistics, another revision of the birth certificate is planned for 2003. Changes will include a format conducive to electronic processing, more explicit demographic data on the parents, and an improved selection of information regarding antepartum and intrapartum complications. Some examples of new data to be collected include labor progress, uterine rupture, blood transfusions, and pregnancy resulting from infertility treatment.

DEFINITIONS

To allow comparison of data from not only one state or region of the country to another, but from one country to another, uniform use of standard definitions is encouraged by the World Health Organization as well as the [American Academy of Pediatrics and the American College of Obstetricians and Gynecologists \(1997\)](#). It is recommended that United States statistics include all fetuses and infants born weighing at least 500 g, whether alive or dead. It should be clarified, however, that the states are not uniform in their reporting requirements for fetal deaths. For example, 28 states stipulate that fetal deaths beginning at 20 weeks' gestation should be recorded, eight states report all products of conception as fetal deaths, and still others use birthweights of 350 g, 400 g, or 500 g or greater to identify fetal deaths.

Definitions recommended by the National Center for Health Statistics and the Centers for Disease Control and Prevention are as follows:

- **Perinatal period.** This includes all births weighing 500 g or more and ends at 28 completed days after birth. When perinatal rates are based on gestational age, rather than birthweight, it is recommended that the perinatal period be defined to commence at 20 weeks.
- **Birth.** The complete expulsion or extraction from the mother of a fetus, irrespective of whether the umbilical cord has been cut or the placenta is attached. Fetuses weighing less than 500 g are usually not considered as births, but rather are termed abortuses for purposes of vital statistics.
- **Birthweight.** The weight of a neonate determined immediately after delivery or as soon thereafter as feasible. It should be expressed to the nearest gram.
- **Birthrate.** This is the number of live births per 1000 population.
- **Fertility rate.** This is the number of live births per 1000 females 15 through 44 years of age.
- **Live birth.** Whenever the infant at or sometime after birth breathes spontaneously, or shows any other sign of life such as a heartbeat or definite spontaneous movement of voluntary muscles, it is recorded as a live birth. Heartbeats are to be distinguished from transient cardiac contractions, and respirations are to be distinguished from fleeting respiratory efforts or gasps.
- **Stillbirth (fetal death).** No signs of life are present at or after birth.
- **Neonatal death.** Early neonatal death refers to death of a live-born infant during the first 7 days after birth. Late neonatal death refers to death after 7 days, but before 29 days.
- **Stillbirth rate (fetal death rate).** The number of stillborn infants per 1000 infants born, including live births and stillbirths.
- **Neonatal mortality rate.** The number of neonatal deaths per 1000 live births.
- **Perinatal mortality rate.** The number of stillbirths plus neonatal deaths per 1000 total births.
- **Infant death.** Includes all deaths of live-born infants from birth through 12 months of age.
- **Infant mortality rate.** The number of infant deaths per 1000 live births.
- **Low birthweight.** The first newborn weight obtained after birth is less than 2500 g.
- **Very low birthweight.** The first newborn weight obtained after birth is less than 1500 g.
- **Extremely low birthweight.** The first newborn weight obtained after birth is less than 1000 g.
- **Term infant.** An infant born anytime after 37 completed weeks of gestation and up until 42 completed weeks of gestation (260 to 294 days) is considered to be a term infant.
- **Preterm infant.** An infant born before 37 completed weeks (259th day).
- **Postterm infant.** An infant born anytime after completion of the 42nd week beginning with day 295.
- **Abortus.** A fetus or embryo removed or expelled from the uterus during the first half of gestation (20 weeks or less), weighing less than 500 g.
- **Induced termination of pregnancy.** The purposeful interruption of an intrauterine pregnancy with the intention other than to produce a live-born infant, and which does not result in a live birth. This definition excludes retention of products of conception following fetal death.
- **Direct maternal death.** This includes death of the mother resulting from obstetrical complications of pregnancy, labor, or the puerperium, and from interventions,

omissions, incorrect treatment, or a chain of events resulting from any of these factors. An example is maternal death from exsanguination from rupture of the uterus.

- **Indirect maternal death.** This includes a maternal death not directly due to an obstetrical cause, but resulting from previously existing disease, or a disease that developed during pregnancy, labor, or the puerperium, but which was aggravated by maternal physiological adaptation to pregnancy. An example is maternal death from complications of mitral stenosis.
- **Nonmaternal death.** Death of the mother resulting from accidental or incidental causes not related to pregnancy are classified as nonmaternal deaths. An example is death from an automobile accident or concurrent malignancy.
- **Maternal mortality ratio.** The number of maternal deaths that result from the reproductive process per 100,000 live births. Used more commonly, but less accurately, are the terms *maternal mortality rate* or *maternal death rate*. The term ratio is more accurate because it includes in the numerator the number of deaths regardless of pregnancy outcome—for example, live births, stillbirths, ectopic pregnancies—while the denominator includes the number of live births.

PREGNANCY IN THE UNITED STATES

Pregnancy, and by extension obstetrics, has a major impact on the health of the nation. Data from diverse sources have been used to provide the following snapshot of pregnancy during the last years of the 20th century in the United States.

In 1998, the population of the United States was 269 million people and the fertility rate for women 15 to 44 years of age was 67 live births per 1000 women ([National Center for Health Statistics, 2000](#)). There were 3.94 million live births in 1998 which, when offset by 2.34 million deaths, resulted in a net increase in the population of 1.6 million people. Life expectancy for those born in 1998 was 76.5 years ([Anderson, 1999](#)).

The number of births in 1998 increased by 2 percent, and this was the first annual increase in the United States after a 7-year decline between 1990 and 1997 ([U.S. News and World Report, 2000](#)). American women average 3.2 pregnancies over their lifetimes, and 1.8 of these were considered wanted pregnancies ([Ventura and colleagues, 1999](#)). As shown in [Figure 1-3](#), unwanted pregnancies are related to lesser amounts of education in the mother. About 1 percent of infants born to never-married women were relinquished for adoption in 1995, which is down from 9 percent of births before 1979 ([Chandra and associates, 1999](#)). After exclusion of fetal losses and induced terminations, American women on average deliver 2.0 live births in a lifetime.

Using 1996 as an example, there were 6.24 million pregnancies in the United States ([Table 1-2](#) and [Fig. 1-4](#)); 62 percent ended with live births, 22 percent ended by induced terminations, and 16 percent were spontaneous miscarriages. Notable changes with regard to the setting and timing of births as well as in the birth attendant have taken place in the United States ([Curtin and Park, 1999](#)). Osteopaths and midwives are delivering an increasing share of births, but nearly all of these increases have been for in-hospital births. The use of electronic fetal monitoring, ultrasound, and labor induction and stimulation all increased, with the most dramatic change being the doubling in the number of births that were induced. Partly as a result of the rise in inductions, there are more births on weekdays. The highest number of births occur in the summer months, with births most likely to occur on Tuesday throughout the year.

Pregnancy care is a major component of the American health care scene. In 1998, delivery was the second leading cause for hospitalization behind heart disease ([Hall and Popovic, 2000](#)). The average length of hospital stay for all deliveries was 2.5 days. Prenatal care was the fourth leading reason for office visits to physicians and accounted for nearly 23 million visits in 1997 ([Woodwell, 1999](#)). In 1991 and 1993 there were approximately 720,000 non-delivery-related hospitalizations for pregnancy complications, amounting to hospitalization for one in five pregnancies ([Bennett and co-authors, 1998](#)). Nondelivery hospitalizations have decreased substantially since the late 1980s, presumably due to managed care efforts to minimize expenditures. The leading indication for hospitalization unrelated to delivery was preterm labor. [Nicholson and co-workers \(2000\)](#) have estimated that the total national cost, in 1996 dollars, for hospitalization for preterm labor that did not eventuate in delivery was \$360 million. This number increased to \$820 million when those women with preterm labor and who actually delivered early, were added.

The magazine [OBG Management \(1999\)](#) surveyed approximately 1 percent of obstetricians-gynecologists in the United States in an effort to assess the state of obstetrics at the turn of the 20th century. The average number of deliveries in 1998 was 140 per obstetrician ([Fig. 1-5](#)). More than 80 percent of those who responded to the survey reported that they continued to practice obstetrics as well as gynecology. Those who gave a reason for discontinuing their obstetrics practice cited medicolegal concerns, professional-liability premiums, and declining reimbursement as the reasons they stopped. Among those who still practice obstetrics, about 40 percent anticipated that their obstetrical case-load would increase in 1999.

HEALTHY PEOPLE 2010

In 1991, the United States Public Health Service issued a report titled *Healthy People 2000*, which proposed goals for improving the health of mothers and infants by the year 2000. Of the 17 maternal and infant health objectives included in *Healthy People 2000*, progress was made in eight objectives. In five objectives, however, movement was away from the target. Notable gains were made in the areas of infant death, fetal death, cesarean delivery (particularly repeat cesareans), breast feeding, early use of prenatal care, hospitalization for pregnancy complications, abstinence from tobacco use during pregnancy, and screening for fetal abnormalities and genetic disorders. For the remaining objectives, changes were neither positive or negative. These included maternal death, fetal alcohol syndrome, and low birthweight.

New objectives for maternal and infant health have been promulgated for this decade as *Healthy People 2010*. Some of these goals are shown in [Table 1-3](#), using 1997 data for a baseline. There were 27,968 infant deaths in 1997, and as shown in [Figure 1-6](#), two thirds of these were within the first month of life. When analyzed by birthweight, two thirds of infant deaths were in low-birthweight infants ([Fig. 1-7](#)). Of particular interest are those births less than 500 g where neonatal intensive care is now often offered. In 1997 there were 5994 live births weighing less than 500 g and 87 percent of these died during the first 28 days of life. Of the 784 who survived the first 28 days of life, 696—12 percent of all births less than 500 g—survived infancy. [St. John and associates \(2000\)](#) have estimated the total cost of initial care in this country for all newborn infants was \$10.2 billion annually. Almost 60 percent of this expenditure is attributed to preterm births before 37 weeks, and 12 percent is spent on infants born between 24 and 26 weeks.

In addition to deaths during infancy, the effect of pregnancy and childbirth on women's health is an important indicator of national health. In 1997, a total of 327 maternal deaths were identified by vital statistics ([Hoyert and colleagues, 1999](#)). It should be emphasized, however, that it is estimated that more than half of maternal deaths are not ascertained ([Koonin and colleagues, 1997](#)). As shown in [Figure 1-8](#), there is considerable disparity in maternal mortality when analyzed according to race. Pregnancy-related mortality for black women is three to four times higher than for white women. The maternal death differential between African-Americans and whites is highest for those pregnancies that did not end in birth of an infant. These include ectopic pregnancy, spontaneous and induced abortions, and gestational trophoblastic disease ([Centers for Disease Control and Prevention, 1995](#)). Shown in [Table 1-4](#) are the causes of maternal death according to the outcome of pregnancy. Hemorrhage and infection are prominent causes of death in ectopic pregnancies and abortions, whereas hypertension, embolism, hemorrhage, and infection are the leading causes of maternal death in women delivered after midpregnancy.

PERSPECTIVES ON OBSTETRICS

Medical writers have recently turned to the opening line of Charles Dickens's *A Tale of Two Cities* to describe these prevailing times in medicine and obstetrics as "the best of times. . . the worst of times. . ." ([Grumbach, 1999](#); [Morrison, 2000](#)). Why are these times at once the best and worst of times for obstetrics? There are many reasons for this, and some are now considered.

BEST OF TIMES

The chronicle of maternal and infant mortality during the 20th century described earlier should suggest that much is good in the health care of women and their infants—indeed, better than it has ever been. "Better than ever" should be read here as previously unparalleled rather than unsurpassable because continual improvement must inevitably remain the goal in obstetrics.

These times could be the best of times for many other reasons. Just to mention a few would include the ascendance of evidence-based medicine. There have been striking developments in the study of the molecular basis for many diseases. In fact, gene therapy was recently first reported successful to "cure" severe combined immunodeficiency disease ([Cavazzana-Calvo and colleagues, 2000](#)). There has been completion of the mapping of the human genome. Importantly, the swelling ranks of women in obstetrics and gynecology is expected to reach parity with men by 2014 ([American College of Obstetricians and Gynecologists, 1999b](#)).

The National Institutes of Health is leading the current emphasis on outcomes-based research. In obstetrics, the National Institute of Child Health and Human

Development has formed two clinical networks that are crucial to the study of obstetrical outcomes. The Maternal-Fetal Medicine Units Network and the Neonatal Units Network are multicenter groups that conduct investigations to study some of the more vexing and important problems in obstetrics and neonatal medicine. Not surprisingly, preterm labor and delivery as well as preeclampsia are in the foreground of these efforts.

The year 2000 marks the 50th anniversary of the American College of Obstetricians and Gynecologists ([Pearse, 2000](#)). Originally formed to promote continuing education, in 1975 the college became involved in legislative initiatives in a number of important arenas to include regionalization of perinatal care, maternal and child health, patient education, and most recently, to provide uninterrupted access of women to the obstetrician-gynecologist as their primary care physician.

In the 20th edition of *Williams Obstetrics* we offered the cartoon shown in [Figure 1-9](#) to highlight the effects of for-profit managed care on obstetrics. We could use this same cartoon to highlight in this 21st edition the tempering of the effects of HMOs that has transpired in the last 5 years. Notably, mandatory early discharge was curtailed by federal legislation through the Newborns' and Mothers' Health Protection Act that went into effect in January 1998 ([Bragg and colleagues, 1997](#)). Because of this, it is no longer legally possible to "heave mom out" before 48 hours. Because this is a victory of sorts, the cartoon is republished. If so much is fundamentally good in obstetrics, why the ambiguous contradiction that these are also the worst of times?

WORST OF TIMES

Among the most pressing challenges facing obstetrics and gynecology is that of epidemic *human immunodeficiency viral infection* (HIV). But there is even some good news here. Specifically, in 1995, according to the [Centers for Disease Control and Prevention \(1996\)](#), HIV infection was the leading cause of death in women 25 to 44 years old. By 1998, however, HIV-infection had dropped to the fifth leading cause of death in all 25- to 44-year-old Americans ([Martin and colleagues, 1999](#)). It unfortunately remained the number one cause of mortality for African-American men in this age group.

There are a number of other indicators from the National Center for Health Statistics and the Centers for Disease Control and Prevention that indicate African-American women are at a significant reproductive disadvantage. Although as shown in [Figure 1-8](#), appreciable progress has been made in decreasing the maternal mortality ratio in both races, a disparate fourfold mortality rate endures in black women compared with whites. Not shown are data indicating that Hispanic women also have higher mortality ratios compared with white women, although the disparity is not as great as for African-American women ([Hopkins and co-authors, 1999](#)). Federal agencies reporting these statistics continue to emphasize that much of the disparity in mortality results from poor availability of medical care for minority women. This is even more apparent in deaths from ectopic pregnancy ([Chap. 34, p. 886](#)).

Unplanned pregnancy, especially among teenagers, is also a best and worst of times contradiction. According to the [Centers for Disease Control and Prevention \(2000a\)](#), the birth rate for teenagers in the United States has continually declined during the 1990s, and in 1998 was near the 1986 low record ([Fig. 1-10](#)). While this is good news, there still were 173,252 births recorded in 1998 to 15- to 17-year-old teenagers. These accounted for 4.5 percent of all births in the nation.

Obesity continues to increase in America. Results from the 1997 National Health Interview Survey indicate that half of adults are overweight and 20 percent are frankly obese ([Centers for Disease Control and Prevention, 2000](#)). The impact of this in current pregnancy is considered in [Chapter 48 \(p. 1298\)](#), and its impact on future generations in [Chapter 29 \(p. 757\)](#).

Domestic violence is a large problem in our country where nearly 5 million adult women experience physical abuse each year ([American College of Obstetricians and Gynecologists, 1999a](#)). As discussed in [Chapter 43 \(p. 1171\)](#), such abuse does not stop with pregnancy, and indeed, it may be exacerbated.

Other pressing problems include the erosion of health-care safety nets for the uninsured by for-profit plans that all too often quickly abandon the most vulnerable patients when profits are in jeopardy ([Bodenheimer, 1997](#)). There is evidence that the shifting of uninsured patients to for-profit medicine has substantially reduced the capacity to deliver the uncompensated care that is essential for the medically indigent ([Lu and colleagues, 2000](#); [Smith, 1997](#)). It has also put minority communities at further risk for inferior health care and widened their already tragic disparity in health status ([Murray-Garcia, 1997](#)).

Another profound effect of transferring health care to the custody of the for-profit sector is the overwhelmingly negative effect that this has on the infrastructure that provides for teaching the coming generations of health-care providers. There is a similar deleterious effect on efforts to conduct the research necessary to move obstetrics forward ([Weissman and colleagues, 1999](#)). As [Kuttner \(1998\)](#) aptly described the situation, there are ". . . too many promoters, marketers, attorneys, underwriters, consultants, reviewers, and shareholders—all taking too big a cut of the premium dollar. . . ."

PORK BELLIES VERSUS PEOPLE. Dr. Marcia Angell, editor emeritus of the *New England Journal of Medicine*, summarized the current state of American health care in 1999: "The hallmark of the system is its reliance on the private market to deliver and, to a lesser extent, to fund health care. Accordingly, health care is treated as a commodity . . . other developed countries . . . consider it a social service, not a commodity." Hence the subtitle that juxtaposes pork bellies and people. Undoubtedly, the force most greatly affecting obstetrics as we begin the 21st century is the transformation for-profit medicine is forcing upon medicine.

The cost for medical malpractice—insurance premiums, attorney fees, and settlements and awards also continues to erode the health-care dollar. Tort reform has also had the best and worst of times in the recent decade. The *Daubert standard*, used in federal and most state courts, demands scientific evidence to support some of these claims of wrongdoing ([Sturmer and colleagues, 2000](#)). Thus, in at least some cases, an "expert" with a degree and an opinion for sale cannot be heard without peer-reviewed evidence to support (frequently ludicrous) opinions. According to [Mohr \(2000\)](#), contingent fees are one of three legal factors that have helped to sustain malpractice litigation for 150 years. The contingency-fee system continues to offer personal injury attorneys the perverse incentive that encourages mendacity and promotes the "sleaze factor." Nowhere in obstetrics is this more prevalent than in "birth injury" litigation ([Chap. 39, p. 1048](#)). According to [Collins \(2000\)](#), in such cases it is not uncommon that obstetricians are expected to prove that their (in)actions did not cause neurological injury.

Attempts to mitigate some of these contentious issues have been only partially successful because of watered-down versions of legislations engineered by the plaintiffs bar. For example, Florida's Birth-Related Neurological Injury Compensation Plan was an experiment in no-fault compensation for brain-damaged babies. A RAND Corporation study by [Studdert and associates \(2000\)](#) found that within the first 10 years of the experiment, "bad baby" litigation continued unfettered in Florida. In fact, many plaintiff attorneys have pursued judgments both under the plan as well as in the courts! There can be no doubt that neurological impairment in a child is horrific and devastating, and as [Brennan and colleagues \(1996\)](#) have reported, it is the severity of injury that dictates payment, not the occurrence of an adverse event, even if due to negligence. Indeed, [Cassidy and co-authors \(2000\)](#) have shown that elimination of pain and suffering from insurance claims actually speeds recovery!

The impact of for-profit managed care was first addressed in the 20th edition of *Williams Obstetrics*. Much that has happened since that time gives us reason for optimism that these worst of times when health care is bought, sold, and traded like pork bellies, has perhaps run its course. Since our last writing, there has been an intense backlash from both the profession and the American health-care "consumer" (sic patient). For example, more than 89 articles on managed care—mostly on the abuses wrought by for-profit medicine—have appeared in the *New England Journal of Medicine* and the *Journal of the American Medical Association*. Shown in [Table 1-5](#) is a selection of these articles that each serve to cross-section the unsavory effects for-profit medicine is having on health care as a profession and, more importantly, as a service to patients. The titles are self-explanatory.

SUMMARY OF THE STATE OF OBSTETRICS

Dr. Arnold Relman, editor emeritus of the *New England Journal of Medicine*, warned in 1980 that "The most important health-care development of the day is the recent, relatively unheralded use of a new industry that supplies health-care services for profit. Closer attention from the public and the profession, and careful study are necessary to ensure that the *medical-industrial complex* puts the interests of the public before those of the stockholders." At the 2000 Annual Clinical Meeting of the American College of Obstetricians and Gynecologists, Relman gave an interim report: "Our present medical care system, which is largely based on investor owned managed care firms, is fatally flawed and will not survive in its present condition much longer." He also reported that while the current investor-owned managed care system has succeeded in squeezing out excess costs, and for a time also held down premiums, these savings have benefited the managed care industry rather than patients. Relman reported that the number of uninsured in the United States had reached 44 million and continues to climb annually. At the same time, teaching hospitals and community clinics have been crippled. His comments that the cause of the current "worst of times" may be ending was received with applause.

There is room for optimism. Recalling the 20th edition: "As obstetrics enters the 21st century, what needs reform is the new managed for-profit obstetrics." It seems such reform is now possible and we therefore cautiously look forward to the "best of times."

2. Pregnancy Overview, Organization, and Diagnosis

The clinical and basic sciences of obstetrics are concerned with all aspects of human reproduction and the health of women and their fetuses. These aspects include sexual maturation, gonadal function, gamete release and transport, ovum fertilization, zygote cleavage, blastocyst transport and implantation, embryo development, sexual differentiation of the embryo-fetus, pregnancy adaptations, fetal development, parturition, puerperal adaptation, lactation and breast feeding, and gonadal senescence. Any number of abnormalities can affect each of these processes.

OVERVIEW OF HUMAN REPRODUCTIVE FUNCTION

All physicians should be aware of the impact that reproductive biological processes may have on the physical and mental well-being of nonpregnant women. As is true of the female of all mammals, women are the limiting resource in human reproduction, but the physiological expenditures involuntarily obliged in women to ensure the perpetuation of humankind are enormous. In other mammalian species, including subhuman primates, the adult female experiences periodic episodes of estrus, usually during a defined time of the year (the breeding season). In women, however, spontaneous, cyclical ovulation at 25- to 35-day intervals continues throughout the year and from menarche to menopause, that is, for about 38 years. For the woman who does not use contraception, there are approximately 500 opportunities for pregnancy, which may occur with sexual intercourse on any one of 1500 days (the day of, and 2 days preceding, ovulation; see [Chap. 5](#)). Consequently, all physicians must be constantly vigilant and sensitive to the possibility that women of reproductive age, irrespective of their presenting complaint, may be pregnant. For the woman who chooses not to be pregnant, this means 500 ovarian cycles, with massive progesterone secretion/withdrawal, and then menstruation, occur for no physiological purpose. Many women choose to use some form of contraception, but most select a method that necessitates continued cyclical uterine bleeding because safe and effective methods for producing amenorrhea and infertility have not been developed.

HUMAN REPRODUCTION TODAY

From one vantage point, the success of human reproduction is the cause of one of the greatest problems of humankind—that is, overpopulation—which is a worldwide tragedy that is worsening each day. This is considered by many scholars, with considerable justification, to be the greatest hazard to the health and the environmental and economical future of humankind. One of the momentous social problems in the United States today is the high and increasing number of unwanted pregnancies among teenage girls. Acquired immune deficiency syndrome (AIDS), a sexually transmitted disease, threatens the world with a horrific, deadly epidemic. From one perspective, human reproduction is little encumbered by the use of contraceptive methods or protection against sexually transmitted disease.

From another vantage point, the problem of human reproduction that haunts many women and men (and their physicians) is relative infertility, which may affect 20 percent of couples. This major cause of human reproductive failure is coupled with a living newborn pregnancy success rate for in vitro fertilization and embryo transfer of less than 25 percent in most clinics. To compound this dilemma, pregnancy failure caused by embryonic or fetal wastage can occur at every possible step of human reproduction. Commencing with failure of oocyte fertilization, and proceeding through failure of zygote cleavage and blastocyst implantation, embryonic losses are appreciable; and fetal losses from spontaneous abortion, fetal malformations, and preterm birth are major problems. From this perspective, it may be concluded that difficulty will be encountered in maintaining the human race, either quantitatively or qualitatively.

BIOLOGICAL AND INTELLECTUAL EVOLUTIONARY PERSPECTIVE. For physicians, researchers, demographers, anthropologists, all those interested in the reproductive biology sciences, and those entrusted with the health care of women, it would be helpful if a theoretical norm could be defined—one of human reproduction uncluttered by social, religious, or pharmacological intervention. To gain such a view, a vision of the natural history of human reproduction is required. But such an understanding is difficult to attain because of social customs.

According to [Short \(1980\)](#), the reproductive variables that ordinarily would lead to some sort of reproductive equilibrium include:

1. Age of puberty.
2. Frequency of embryonic and fetal death.
3. Neonatal (perinatal) mortality.
4. The duration of lactational amenorrhea, that is, breast feeding-induced anovulation or infertility.

But in humans, these constraints have been modified, even if unwittingly, such that the natural history of reproduction in our species has been diverted by social overlay ([Short, 1976a](#)). Three examples follow.

REPRODUCTION IN OTHER PRIMATES. To remove some of the social overlay that obscures our view of natural human reproduction, examination of reproduction in closely related primates living in the wild is valuable. Among female chimpanzees in the jungle, for example, the interval between births is almost 6 years; but this interval is shortened by infant death, suggesting that the long time between successive chimpanzee births normally is the result of lactation-induced infertility (anovulation and amenorrhea). Chimpanzees in the wild suckle their young several times per hour, secrete a milk similar to that of humans, and sleep with the infant at their breast during the night ([Short, 1984](#)). Menstruation is a phenomenon confined to only a few primates—the great apes, Old World monkeys, and women—and no other mammals ([Chap. 4](#)). Chimpanzees experience menstruation at intervals similar to women, but in those animals living in the wild, menstruation is rare because of repeated pregnancy and prolonged lactation-induced anovulation with amenorrhea.

Is it possible that the same would be true of ovulation and menstruation in women were it not for their advanced intellectual development—a development that has enabled women to choose infertility and to limit the duration of breast feeding? The social evolution of human reproduction did, indeed, involve the changing practices of breast feeding. Before modern times, its duration usually was dictated by the availability of soft foods for infants. Women today have the choice of ovulation and menstruation and infant formula feeding instead of near-continuous pregnancy and prolonged lactation.

REPRODUCTION IN PRIMITIVE SOCIETIES. In previous editions of this textbook, the reproductive success of the primitive nomadic hunter-gatherer !Kung tribe was described in detail and contrasted to their relatives who have become farmers. Simply stated, the nomadic branch of the tribe has fewer infants per woman when compared with the farmers. This likely is due to later childbearing in the nomads because of lean body mass, which is associated with delayed menarche. Also, their prolonged lactation, dictated by their mobility, prohibits quick return to ovulation. By contrast, the farmer tribe women can limit lactation because of increased availability of soft food and animal milk for their infants ([Kolata, 1974](#); [Short, 1976a, 1976b, 1984](#)).

REPRODUCTION IN NORTH AMERICAN HUTTERITES. The Hutterites are a religious sect with an exceptionally high rate of fertility. The mean age of marriage for Hutterite women is 22.0 years of age ([Eaton and Mayer, 1953](#)). Reproduction is encouraged, but premarital sex is forbidden and rarely practiced. The 25 to 29 age-specific nuptial fertility rate among Hutterite women is 498—that is, there are 498 births per year for each 1000 married women in that age group. Stated differently, there is one birth per woman every 2 years, and the average completed family size of Hutterite women is 10.6 children.

Compared with the nomadic !Kung women, Hutterite women experience earlier puberty and ovulation, suckle their children on a rigid schedule, and choose to supplement breast feeding with soft foods earlier. Based on the reproductive history of the Hutterite women, the population doubling time of this group has been estimated to be 16 years ([Eaton and Mayer, 1953](#); [Short, 1984](#)).

REPRODUCTION IN MODERN WOMEN

It seems reasonable to conclude that the sedentary, agrarian way of life of the past few centuries has contributed to a change in body composition and mass that favors earlier menarche and ovulation. Menarche in women in the United States today occurs at about 12 ¹/₂ years of age ([Fig. 2-1](#)); and whereas anovulation is more common immediately after menarche than later in reproductive life, most young postmenarchal girls are ovulatory and, therefore, potentially fertile. Most women today who choose to breast feed their newborns will do so for no more than a few weeks or at most a few months, and will suckle the baby no more than eight times per 24 hours compared with 48 times per 12 hours of daylight for !Kung women.

Therefore, two major factors have affected the natural course of human reproduction. These factors are nutrition and women's advanced intellectual capacity, which permits women the choice of infertility. Nutritional advances have led to:

1. Earlier menarche (and ovulation).
2. Artificial feeding of the newborn, resulting in decreased duration of lactation with associated anovulation and amenorrhea after childbirth.
3. More frequent and longer infant survival.

Because women in the United States today, on average, choose to have two pregnancies and to breast feed for only a few weeks, no more than 20 ovarian (menstrual) cycles are eliminated by pregnancy and the anovulation/amenorrhea of lactation. In the absence of pharmacological or surgical intervention, therefore, modern women experience nearly 500 ovulatory cycles, each of which is accompanied by massive progesterone secretion/withdrawal intervals and attendant menstruation, because of their intellectual capacity to choose infertility ([MacDonald and colleagues, 1991](#)).

OVULATION IS THE CARDINAL FUNCTION OF THE OVARY

The endocrine changes of the ovarian cycle are optimized to create a hormonal environment that promotes ovulation. The endocrine milieu that evolves during the ovarian cycle also is optimal for the regeneration of endometrium after completion of a failed fertility cycle (menstruation) to prepare this tissue for the next pregnancy (implantation) opportunity.

Follicular estrogen (synthesized in granulosa cells) is produced in a cyclical manner that regulates ovarian-brain-pituitary function and follicular maturation, eventuating in ovulation. But the somatic effects of estrogen, such as those on bone density, must be accepted as coincidental benefits. There is no currently recognized physiological mechanism in place whereby somatic tissues can act to regulate the rate of ovarian estrogen secretion. Except for ovary and brain-pituitary, this is true of all estrogen-responsive tissues, including breast, uterus, bone, skin, vagina, and liver. For metabolic processes, other than those directly involved in reproduction, there also is no apparent advantage provided by the wide fluctuations in the levels of estrogen that are characteristic of the ovarian cycle. These considerations are important not only to an understanding of reproductive processes but for the development of rational therapeutic practices of estrogen replacement. Specifically, there is no merit in attempting to pharmacologically recreate the cyclical fluctuations in estrogen of the ovarian cycle in hypogonadal, castrate, or postmenopausal women.

It seems reasonable to deduce that repetitive, cyclical ovulation and menstruation are not the biological evolutionary norm. The relatively uncommon occurrence of menstruation among female chimpanzees living in the wild and among hunter-gatherer !Kung and Hutterite women is more likely to be representative of the biological norm. Recurrent ovulation and menstruation are the consequence of the more rapid intellectual than biological evolution of humans. Infertility can be chosen; but the physiological result, and the endocrinopathies that may accrue in women from this choice, is appreciable.

PREGNANCY ORGANIZATION: THE FETAL-MATERNAL COMMUNICATION SYSTEM

DEVELOPMENT OF THE FETAL-MATERNAL COMMUNICATION SYSTEM

Ovulation is dependent upon brain-pituitary-ovarian interactions. After conception, the establishment and maintenance of human pregnancy is driven by the blastocyst and then the embryonic-fetal and extraembryonic tissues. A biomolecular communication system is established between the zygote-blastocyst-embryo-fetus and the mother that is operative from before nidation and continues through parturition and beyond. By way of breast feeding, this communication persists during infancy; and through maternal-infant bonding, a communication system between mother and child, in some form, may be created that is lifelong.

In the past, this communication system was believed to be unidirectional, delivering nutritive supplies from mother to fetus. It was presumed that the mother provided nutrients that were effectively taken up by the trophoblasts and transferred to the embryo-fetus. It is now known that numerous fetal messages are sent toward the mother in this bidirectional communication system.

The fetal-maternal communication system is essential for the success of blastocyst implantation, maternal recognition of pregnancy, immunological acceptance of the conceptus, the maintenance of pregnancy, maternal adaptations to pregnancy, fetal nutrition and maturation, and perhaps for the initiation of parturition. These physiological processes evolve primarily from embryonic-fetal tissue-directed modifications of maternal responses.

There are two major anatomical and functional arms of the fetal-maternal communication system. One is the **placental arm**, the functional components of which include nutritive, endocrine, and immunological processes. The other is the **paracrine arm**, the functional components of which include pregnancy maintenance, immunological acceptance, amniotic fluid volume homeostasis, and physical protection of the fetus ([Fig. 2-2](#)).

The placental arm of the fetal-maternal communication system is established by two factors. The first is the supply of maternal blood to the placental intervillous space via the endometrial/decidual spiral arteries. Maternal blood leaves these vessels and directly bathes the villous syncytiotrophoblast. The second factor is the fetal blood, which is confined within the capillaries that traverse within the intervillous spaces of the placental villi.

The paracrine arm of the communication system is established by direct cell-to-cell contact and biomolecular trafficking between fetal membranes (chorion laeve) and maternal decidua parietalis. In turn, the amnion, the innermost avascular fetal membrane, which is contiguous with the chorion laeve on the outer surface and bathed by the amniotic fluid on the inner surface, also is a component of this paracrine system. Amniotic fluid is rich in fetal excretions (kidney) and secretions (lung, skin), and provides for a unique but direct signal transmission system between the fetus and mother.

ORGANIZATION OF THE FETAL-MATERNAL COMMUNICATION SYSTEM

At the very commencement of pregnancy, at the time of blastocyst implantation, there is only one anatomically distinguishable communication link between blastocyst and mother. This is established between the trophoblast of the blastocyst and the uterine endometrium (decidua) and then maternal blood. Even this early, the functional progenitors of the two mature arms of the communication system have begun.

PLACENTAL ARM: NUTRIENT TRANSFER AND ENDOCRINE SYSTEM. The placenta (villous trophoblast; syncytium) becomes the principal site of nutrient transfer between mother and fetus. The placenta also is the principal endocrine tissue of pregnancy, albeit one that is highly dependent upon the provision of blood-borne, preformed maternal and fetal precursors for placental steroid hormone formation ([Chap. 6](#)). The proximal anatomical parts of the placental arm (nutrient transfer and endocrine function) of the fetal-maternal communication system are the fetal blood, the syncytium, and the maternal blood. Human placentation is hemochorioendothelial. The microvillar surface of the syncytiotrophoblast is bathed directly by maternal blood, but fetal blood is contained within fetal capillaries located in the villi of the placenta. Therefore, fetal blood is separated from the syncytiotrophoblast by the wall of the fetal capillaries, the mesenchyme in the villous space, and the cytotrophoblasts ([Chap. 5](#)). Importantly, fetal and maternal blood do not come into direct contact except in abnormal conditions.

PARACRINE ARM: FETAL MEMBRANES AND DECIDUA PARIETALIS. As the embryo and extraembryonic tissues grow, the amnion and chorion laeve develop as tough, avascular membranous structures that will come to lie adjacent to the entire surface of the decidua parietalis, that portion of decidua that is not occupied by the placenta ([Chap. 5](#)). This anatomical arrangement gives rise to the paracrine arm of the fetal-maternal communication system. The proximal anatomical parts of the paracrine arm of the fetal-maternal communication system are the amniotic fluid, amnion, chorion laeve, and decidua parietalis. Communication between fetus and mother through this paracrine arm is possible through constituents of amniotic fluid such as fetal urine and fetal lung secretions. In the reverse direction, decidual products as well as some maternal blood constituents enter amniotic fluid, and these products then can enter the fetus by fetal "inspiration" and swallowing of amniotic fluid. Some decidual products, such as prolactin ([Chap. 5](#)), preferentially enter the amniotic fluid. In addition, potent vasoactive peptides and growth factors are synthesized in the amnion, enter amniotic fluid, and are available to the fetus.

DYNAMIC ROLE OF THE FETUS IN PREGNANCY

In the past, the fetus was envisioned as a passive passenger of the pregnancy unit; but nothing could be further from the truth. It is important to recognize that whereas the embryo-fetus enjoys a position of protection from the external environment that is never to be experienced again in life, it is the dynamic force in the orchestration of its own destiny. The chemical impetus for implantation is provided by the trophoblasts and blastocyst products; invasion of the maternal endometrium and blood vessels is under the active direction of bioactive products synthesized in the trophoblasts; the maternal recognition of pregnancy is brought about by way of signals generated by the trophoblasts that act upon the maternal ovary; the immunological acceptance of the semiallogenic tissues of the conceptus is modulated by the regulation of human lymphocyte antigen (HLA) expression by trophoblasts; the maintenance of pregnancy is directed by fetal contributions to steroid hormone

formation in the trophoblast; the maternal physiological changes of pregnancy are promoted by products formed and secreted by the placenta; and, indeed, it even is possible that the fetus initiates parturition at term ([Chap. 11](#)). From these multiple interactions, molecular trafficking and signal transmission/response between tissues of the fetus and its mother are clear ([Fig. 2-3](#)).

IMPLANTATION. Fertilization of the human ovum by a spermatozoan occurs in the fallopian tube within a short time (minutes to at most a few hours) after ovulation. By 6 days after fertilization, the blastocyst begins to implant in the endometrium. Clearly, the endometrium is not essential to implantation. The blastocyst sometimes is implanted in the fallopian tube, ovary, peritoneal cavity, or even in the spleen; and in experimental studies, it can be implanted successfully into many tissues, including the testis.

Thus, it is the blastocyst (trophoblast) that is the driving force in implantation. There are neoplastic and inflammatory processes involved in blastocyst implantation; the blastocyst produces or else provokes the formation of prostaglandins, platelet-activating factor, and plasminogen activator. In fact, complete decidualization of endometrium in human pregnancy takes place only after blastocyst implantation. The trophoblasts produce metalloproteinases that effect degradation of the endometrial extracellular matrix proteins in a manner similar to that of metastasizing neoplastic cells. Selected cytotrophoblasts (Langhans cells) express an unusual monomeric class I (HLA-G) antigen ([Chap. 5, p. 90](#)).

FETAL-INDUCED MATERNAL RECOGNITION OF PREGNANCY. Among the early physiological arrangements provided by the fetal-maternal communication system is one referred to by [Short \(1969\)](#) as the maternal recognition of pregnancy. This is an extraordinarily important concept in mammalian pregnancy physiology. This arrangement, however, likely should be redesignated, as the fetal-induced maternal recognition of pregnancy. There is no doubt that there is maternal recognition of pregnancy, but this recognition is evoked by fetal signals.

The maternal recognition of pregnancy encompasses a series of processes that culminate in:

1. Prolongation of the life span of the corpus luteum with continued progesterone secretion.
2. Modifications of the trophoblast expression of major histocompatibility complex (HLA) antigens to facilitate maternal tissue acceptance of the fetal graft ([Bazer and colleagues, 1986](#)).

Chorionic gonadotropin (hCG), produced by trophoblasts, acts to "**rescue**" or **maintain the corpus luteum**, to promote continued progesterone formation by the ovary until such time as the placenta is able to synthesize sufficient amounts of progesterone to maintain pregnancy ([Chaps. 6 and 11](#)).

There also is appreciable evidence, largely based on findings in sheep, that mammalian blastocysts and embryos produce agents, called trophoblast proteins—with similarities to interferons—that effect **decidual quiescence**, thus facilitating the maintenance of pregnancy ([Godkin and co-workers, 1984](#); [Hansen and colleagues, 1985](#); [Imakawa and associates, 1987](#); [Li and Roberts, 1994](#)).

CORPUS LUTEUM AND PREGNANCY. The duration of corpus luteum function during early pregnancy has been the subject of many investigations. During infertile ovarian cycles, the corpus luteum produces progesterone in prodigious amounts for only about 1 week. Thereafter, in the next 5 to 6 days of infertile ovarian cycles, the rate of secretion of progesterone by the corpus luteum declines, reaching a nadir about 12 to 14 days after ovulation.

PROGESTERONE SECRETION. With blastocyst implantation, the corpus luteum of menstruation is "rescued" by the action of hCG (and probably other factors originating in the blastocyst). As a result, progesterone synthesis is continued, but for only a relatively short time in the human. It is generally agreed that progesterone produced by the corpus luteum during the first 8 weeks (menstrual age) of human gestation is important for the **maintenance of pregnancy**. Thereafter, progesterone synthesis in the syncytiotrophoblast becomes dominant, as progesterone secretion by the corpus luteum declines between 6 and 8 weeks. Sometimes, however, with removal of the corpus luteum—usually because of bleeding from this structure—from the ovary prior to 10 weeks, pregnancy can still be maintained with intramuscular injection of 17-hydroxyprogesterone caproate (150 mg). This agent is chosen because:

1. The duration of action is predictable.
2. Rarely, if ever, does such treatment lead to virilization of a female fetus.
3. It can be given intramuscularly.

Between 8 and 10 weeks, the progestin is administered only at the time of surgery. Between 6 and 8 weeks, there may be some merit in a second injection of the progestin 1 week after surgery.

FETAL CONTRIBUTIONS TO MATERNAL ACCEPTANCE OF THE SEMIALLOGENIC FETAL GRAFT. Just after, or at about the time of blastocyst implantation, the expression of major histocompatibility complex (HLA) antigens is suppressed in extraembryonic fetal tissues (trophoblasts)—that is, in tissues that directly contact maternal tissues. This may be the most critical mechanism by which the blastocyst and embryo-fetus gain immunological acceptance by maternal tissues. As described in [Chapter 5](#), the trophoblasts form an uninterrupted shell around the embryo such that, normally, maternal tissues never come into direct contact with blood or other tissues of the embryo-fetus.

FETAL CONTRIBUTIONS TO THE ENDOCRINOLOGY OF PREGNANCY. The hormonal changes of human pregnancy—in breadth and amount—are monumental and unmatched in endocrinology and endocrinopathology. Without exception, the endocrine changes of human pregnancy evolve as the consequence of embryonic-fetal-placental function, either directly or indirectly; thus, the conceptus is also responsible for the endocrine milieu of human pregnancy. The formation of estrogens during pregnancy takes place by way of the placental aromatization (the enzymatic reaction essential for estrogen synthesis) of C₁₉-steroids, which in turn are produced primarily in the fetal adrenal glands. Progesterone also is produced in the syncytium in massive quantities, but by way of the use of maternal plasma low-density lipoprotein (LDL) cholesterol. Indeed, the rate of trophoblast consumption of maternal plasma LDL for progesterone formation at term is so great in some pregnancies that it is equivalent to the total daily turnover of LDL in nonpregnant women ([Chap. 6](#)). But even in capturing LDL cholesterol, the fetus is aggressive and efficient. Placental hydrolysis of the LDL cholesteryl esters yields essential fatty acids, and the hydrolysis of the LDL apoprotein gives free amino acids, including essential amino acids.

Progesterone secreted by syncytium is converted to deoxycorticosterone, a potent mineralocorticosteroid, in extraadrenal maternal and fetal tissues. Placental progesterone, secreted into the maternal compartment, also serves indirectly, by way of increased angiotensin II formation, as the stimulus for increased maternal adrenal aldosterone secretion to a rate 20 times or more than that in men and nonpregnant women. Increased mineralocorticosteroid formation (aldosterone and deoxycorticosterone) is essential for normal blood volume expansion ([Chap. 8](#)). All of these endocrine changes, and many more, are effected by way of fetal tissue-produced or fetal tissue hormone-induced endocrine changes of normal human pregnancy ([Chap. 6](#)).

PLACENTAL SEQUESTRATION OF NUTRIENTS. Fetal villous syncytiotrophoblast is remarkably efficient in extracting and sequestering essential nutrients from maternal circulation ([Chap. 7](#)). In pregnant women with profound iron-deficiency anemia, for example, the iron stores of the fetus are normal; in pregnant women with severe folic acid deficiency causing severe anemia, the fetal hematocrit is normal. The fetus is a demanding and efficient parasite! We have long been fascinated by the observation that the amount of calcium assembled into the shell of the egg of the chicken in a period of 18 hours is equivalent to the amount of calcium contained in the entire bony skeleton of the hen. Thus, even in the avian, a species that arguably is never pregnant (no implantation), the demands of the embryo are met at whatever cost to the maternal organism.

FETAL RETREAT FROM PARTICIPATION IN PREGNANCY MAINTENANCE: INITIATION OF PARTURITION. The fetus also may be in control of its own destiny with respect to the timely onset of parturition. This may come about by way of fetal-induced retreat from the continued maintenance of the remarkable uterine quiescence that characterizes the first 90 to 95 percent of normal pregnancy (phase 0 of parturition; see [Chap. 11](#)). The importance of the fetus in the maintenance of pregnancy and in the initiation of parturition can be understood by the natural outcome of many pregnancies after fetal death. After the fetus has died, labor may not immediately ensue; pregnancy may continue for days, weeks, or even months before spontaneous labor begins. It has been observed that with fetal death caused by Rh isoimmunization before 35 weeks, 50 percent of these pregnancies remain undelivered, in the absence of intervention, for up to 5 weeks ([Townsend and Shelton, 1964](#)). After removal of the fetus in rhesus monkey pregnancy, with the placenta left in situ, the placenta does not deliver spontaneously until sometime well after the expected due date of the pregnancy ([Nathanielsz and associates, 1992](#)). It seems that in response to death or removal of the fetus, there is no built-in mechanism for emptying the uterus through processes independently initiated within the maternal compartment. Spontaneous delivery in these circumstances may come about only with "progesterone withdrawal," which may eventuate with degeneration of the placenta after prolonged absence of fetal-placental blood flow.

FETAL AND NEWBORN CONTRIBUTIONS TO LACTATION AND MILK LET-DOWN. During pregnancy, estrogen and progesterone, together with prolactin and cortisol, act on maternal mammary tissues to induce optimal morphological and biochemical maturational processes that prepare the breasts for lactation. Progesterone also acts, however, to prevent lactogenesis itself; but with progesterone withdrawal after delivery of the placenta, lactogenesis promptly commences. Thereafter, newborn suckling induces episodic oxytocin secretion from the maternal neurohypophysis-posterior pituitary; and oxytocin acts on the myoepithelial cells of the breast ducts to cause milk let-down. Clearly, the fetus-infant acts to ensure its own survival.

These are but a few examples to indicate unambiguously that the embryo-fetus, extraembryonic fetal tissues, or both, direct the orchestration of the physiological adaptations of pregnancy. The maternal organism passively responds—even at times to her own detriment. Each of these arrangements will be referred to frequently: acceptance of the fetal semiallogenic graft ([Chap. 5](#)), the endocrinology of pregnancy ([Chap. 6](#)), fetal growth and development ([Chap. 7](#)), the physiological adaptations of maternal systems to pregnancy ([Chap. 8](#)), and the initiation of parturition ([Chap. 11](#)). The embryo-fetus-extraembryonic tissue initiatives that promote the success of pregnancy are summarized in [Figure 2-3](#).

DIAGNOSIS OF PREGNANCY

Pregnancy is a physiological state, but the importance of the diagnosis of pregnancy cannot be overstated. In the life of women, few diagnoses are more important than that of pregnancy. There are few life experiences that can evoke emotions of such absolute joy or else such pains of profound despair. Moreover, for all physicians entrusted with the medical management of women of reproductive age, knowledge of the existence of pregnancy is crucial to the proper diagnosis and treatment of all disease processes. Every physician who assumes the responsibility for the medical care of women of reproductive age, irrespective of the nature of the physician's practice or special interest, must always consider the question: Is she pregnant? Failure to do so may lead to incorrect diagnoses, inappropriate treatments, and, at times, medicolegal embroilment.

Many of the manifestations of the normal physiological adaptations of pregnancy are easily recognized and constitute important clues to the diagnosis of pregnancy and the evaluation of pregnancy progress. Some of these pregnancy changes are predictable with sufficient timeliness to constitute important milestones that verify the gestational age of the fetus. Meanwhile, the woman physiologically accommodates to the growth, maturation, and function of the uterus and conceptus.

The diagnosis of pregnancy is ordinarily very easy to establish; but unfortunately, this is not always the case. On occasion, pharmacological or pathophysiological processes may induce endocrine or anatomical changes that mimic those of pregnancy, causing confusion for the woman and sometimes the physician. At times, therefore, the diagnosis of pregnancy is not easy to make; but rarely is it impossible if appropriate clinical and laboratory tests are carefully conducted and evaluated.

Ordinarily, the woman is aware of the likelihood, or at least the possibility, of pregnancy when she consults a physician, although she may not volunteer this information unless questioned specifically. Mistakes in diagnosis of pregnancy are made most frequently in the first several weeks of pregnancy, while the uterus is still a pelvic organ. Although it is possible to mistake the enlarged uterus of pregnancy, even at term, for a tumor of some nature, such errors commonly are the result of a hasty or incomplete examination.

The endocrinological, physiological, and anatomical alterations that accompany pregnancy give rise to symptoms and signs that provide evidence that pregnancy exists. These symptoms and signs are classified into three groups: presumptive evidence, probable signs, and positive signs of pregnancy.

PRESUMPTIVE EVIDENCE OF PREGNANCY

Presumptive evidence of pregnancy is based largely on subjective symptoms that include:

1. Nausea with or without vomiting.
2. Disturbances in urination.
3. Fatigue.
4. The perception of fetal movement.

Presumptive signs include:

1. Cessation of menses.
2. Changes in the breasts.
3. Discoloration of the vaginal mucosa.
4. Increased skin pigmentation and the development of abdominal striae.
5. Especially important, does the woman believe that she is pregnant?

SYMPTOMS OF PREGNANCY. There are a number of symptoms that frequently alert the parous woman to an early pregnancy.

NAUSEA WITH OR WITHOUT VOMITING. Pregnancy is commonly characterized by disturbances of the digestive system, manifested particularly by nausea and vomiting. This so-called morning sickness of pregnancy usually commences during the early part of the day but passes in a few hours, although occasionally it persists longer and may occur at other times. This disturbing symptom usually begins about 6 weeks after the commencement (first day) of the last menstrual period, and ordinarily disappears spontaneously 6 to 12 weeks later. The cause of this disorder is unknown but seems to be associated with higher levels of selected forms of hCG (variations in glycosylation) with the greatest thyroid-stimulating capacity. Chorionic gonadotropin, especially isoforms with relatively diminished amounts of sialic acid, act via the thyroid-stimulating hormone (TSH) receptor to accelerate iodine uptake ([Chap. 6](#)).

DISTURBANCES IN URINATION. During the first trimester, the enlarging uterus, by exerting pressure on the urinary bladder, may cause frequent micturition. As pregnancy progresses, the frequency of urination gradually diminishes as the uterus rises up into the abdomen. The symptom of frequent urination reappears near the end of pregnancy, however, when the fetal head descends into the maternal pelvis, impinging upon the volume capacity of the bladder.

FATIGUE. Easy fatigability is such a frequent characteristic of early pregnancy that it provides a noteworthy diagnostic clue.

PERCEPTION OF FETAL MOVEMENT. Sometime between 16 and 20 weeks (menstrual age), the pregnant woman becomes conscious of slight fluttering movements in the abdomen, and these movements gradually increase in intensity. These sensations are caused by fetal movements, and the day that these are first recognized by the pregnant woman is designated as **quickening**, or the perception of life. This sign provides only corroborative evidence of pregnancy, however, and in itself is of little diagnostic value. Quickening is, nonetheless, a milestone of the progress of pregnancy that, if dated accurately, can provide corroborative evidence in establishing the duration of gestation.

SIGNS OF PREGNANCY. There are a number of clinical findings that frequently herald pregnancy.

CESSATION OF MENSES. The abrupt cessation of menstruation in a healthy reproductive-age woman who previously has experienced spontaneous, cyclical, predictable menses is highly suggestive of pregnancy. There is appreciable variation in the length of the ovarian (and thus menstrual) cycle among women, and even in the same woman. It is not until 10 days or more after the time of expected onset of the menstrual period, therefore, that the absence of menses is a reliable indication of pregnancy. When a second menstrual period is missed, the probability of pregnancy is much greater.

Although cessation of menstruation is an early and important indication of pregnancy, conception may occur without prior menstruation, that is, in a girl before menarche. In certain Asian countries, where girls marry at a very early age, and in sexually promiscuous groups, pregnancy sometimes commences before menarche. Nursing mothers, who usually sustain amenorrhea during lactation because of lactation-induced hypogonadism and anovulation, sometimes ovulate and conceive at

that time; and more rarely, women who believe they have passed the menopause may ovulate again after a few months of anovulation/amenorrhea and become pregnant.

Uterine bleeding somewhat suggestive of menstruation occurs occasionally after conception. One or two episodes of bloody discharge, somewhat reminiscent of and sometimes misinterpreted as menstruation, are not uncommon during the first half of pregnancy. Almost always, however, such bleeding is brief and scant. In a series of 225 consecutive pregnant women who did not abort, [Speert and Guttmacher \(1954\)](#) observed that macroscopical vaginal bleeding, which occurred between the time of conception and the 196th day of pregnancy, was reported by 22 percent of these women. In the absence of cervical lesions, bleeding began on or before the 40th day of pregnancy in 8 percent. These investigators interpreted these bleeding episodes to be "physiological," that is, the consequence of blastocyst implantation. Bleeding during pregnancy was three times more frequent among multiparas than among primigravidas. Of 83 multiparas, 25 percent experienced bleeding. Alleged instances of women having "menstruated" every month throughout pregnancy are incorrect; true uterine bleeding during pregnancy is undoubtedly the result of some abnormality of the reproductive organs. Bleeding per vagina at any time during pregnancy must be regarded as abnormal and portends an increased likelihood of serious pregnancy complications.

Cessation of menstruation can be caused by a number of conditions other than pregnancy. The most common cause of a delay in the time of onset of the expected next menstrual period (other than pregnancy) is anovulation. This, in turn, may be the consequence of a number of factors that include severe illness and physiological aberrations induced by emotional disorders, including the fear of pregnancy. Environmental changes as well as a variety of chronic disease processes also may suppress menstruation by causing anovulation. Delays in the onset of menstruation also have been attributed to persistent function of a cystic corpus luteum; but the evidence for such an entity is not convincing. Most, if not all, instances of prolonged function of the corpus luteum, we believe, are caused by a pregnancy episode, even though the pregnancy may be unrecognized, as in the case of early missed or incomplete abortion or undiagnosed ectopic pregnancy.

CHANGES IN CERVICAL MUCUS. If cervical mucus is aspirated, spread on a glass slide, allowed to dry for a few minutes, and examined microscopically, characteristic patterns can be discerned that are dependent on the stage of the ovarian cycle and the presence or absence of pregnancy, that is, on progesterone secretion in large amounts. From about the 7th to about the 18th day of the menstrual cycle, a fernlike pattern of dried cervical mucus is seen ([Fig. 2-4](#)). It is sometimes called a process of arborization or the palm leaf pattern. After approximately the 21st day, this fern pattern does not develop, but rather there is a quite different pattern that forms, giving a beaded or cellular appearance ([Fig. 2-5](#)). This pattern also is usually encountered in pregnancy. The crystallization of the mucus, which is necessary for the production of the fern, or arborized pattern, is dependent upon the concentration of electrolytes, principally sodium chloride, in the secretion. In general, a concentration of sodium chloride of 1 percent is required for the full development of a fern pattern; below that concentration, either a beaded pattern or an atypical or incomplete arborization is seen.

The concentration of sodium chloride, and in turn the presence or absence of the fern pattern, is determined by the response of the cervix to hormonal action. Whereas the cervical mucus is relatively rich in sodium chloride when estrogen, but not progesterone, is being produced, the secretion of progesterone (even without a reduction in the rate of secretion of estrogen) promptly acts to lower the sodium chloride concentration to levels at which ferning will not occur. During pregnancy, progesterone usually exerts a similar effect, even though the amount of estrogen produced is enormous compared with that produced during a normal ovarian cycle.

If copious thin mucus is present and if a fern pattern develops on drying, early pregnancy is very unlikely, and the woman almost certainly will experience uterine bleeding after treatment with and withdrawal of progestin. If relatively little cervical mucus is present and a highly cellular pattern forms, she may or may not be pregnant. If not pregnant, she may or may not sustain uterine bleeding after receiving progestin, depending upon her own supply of endogenous progesterone. Moreover, there is fear that progestins are potential teratogens ([Chap. 38, p. 1017](#)). Therefore, progestins should not be administered to women who are believed to be pregnant except in unusual circumstances, such as that discussed earlier concerning surgical removal of the corpus luteum before completion of 8 weeks.

CHANGES IN THE BREASTS. Generally, the anatomical changes in the breasts that accompany pregnancy are quite characteristic in primiparas. These are less obvious in multiparas, whose breasts may contain a small amount of milky material or colostrum for months or even years after the birth of their last child, especially if breast feeding was chosen. Occasionally, changes in the breasts similar to those caused by pregnancy are found in women with prolactin-secreting pituitary tumors, and in women taking prescribed drugs such as most commonly prescribed anxiolytic agents like benzodiazepines, which induce hyperprolactinemia. Instances of similar breast changes in women with spurious or imaginary pregnancy also have been reported as discussed subsequently.

DISCOLORATION OF THE VAGINAL MUCOSA. During pregnancy, the vaginal mucosa usually appears dark bluish or purplish-red and congested; this is the so-called **Chadwick sign** ([Chadwick, 1886](#)). This appearance is presumptive evidence of pregnancy, but it is not conclusive. Similar changes in the appearance of the vaginal mucosa may be induced by any condition that causes intense congestion of the pelvic organs.

INCREASED SKIN PIGMENTATION AND APPEARANCE OF ABDOMINAL STRIAE. These cutaneous manifestations are common to, but not diagnostic of pregnancy. They may be absent during pregnancy; conversely, these changes can occur with the ingestion of estrogen-progestin contraceptives.

PROBABLE EVIDENCE OF PREGNANCY

The probable signs of pregnancy include:

1. Enlargement of the abdomen.
2. Changes in the shape, size, and consistency of the uterus.
3. Anatomical changes in the cervix.
4. Braxton Hicks contractions.
5. Ballotement.
6. Physical outlining of the fetus.
7. Presence of chorionic gonadotropin in urine or serum.

ENLARGEMENT OF THE ABDOMEN. By 12 weeks, the uterus usually is palpable through the abdominal wall as a tumor just above the symphysis; thereafter, the uterus gradually increases in size until the end of pregnancy. Any enlargement of the abdomen in women during the childbearing period is strongly suggestive of pregnancy. Abdominal enlargement in nulliparous women may be less pronounced than in multiparous women, in whom some of the abdominal muscle tone was lost during previous pregnancies. Indeed, the abdominal wall in some multiparous women is so flaccid that the uterus sags forward and downward, producing a pendulous abdomen. This difference in abdominal tone between first and subsequent pregnancies is sometimes so obvious that women in the latter part of a second pregnancy commonly suspect a twin pregnancy because of the apparent greater size of their abdomen, as compared with their previous pregnancy. The abdomen of the pregnant woman also undergoes significant changes in shape depending on the woman's body position. The uterus is much less prominent, of course, when the pregnant woman is in the supine position.

CHANGES IN SIZE, SHAPE, AND CONSISTENCY OF THE UTERUS. During the first few weeks of pregnancy, the increase in size of the uterus is limited principally to the anteroposterior diameter, but a little later in gestation, the body of the uterus is almost globular; an average uterine diameter of 8 cm is attained by 12 weeks. On bimanual examination, the body of the uterus during pregnancy feels doughy or elastic and sometimes becomes exceedingly soft. At about 6 to 8 weeks after the onset of the last menstrual period, the **Hegar sign** becomes evident. With one hand of the examiner on the abdomen and two fingers of the other hand placed in the vagina, the still-firm cervix is felt, with the elastic body of the uterus above the compressible soft isthmus, which is between the two. Occasionally, the softening at the isthmus is so marked that the cervix and the body of the uterus seem to be separate organs. At this time in pregnancy, the inexperienced examiner may mistakenly conclude that the cervix is a small uterus, and that the softened body of the fundus is an adnexal mass. This sign is not, however, positively diagnostic of pregnancy, because occasionally it may be present when the walls of the uterus of a nonpregnant woman are excessively soft for reasons other than pregnancy.

CHANGES IN THE CERVIX. By 6 to 8 weeks, the cervix usually is considerably softened. In primigravidas, the consistency of cervical tissue that surrounds the external os is more similar to that of the lips of the mouth than to that of the nasal cartilage, which is characteristic of the cervix in nonpregnant women. Other conditions, however, may cause softening of the cervix, such as estrogen-progestin contraceptives. As pregnancy progresses, the cervical canal may become sufficiently patulous to admit the fingertip. In certain inflammatory conditions, as well as with carcinoma, the cervix may remain firm during pregnancy, yielding only

with the onset of labor, if at all.

BRAXTON HICKS CONTRACTIONS. During pregnancy, the uterus undergoes palpable but ordinarily painless contractions at irregular intervals from the early stages of gestation. These contractions, referred to as Braxton Hicks contractions, may increase in number and amplitude when the uterus is massaged. These are not, however, positive signs of pregnancy, because similar contractions are sometimes observed in uteri of women with hematomata and occasionally in the uterus in which there are soft myomas, especially those of the pedunculated, submucous variety. The detection of Braxton Hicks contractions, however, may be helpful in excluding the existence of an ectopic abdominal pregnancy. In the last few days of pregnancy, the frequency of contractions increases, especially during nighttime hours. This is associated with uterine preparedness for labor, that is, phase 1 of parturition ([Chap. 11, p. 265](#)).

BALLOTTEMENT. Near midpregnancy, the volume of the fetus is small compared with that of amniotic fluid. Consequently, sudden pressure exerted on the uterus may cause the fetus to sink in the amniotic fluid and then rebound to its original position; the tap produced (ballottement) is felt by the examining fingers.

OUTLINING THE FETUS. In the second half of pregnancy, the outlines of the fetal body may be palpated through the maternal abdominal wall, and the outlining of the fetus becomes easier the nearer that term is approached. Occasionally, subserous myomas may be of such a size and shape as to simulate the fetal head, small parts, or both, thus causing serious diagnostic errors. Therefore, a positive diagnosis of pregnancy cannot be made from this sign alone.

DETECTION OF CHORIONIC GONADOTROPIN. The presence of chorionic gonadotropin (hCG) in maternal plasma and its excretion in urine provides the basis for the endocrine tests for pregnancy. This hormone can be identified in body fluids by any one of a variety of immunoassay or bioassay techniques.

Chorionic gonadotropin is important for maternal recognition of pregnancy because it acts to "rescue" the corpus luteum, the principal site of progesterone formation during the first 6 weeks. It prevents corpus luteum involution. It also is a luteinizing hormone (LH)-like agent that acts as a surrogate in responsive tissues, such as the ovary (corpus luteum) and testis (Leydig cells). Specifically, hCG acts by way of the plasma membrane LH receptor.

As discussed in [Chapter 6 \(p. 110\)](#), hCG is a glycoprotein with a high carbohydrate content; the molecule is a heterodimer composed of two dissimilar subunits, designated **a** and **β**, which are noncovalently linked. These subunits have been separated and isolated in pure form, the primary structure of each has been characterized, and the genes encoding these subunits have been analyzed in appreciable detail.

LEVELS OF hCG IN PREGNANCY. The hormone is produced exclusively by the syncytiotrophoblast, not by cytotrophoblast. Production begins very early in pregnancy, almost certainly by the day of implantation. Thereafter, hCG levels in maternal plasma and urine rise very rapidly. With a sensitive test, it can be detected in maternal plasma or urine by 8 to 9 days after ovulation. The doubling time of plasma hCG concentration is 1.4 to 2.0 days ([Chartier and colleagues, 1979](#)). Levels increase from the day of implantation to reach peak levels at about 60 to 70 days. Thereafter, the concentration declines slowly until a nadir is reached at about 100 to 130 days ([Fig. 2-6](#)).

PREGNANCY TESTS. There are a number of inexpensive, commercially available kits for pregnancy testing. They can be completed in 3 to 5 minutes, with high accuracy and, with certain precautions, high precision. Many different test systems are available in kit form; each, however, is dependent upon the same principle: recognition of hCG (or a subunit) by an antibody to the hCG molecule or epitopes of the β -subunit. Nearly 15 years ago, [Bandi and colleagues \(1987\)](#) reported that there were 39 commercially available kits for *urine* pregnancy tests. By 1991, [Cole and Kardana \(1992\)](#) observed that there were more than 50 commercial kits for *serum* measurement.

With the recognition that LH and hCG were composed of an α - and a β -subunit, that the two subunits of each molecular species could be separated and purified, and that the β -subunits of each were structurally distinct, antibodies were developed with high specificity for the β -subunit of hCG. These have little or no discernible cross-reactivity against LH. They have been raised by immunization of animals (polyclonal antibodies) or by hybridoma techniques (monoclonal antibodies) against recognition sites on the β -subunit of hCG. Immunogenicity of gonadotropin subunits is very great, and vaccines that prevent pregnancy have been developed using human β -hCG as a heterospecies dimer with the α -subunit of ovine LH ([Talwar and co-workers, 1994](#)).

IMMUNOASSAYS WITHOUT RADIOISOTOPES. In many immunoassay procedures, the principle of **agglutination inhibition** is used. This involves prevention of flocculation of hCG-coated particles, such as latex, to which hCG is covalently bound. The commercially available kits contain two reagents. One is a suspension of latex particles coated with or covalently bound to hCG, and the other contains a solution of hCG antibody. To test for hCG, one drop of urine is mixed with one drop of the antibody-containing solution on a black glass slide. If hCG is not present in the test sample, antibody will remain available to agglutinate the hCG-coated latex particles, which are added subsequently. Agglutination of the latex particles can be easily observed. If hCG were present in the urine, it would bind to the antibody and thus prevent antibody-induced agglutination of the hCG-coated latex particles. Therefore, the pregnancy test is positive if no agglutination occurs; the pregnancy test is negative when agglutination occurs.

The **enzyme-linked immunosorbent assay (ELISA)** is useful for quantification of extremely small amounts of hormone. The [ELISA¹](#) test uses a monoclonal antibody bound to a solid-phase support (usually plastic), which binds the hCG in the test sample. A second antibody is added to "sandwich" the test sample hCG. It is the second antibody to which an enzyme, such as alkaline phosphatase, is linked. When substrate for this enzyme is added, a blue color develops, the intensity of which is proportional to the amount of enzyme and thus to the amount of second antibody bound. This, in turn, is a function of the amount of hCG in the test sample. The sensitivity of ELISA for hCG in serum is 50 mIU per mL.

The **immunofluorometric assay (IFMA)** uses photon emission from a fluorescent label to provide sensitivity almost comparable with that of radioimmunoassay. The assays are sufficiently sensitive to detect hCG, presumably of anterior pituitary origin, in serum of postmenopausal women ([Tyrey, 1995](#)).

IMMUNOASSAYS OF hCG USING RADIOISOTOPES. In the classical **radioimmunoassay (RIA)**, [¹²⁵I] iodo-hCG is used as the radiolabeled ligand for antibodies against hCG. This assay is dependent upon displacement of, or competition with, the radiolabeled ligand by nonradiolabeled hCG in the biological sample tested. In radioimmunoassays, "free" and "bound" [¹²⁵I] iodo-hCG are separated and the unbound radioactivity is assayed. By construction of standard curves, hCG is quantified with great accuracy and sensitivity.

The **immunoradiometric assay (IRMA)** is characterized by the use of antibody (binding sites) in excess as the radiolabeled material, rather than the ligand (hCG). One approach is the use of two antibodies that recognize separate epitopes on the hCG. One antibody, connected to a solid support, is used to capture the hCG from the sample. The second antibody is the radiolabeled probe and functions to quantify the captured ligand. Immunoradiometric assays also can be specific for the β -subunit of hCG.

ACCURACY. In a multicenter collaborative study sponsored by the National Institutes of Health, [Jovanovic and associates \(1987\)](#) found that laboratories conducting routine clinical tests could detect hCG accurately at the time of first "missed" menses, but not necessarily before this time.

QUANTIFICATION OF hCG. Precise quantification of hCG in biological fluids is important in the management of some conditions. These include pregnancy monitoring to exclude ectopic pregnancy and to evaluate the course and treatment of neoplastic trophoblastic disease. By use of very sensitive radioimmunoassays, hCG can be detected even in many normal persons, presumably because this small amount of hCG arises by pituitary secretion.

HOME PREGNANCY TESTS. A number of relatively inexpensive over-the-counter pregnancy test kits are available. In several, the principle of hemagglutination inhibition using sheep erythrocytes and antibodies to hCG is used to test a urine sample. Home pregnancy-testing kits are one-step tests. Essential features are the use of:

1. An absorbent wick that is held in contact with a porous membrane, which contains three separate zones of antibody.
2. The principles of immunochromatography.

The first zone of antibody is deposited so as to be mobilizable; it consists of colored latex particles sensitized with monoclonal antibodies to the β -subunit of hCG, which is immobilized in the membrane. If the urine contains hCG, it will react with the anti- β -hCG on the latex, and this will be trapped by the second, anti- β -subunit hCG zone antibody, causing the formation of a colored line in the large window ([May, 1991](#)).

In early studies, the false-negative rate was about 25 percent ([Valanis and Perlman, 1982](#)). Later, [Lee and Hart \(1990\)](#) showed that while tests were capable of 97 percent accuracy, this was only when done by trained technologists. [Bastian and colleagues \(1998\)](#) evaluated published results of 16 kits, of which only five met their

inclusion criteria. If testing was done by volunteers, a mean 91-percent sensitivity was obtained. Importantly, however, actual patients only obtained 75 percent sensitivity.

ECTOPIC PREGNANCY. Because hCG is present in plasma and urine of all women with ectopic pregnancies, its measurement has become indispensable as part of modern clinical management of these. This subject is discussed in detail in [Chapter 34](#).

POSITIVE SIGNS OF PREGNANCY

The three positive signs of pregnancy are:

1. Identification of fetal heart action separately and distinctly from that of the pregnant woman.
2. Perception of active fetal movements by the examiner.
3. Recognition of the embryo and fetus any time in pregnancy by sonographic techniques or of the more mature fetus radiographically in the latter half of pregnancy.

FETAL HEART ACTION. Hearing or observing the pulsations of the fetal heart assures the diagnosis of pregnancy. Fetal heart contractions can be identified by auscultation with a special fetoscope, by use of the Doppler principle with ultrasound, and by sonography.

The fetal heartbeat can be detected by auscultation with a stethoscope by 17 weeks, on average, and by 19 weeks in nearly all pregnancies in non-obese women ([Jimenez and co-workers, 1979](#)). The fetal heart rate at this stage and beyond ranges from 120 to 160 bpm and is heard as a double sound resembling the tick of a watch under a pillow. It is not sufficient merely to "hear" the "fetal" heart; it must be different from that of the maternal pulse. During much of pregnancy, the fetus moves freely in amniotic fluid, and consequently, the site on the maternal abdomen where fetal heart sounds can be heard best will vary.

Several instruments are available that make use of the Doppler principle to detect the action of the fetal heart. Ultrasound is directed toward moving fetal blood. The sound reflected by moving blood undergoes a frequency shift, the echo of which is detected by a receiving crystal immediately adjacent to the transmitting crystal. Because of the difference in heart rates, pulsatile flow in the fetus is easily differentiated from that of the mother unless there is severe fetal bradycardia or significant maternal tachycardia. Fetal cardiac action can be detected almost always by 10 weeks with appropriate Doppler equipment.

Echocardiography can be used to detect fetal heart action as early as 48 days after the first day of the last normal menses. Real-time sonography with a vaginal probe can detect fetal heart action as early as 5 weeks of amenorrhea.

In the later months of pregnancy, the examiner may often hear sounds other than those produced by fetal heart action. The most common of these are:

1. The funic (umbilical cord) souffle.
2. The uterine souffle.
3. Sounds resulting from fetal movement.
4. Maternal pulse.
5. Gurgling sounds produced by gas or liquid propulsion through the maternal intestine.

The funic souffle is caused by the rush of blood through the umbilical arteries. It is a sharp, whistling sound that is synchronous with the fetal pulse. It is inconstant, sometimes being recognizable distinctly at the time of one examination, but not found in the same pregnancy on other occasions.

The uterine souffle is heard as a soft, blowing sound that is synchronous with the maternal pulse. It is usually heard most distinctly during auscultation of the lower portion of the uterus. This sound is produced by the passage of blood through the dilated uterine vessels and is characteristic not only of pregnancy but of any condition in which the blood flow to the uterus is greatly increased. Accordingly, a uterine souffle may be heard in nonpregnant women with large uterine myomas or large ovarian tumors.

Frequently, the maternal pulse can be heard distinctly by auscultation of the abdomen; and in some women, the pulsation of the aorta is unusually loud. Occasionally during examination, the pulse of the mother may become so rapid as to simulate the fetal heart sounds.

PERCEPTION OF FETAL MOVEMENTS. Detection by the examiner of fetal movements can occur after about 20 weeks. Fetal movements vary in intensity from a faint flutter early in pregnancy to brisk motions at a later period; the latter are sometimes visible as well as palpable. Occasionally, somewhat similar sensations may be produced by contractions of the abdominal muscles or intestinal peristalsis, although these should not deceive an experienced examiner.

ULTRASONIC RECOGNITION OF PREGNANCY. The use of transvaginal sonography has revolutionized imaging of early pregnancy and its growth and development. A gestational sac may be demonstrated by abdominal sonography after only 4 to 5 weeks' menstrual age ([Fig. 2-7](#)). By 35 days, all normal sacs should be visible, and after 6 weeks, a heartbeat should be detectable ([American College of Obstetricians and Gynecologists, 1995](#)). By 8 weeks, the gestational age can be estimated quite accurately (see [Table 41-3](#)). Up to 12 weeks, the crown-rump length is predictive of gestational age within 4 days. This measurement is discussed in detail in [Chapter 41 \(p. 1114\)](#).

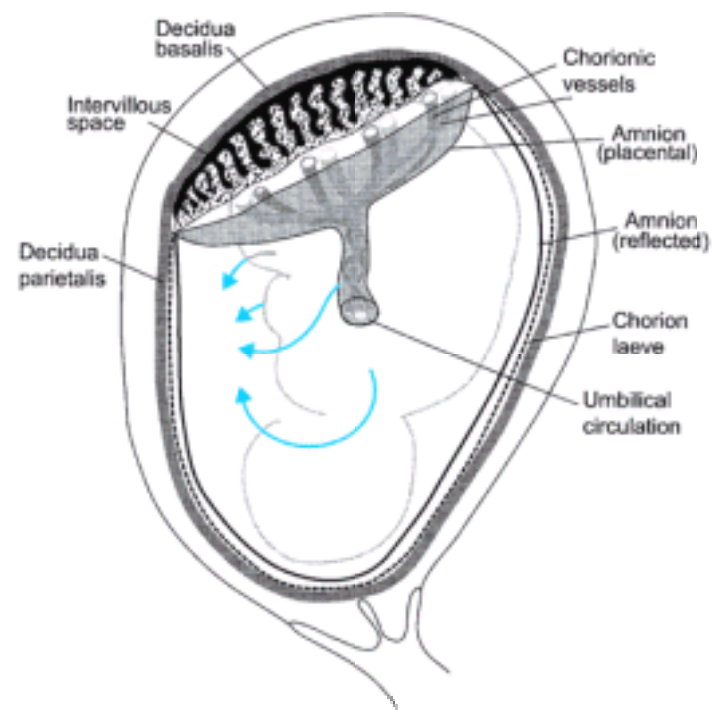

FIGURE 2-2. The fetal-maternal communication system. The proximal anatomical parts of the two arms of this system, the placental arm and the paracrine arm, are depicted. Fetal blood perfuses the placenta by way of the fetal villous capillaries. Maternal blood directly bathes the trophoblasts. Amniotic fluid, composed in large measure of fetal urine, and containing secretions from fetal lung and skin, bathes the avascular amnion, which is contiguous with avascular chorion laeve. The chorion laeve and decidua vera (parietalis) are in direct cell-to-cell contact. A trophoblastic "shell" separates the embryo-fetus from maternal cells and blood at all anatomical sites.

3. Anatomy of the Reproductive Tract

The organs of reproduction of women are classified as either external or internal. There may be marked variation in anatomical structures in a given woman, and this is especially true for major blood vessels and nerves.

EXTERNAL GENERATIVE ORGANS

The *pudenda*, or the external organs of generation, are commonly designated the *vulva*, which includes all structures visible externally from the pubis to the perineum, that is, the mons pubis, labia majora and minora, clitoris, hymen, vestibule, urethral opening, and various glandular and vascular structures ([Fig. 3-1](#)).

MONS PUBIS

The mons pubis, or mons veneris, is the fat-filled cushion that lies over the symphysis pubis. After puberty, the skin of the mons pubis is covered by curly hair that forms the *escutcheon*. Generally, the distribution of pubic hair differs in the two sexes. In women, it is distributed in a triangular area, the base of which is formed by the upper margin of the symphysis, and a few hairs are distributed downward over the outer surface of the labia majora. In men, the escutcheon is not so well circumscribed.

LABIA MAJORA

The labia majora are two rounded folds of adipose tissue that are covered with skin, and that extend downward and backward from the mons pubis. Among adult women, these structures vary somewhat in appearance, principally according to the amount of fat that is contained within these tissues. Embryologically, the labia majora are homologous with the male scrotum. The round ligaments terminate at the upper borders of the labia majora. After repeated childbearing, the labia majora are less prominent, and in old age usually begin to shrivel. Ordinarily, these structures are 7 to 8 cm in length, 2 to 3 cm in width, and 1 to 1.5 cm in thickness, and are somewhat tapered at the lower extremities. In children and nulliparous women ([Fig. 3-1](#)), the labia majora usually lie in close apposition, and thereby completely conceal the underlying tissues; whereas in multiparous women, the labia majora may gape widely. The labia majora are continuous directly with the mons pubis above and merge into the perineum posteriorly, at a site where these structures are joined medially to form the *posterior commissure*.

Before puberty, the outer surface of the labia is similar to that of the adjacent skin, but after puberty they are covered with hair. In nulliparous women, the inner surface is moist and resembles a mucous membrane; whereas in multiparous women, the inner surface becomes more skinlike but is not covered with hair. The labia majora are richly supplied with sebaceous glands. Beneath the skin, there is a layer of dense connective tissue that is rich in elastic fibers and adipose tissue but is nearly void of muscular elements. Unlike the squamous epithelium of the vagina and cervix, there are epithelial appendages in parts of the vulvar skin. Beneath the skin, there is a mass of fat, which provides the bulk of the volume of the labium; this tissue is supplied with a plexus of veins that, as the result of injury, may rupture to create a hematoma.

LABIA MINORA

Two flat, reddish folds of tissue are visible when the labia majora are separated. These structures are the labia minora, or nymphae; structures that join at the upper extremity of the vulva. The labia minora vary greatly in size and shape. In nulliparous women, they usually are not visible behind the nonseparated labia majora, whereas in multiparous women, it is common for the labia minora to project beyond the labia majora.

Each labium minus is a thin fold of tissue that, when projected, is moist and reddish in appearance and is similar to that of a mucous membrane. These structures, however, are covered by stratified squamous epithelium into which numerous papillae project. There are no hair follicles in the labia minora, but there are many sebaceous follicles and, occasionally, a few sweat glands. The interior of the labial folds is comprised of connective tissue with many vessels and some smooth muscular fibers, as is the case in typical erectile structures. These structures are supplied with a variety of nerve endings and are extremely sensitive.

The tissues of the labia minora converge superiorly, where each is divided into two lamellae, the lower pair of which fuses to form the *frenulum of the clitoris*, and the upper pair of which merges to form the *prepuce* of the clitoris. Inferiorly, the labia minora extend to approach the midline as low ridges of tissue that fuse to form the *fourchette* in nulliparous women; in multiparous women the labia minora usually are imperceptibly contiguous with the labia majora.

CLITORIS

The clitoris is the homologue of the penis and is located near the superior extremity of the vulva. This erectile organ projects downward between the branched extremities of the labia minora. The clitoris is comprised of a glans, a body (corpus), and two crura. The glans is made up of spindle-shaped cells, and in the body there are two corpora cavernosa, in the walls of which are smooth muscle fibers. The long, narrow crura arise from the inferior surface of the ischiopubic rami and fuse just below the middle of the pubic arch to form the corpus.

Rarely does the clitoris exceed 2 cm in length, even in a state of erection ([Verkauf and associates, 1992](#)), and it is bent sharply by traction that is exerted by the labia minora. As a result, the free end of the clitoris is pointed downward and inward toward the vaginal opening. The glans, which rarely exceeds 0.5 cm in diameter, is covered by stratified squamous epithelium that is richly supplied with nerve endings and is, therefore, extremely sensitive. The vessels of the erectile clitoris are connected with the vestibular bulbs; the clitoris is the principal erogenous organ of women.

In the labia majora, as well as the labia minora and clitoris, [Krantz \(1958\)](#) reported that there is a delicate network of free nerve endings, the fibers of which terminate in small knoblike thickenings in or adjacent to the cells. These nerve endings are encountered more frequently in the papillae than elsewhere; moreover, tactile discs are also found in abundance in these areas. The number of genital corpuscles, which are considered the main structures that are mediators of erotic sensation, varies considerably. These structures are distributed sparsely and randomly in the labia majora deep in the corium, but are abundant in the labia minora and in the skin that overlies the glans clitoris.

VESTIBULE

The vestibule is an almond-shaped area that is enclosed by the labia minora laterally and extends from the clitoris to the fourchette. The vestibule is the functionally mature female structure of the urogenital sinus of the embryo; in the mature state it usually is perforated by six openings: the urethra, the vagina, the ducts of the Bartholin glands, and, at times, the ducts of the paraurethral glands, also called the Skene ducts and glands ([Fig. 3-2](#)). The posterior portion of the vestibule between the fourchette and the vaginal opening is called the *fossa navicularis*, and it is usually observed only in nulliparous women.

The *Bartholin glands* ([Fig. 3-2](#)) are a pair of small compound structures about 0.5 to 1 cm in diameter. Each is situated beneath the vestibule on either side of the vaginal opening and they are the *major vestibular glands*. The Bartholin glands lie under the constrictor muscle of the vagina and sometimes are found to be covered partially by the vestibular bulbs. The gland ducts are 1.5 to 2 cm long and open on the sides of the vestibule just outside the lateral margin of the vaginal orifice. The small gland lumen ordinarily admits only the finest of probes. At times of sexual arousal, mucoid material is secreted from these glands. These glands may harbor *Neisseria gonorrhoeae*, or other bacteria, which in turn may cause suppuration and a Bartholin gland abscess ([Chap. 35, p. 921](#)).

URETHRAL OPENING. The lower two thirds of the urethra lies immediately above the anterior vaginal wall. The urethral opening or meatus is in the midline of the vestibule, 1 to 1.5 cm below the pubic arch, and a short distance above the vaginal opening. The urethral orifice appears as a vertical slit, which can be distended to 4 or 5 mm in diameter. Ordinarily, the *paraurethral ducts*, also known as the Skene ducts, open onto the vestibule on either side of the urethra; but occasionally they open on the posterior wall of the urethra just inside the meatus ([Fig. 3-2](#)). These ducts are about 0.5 mm in diameter, and of variable length.

VESTIBULAR BULBS. Beneath the mucous membrane of the vestibule on either side are the vestibular bulbs, which are almond-shaped aggregations of veins, 3 to 4 cm long, 1 to 2 cm wide, and 0.5 to 1 cm thick. These bulbs lie in close apposition to the ischiopubic rami and are partially covered by the ischiocavernosus and constrictor vaginae muscles. The lower terminations of the vestibular bulbs usually are at about the middle of the vaginal opening, and anteriorly, the vestibular bulbs extend upward toward the clitoris.

Embryologically, the vestibular bulbs correspond to the anlage of the corpus spongiosum of the penis. During childbirth, they usually are pushed up beneath the pubic

arch; because the posterior ends partially encircle the vagina, however, these structures are liable to injury and rupture, which may result in a vulvar hematoma or hemorrhage.

VAGINAL OPENING AND HYMEN. The vaginal opening varies considerably in size and shape. In virginal women, it most often is hidden by the overlapping labia minora, and when exposed, it usually appears almost completely closed by the membranous hymen.

There also are marked differences in shape and consistency of the hymen, which is comprised mainly of elastic and collagenous connective tissue. Both the outer and inner surfaces are covered by stratified squamous epithelium. Connective tissue papillae are more numerous on the vaginal surface and at the free edge. There are no glandular or muscular elements in the hymen, and it is not richly supplied with nerve fibers.

In the newborn, the hymen is very vascular and redundant; in pregnant women, the epithelium is thick and the tissue is rich in glycogen; after menopause, the epithelium of the hymen is thin and focal cornification may develop. In adult virginal women, the hymen is a membrane of various thickness that surrounds the vaginal opening more or less completely, with an aperture varying in diameter from that of a pinpoint to a caliber that admits the tip of one or even two fingers. The hymenal opening usually is crescentic or circular, but occasionally may be cribriform, septate, or fimbriated. The fimbriated type of hymen in virginal women may be indistinguishable from one that has been penetrated during intercourse; thus, it is not possible to determine virginity by such an examination.

As a rule, the hymen is torn at several sites during first coitus, usually in the posterior portion. The edges of the torn tissue soon cicatrize, and the hymen becomes divided permanently into two or more portions that are separated by narrow sulci. The extent to which rupture occurs varies with the structure of the hymen and the extent to which it is distended. Although commonly it is believed that rupture of the hymen is accompanied by bleeding, this is not evident in all women. Occasionally with hymenal rupture, however, there may be profuse bleeding. Rarely, the hymenal membrane may be very resistant and incision of the tissue may be necessary before coitus can be accomplished.

The changes in the hymen that are brought about by coitus are occasionally of medicolegal importance, especially in instances of alleged sexual assault. Usually when nulliparous women are examined a few hours after an attack, the finding of fresh hymenal lacerations, abrasions, or bleeding points on the hymen constitutes corroborative evidence of recent vaginal penetration, possibly by intercourse. The absence of such findings is of no significance, however, because the hymen may not be lacerated even with repeated coitus in a short time period. In fact, many cases of pregnancy have been reported in women in whom the hymen did not appear to have been "ruptured."

As a rule, the changes produced in the hymen by childbirth are readily recognizable. After recovery from delivery, several cicatrized nodules of various sizes are formed, the tissue remnants of the hymen. *Imperforate hymen*, a rare lesion, is a condition in which the vaginal orifice is occluded completely, causing retention of the menstrual discharge.

VAGINA

The vagina is a tubular, musculomembranous structure that extends from the vulva to the uterus, interposed anteriorly and posteriorly between the urinary bladder and the rectum (Figs. 3-3 and 3-4). This organ has many functions: it is the excretory canal of the uterus, through which uterine secretions and menstrual flow escape; the female organ of copulation; and part of the birth canal. The upper portion of the vagina arises from the müllerian ducts, and the lower portion is formed from the urogenital sinus. Anteriorly, the vagina is in contact with the bladder and urethra, from which it is separated by connective tissue, often referred to as the vesicovaginal septum. Posteriorly, between the lower portion of the vagina and the rectum, there are similar tissues that together form the rectovaginal septum. Usually, the upper fourth of the vagina is separated from the rectum by the rectouterine pouch, also called the cul-de-sac of Douglas.

Normally, the anterior and posterior vaginal walls lie in contact with only a slight space that intervenes between the lateral margins. Thus, when not distended, the vaginal canal on transverse section is H-shaped (Fig. 3-5). The vagina can be distended markedly, a characteristic that is most evident during childbirth.

Vaginal length varies considerably; commonly, the anterior and posterior vaginal walls are, respectively, 6 to 8 cm, and 7 to 10 cm in length. The upper end of the vaginal vault is subdivided into the anterior, posterior, and two lateral fornices by the uterine cervix. Because the vagina is attached higher up on the posterior wall than on the anterior wall of the cervix, the depth of the posterior fornix is appreciably greater than the anterior. The lateral fornices are intermediate in depth. The fornices are of considerable clinical importance because the internal pelvic organs usually can be palpated through the thin walls of the fornices. Moreover, the posterior fornix usually provides ready surgical access to the peritoneal cavity.

Prominent longitudinal ridges project into the vaginal lumen from the midlines of both the anterior and posterior walls. In nulliparous women, numerous transverse ridges, or *rugae*, extend outward from and almost at right angles to the longitudinal vaginal ridges. The rugae are such as to form a corrugated surface, which is not present before menarche and is one that gradually becomes obliterated after repeated childbirth and after menopause. In elderly multiparous women, the vaginal walls often are smooth.

The vaginal mucosa is comprised of noncornified stratified squamous epithelium. Beneath the epithelium there is a thin fibromuscular coat, usually consisting of an inner circular layer and an outer longitudinal layer of smooth muscle. There is a thin layer of connective tissue beneath the mucosa and the muscularis; one that is rich in blood vessels, and one in which there are a few small lymphoid nodules. The mucosa and muscularis are attached very loosely to the underlying connective tissue. Some argument remains as to whether this connective tissue, often referred to as perivaginal endopelvic fascia, is a definite fascial plane in the strict anatomical sense.

Normally, glands are not present in the vagina. In parous women, however, fragments of stratified epithelium, which sometimes give rise to cysts, are occasionally embedded in the vaginal connective tissue. These *vaginal inclusion cysts* are not glands, but rather are remnants of mucosal tags that were buried during the healing or repair of vaginal lacerations after childbirth. Occasionally, other cysts may be found that are lined by columnar or cuboidal epithelium and that are believed to be derived from embryonic remnants.

From early in infancy until after menopause, there is a considerable amount of glycogen in the superficial cells of the vaginal mucosa. By examination of cells that are exfoliated from the vaginal epithelium, one can identify the various hormonal events of the ovarian cycle.

In nonpregnant women, the vagina is kept moist by a small amount of secretion from the uterus. During pregnancy, there is copious, acidic vaginal secretion, which normally consists of a curdlike product of exfoliated epithelium and bacteria. *Lactobacillus* species are recovered from most pregnant women in higher concentrations than in nonpregnant women (Larsen and Galask, 1980; McGregor and French, 2000). These are the predominant bacteria of the vagina during pregnancy.

There is an abundant vascular supply to the vagina; the upper third is supplied by the cervicovaginal branches of the uterine arteries, the middle third by the inferior vesical arteries, and the lower third by the middle rectal and internal pudendal arteries. The vaginal artery may branch directly from the internal iliac artery. There is an extensive venous plexus that immediately surrounds the vagina, vessels that follow the course of the arteries; eventually, these veins empty into the internal iliac veins. For the most part, the lymphatics from the lower third of the vagina, along with those of the vulva, drain into the inguinal lymph nodes; those from the middle third drain into the internal iliac nodes; and those from the upper third drain into the iliac nodes. According to Krantz (1958), although the vagina is devoid of any special nerve endings (genital corpuscles), occasionally, free nerve endings are found in the papillae.

PERINEUM

The many structures that make up the perineum are illustrated in Figure 3-6. Most of the support of the perineum is provided by the pelvic and urogenital diaphragms. The *pelvic diaphragm* consists of the levator ani muscles plus the coccygeus muscles posteriorly and the fascial coverings of these muscles. The levator ani muscles form a broad muscular sling that originates from the posterior surface of the superior rami of the pubis, from the inner surface of the ischial spine, and between these two sites, from the obturator fascia. The muscle fibers are inserted in several locations as follows: around the vagina and rectum to form efficient functional sphincters for each; into a raphe in the midline between the vagina and rectum; into a midline raphe below the rectum; and into the coccyx. The *urogenital diaphragm* is positioned external to the pelvic diaphragm, that is, in the triangular area between the ischial tuberosities and the symphysis pubis. The urogenital diaphragm is made up of the deep transverse perineal muscles, the constrictor of the urethra, and the internal and external fascial coverings.

Of particular importance because they may be torn or cut with even normal delivery, are the *external* and *internal anal sphincter* muscles. The external sphincter is shown in Figure 3-6, where its proximity to the posterior vaginal fourchette is apparent. The relationship of the internal and external sphincter is shown in Figure 3-7. Damage to either sphincter increases the likelihood of rectal incontinence following vaginal delivery (Chap. 13, p. 328).

The major blood supply to the perineum is via the internal pudendal artery and its branches. Branches of the internal pudendal artery include the inferior rectal artery and posterior labial artery.

The innervation of the perineum is primarily via the pudendal nerve and its branches. The pudendal nerve originates from the S₂, S₃, and S₄ portion of the spinal cord.

PERINEAL BODY. The median raphe of the levator ani, which is positioned between the anus and the vagina, is reinforced by the central tendon of the perineum, on which converge the bulbocavernosus muscles, superficial transverse perineal muscles, and external anal sphincter. These structures, which contribute to the perineal body, provide much of the support for the perineum.

INTERNAL GENERATIVE ORGANS

UTERUS

The uterus is a muscular organ that is covered, partially, by peritoneum, or serosa. The cavity of the uterus is lined by the endometrium.

ANATOMICAL RELATIONSHIPS. The uterus of the nonpregnant woman is situated in the pelvic cavity between the bladder anteriorly and the rectum posteriorly. Almost the entire posterior wall of the uterus is covered by serosa, or peritoneum, the lower portion of which forms the anterior boundary of the *recto-uterine cul-de-sac*, or pouch of Douglas. Only the upper portion of the anterior wall of the uterus is so covered ([Fig. 3-8](#)). The lower portion is united to the posterior wall of the bladder by a well-defined but normally loose layer of connective tissue ([Fig. 3-3](#)).

SIZE AND SHAPE. The uterus is a structure that resembles a flattened pear in shape ([Fig. 3-8](#)). It consists of two major but unequal parts: an upper triangular portion, the *body*, or corpus; and a lower, cylindrical, or fusiform portion, the *cervix*, which projects into the vagina. The *isthmus* is that portion of the uterus between the internal cervical os and the endometrial cavity. It is of special obstetrical significance because it forms the lower uterine segment during pregnancy ([Chap. 11, p. 254](#)). The anterior surface of the body of the uterus is almost flat, whereas the posterior surface is distinctly convex. The oviducts, or fallopian tubes, emerge from the *cornua* of the uterus at the junction of the superior and lateral margins. The convex upper segment between the points of insertion of the fallopian tubes is called the *fundus*. Laterally, the portion of the uterus below the insertion of the fallopian tubes is not covered directly by peritoneum but is the site of the attachments of the broad ligaments.

The uterus varies widely in size and shape, and the age and parity of women influence this tremendously. Before puberty, the organ varies in length from 2.5 to 3.5 cm ([Orsini and colleagues, 1984](#)). The uterus of adult nulliparous women is from 6 to 8 cm in length as compared with 9 to 10 cm in multiparous women. Uteri of nonparous and parous women also differ considerably in weight, averaging from 50 to 70 g for the former, and 80 g or more for the latter ([Langlois, 1970](#)). The relationship between the length of the body of the uterus and that of the cervix likewise varies widely. In the premenarchal girl, the body of the uterus is only half as long as the cervix. In nulliparous women, the two are about equal in length. In multiparous women, the cervix is only a little more than a third of the total length of the organ.

The bulk of the body of the uterus, but not the cervix, is comprised of muscle. The inner surfaces of the anterior and posterior walls of the uterus lie almost in contact; the cavity between these walls forms a mere slit. On frontal section, the cavity of the body of the uterus is triangular. The cervical canal is fusiform and is open at each end by small apertures, the *internal os* and the *external os*. The margins of parous uteri become concave instead of convex, and hence the triangular appearance of the uterine cavity is less pronounced.

After menopause, the size of the uterus decreases as a consequence of atrophy of both the myometrium and the endometrium. Congenital anomalies of mullerian fusion may give rise to a number of uterine abnormalities, detectable by hysterosalpingogram or magnetic resonance imaging ([Carrington and co-workers, 1990](#)). Obstetrical implications of such malformations are discussed in [Chapter 35](#).

UTERUS DURING PREGNANCY. As described in [Chapter 8 \(p. 168\)](#), the uterus during pregnancy undergoes remarkable growth due to hypertrophy of muscle fibers. Its weight increases from 70 g in the nonpregnant state to about 1100 g at term. Its total volume averages about 5 L. As growth proceeds, the uterine fundus, a previously flattened convexity between tubal insertions, now becomes dome shaped ([Fig. 3-9](#)). The round ligaments now appear to insert at the junction of the middle and upper thirds of the organ. The fallopian tubes elongate, but the ovaries grossly appear unchanged.

UTERINE CERVIX

The cervix is the specialized portion of the uterus that is below the isthmus. Anteriorly, the upper boundary of the cervix, the internal os, corresponds approximately to the level at which the peritoneum is reflected upon the bladder. The cervix is divided by the attachment of the vagina into vaginal and supravaginal portions. The supravaginal segment on its posterior surface is covered by peritoneum. Laterally, it is attached to the cardinal ligaments, and anteriorly, it is separated from the overlying bladder by loose connective tissue. The external os is located at the lower extremity of the vaginal portion of the cervix, the *portio vaginalis*.

The external cervical os varies greatly in appearance. Before childbirth, it is a small, regular, oval opening; after childbirth, the orifice is converted into a transverse slit that is divided such that there are the so-called anterior and posterior lips of the cervix. If the cervix was torn deeply during delivery, it might heal in such a manner that it appears to be irregular, nodular, or stellate. These changes are sufficiently characteristic to permit an examiner to ascertain with some certainty whether a given woman has borne children by vaginal delivery ([Fig. 3-10](#)).

The cervix is composed predominantly of collagenous tissue plus elastic tissue and blood vessels, although it does contain some smooth muscle fibers. The transition from the primarily collagenous tissue of the cervix to the primarily muscular tissue of the body of the uterus, although generally abrupt, may be gradual, and may extend over as much as 10 mm. The results of studies by [Danforth and colleagues \(1960\)](#) suggest that the physical properties of the cervix are determined in large measure by the state of the connective tissue, and that during pregnancy and labor the remarkable ability of the cervix to dilate is the result of dissociation of collagen. [Buckingham and co-workers \(1965\)](#) quantified the amount of muscle and collagen in cervical tissue. In the normal cervix, the proportion of muscle is, on average, about 10 percent, whereas in women with an *incompetent cervix*, sometimes the proportion of muscle is appreciably greater. A number of clinically important structural abnormalities of both cervix and uterus have been described in women exposed in utero to *diethylstilbestrol* ([Chap. 35, p. 918](#)). These are often diagnosed by physical examination or magnetic resonance imaging, and may have important reproductive implications ([Hricak and associates, 1990](#)).

The mucosa of the cervical canal is composed of a single layer of very high, columnar epithelium that rests upon a thin basement membrane. The oval nuclei are situated near the base of the columnar cells, the upper portions of which appear to be rather clear because of content of mucus. These cells are supplied abundantly with cilia.

There are numerous cervical glands that extend from the surface of the endocervical mucosa directly into the subjacent connective tissue; because there is no submucosa as such, these glands furnish the thick, tenacious secretion of the cervical canal. If the ducts of the cervical glands are occluded, retention cysts, known as *Nabothian follicles* or *cysts*, are formed.

Normally, the squamous epithelium of the vaginal portion of the cervix and the columnar epithelium of the cervical canal form a sharp line of demarcation very near the external os, that is, the squamo-columnar junction. In response to inflammation or trauma, however, the stratified epithelium may extend gradually up the cervical canal and come to line the lower third, or occasionally even the lower half, of the canal. This change is more marked in multiparous women, in whom the lips of the cervix often are everted. Uncommonly, the two varieties of epithelium abut on the vaginal portion outside the external os, as in *congenital ectropion*.

BODY OF THE UTERUS

The wall of the body of the uterus is composed of serosal, muscular, and mucosal layers. The serosal layer is formed by the peritoneum that covers the uterus, and to which it is firmly adherent except at sites just above the bladder and at the lateral margins where the peritoneum is deflected in a manner to form the broad ligaments.

ENDOMETRIUM. The endometrium is the mucosal layer that lines the uterine cavity in nonpregnant women. It is a thin, pink, velvet-like membrane, which on close examination is found to be perforated by a large number of minute openings; these are the ostia of the uterine glands. Because of the repetitive cyclical changes during the reproductive years, the endometrium normally varies greatly in thickness, and measures from 0.5 mm to as much as 5 mm. The endometrium is comprised

of surface epithelium, glands, and interglandular mesenchymal tissue in which there are numerous blood vessels.

The epithelium of the endometrial surface is comprised of a single layer of closely packed, high columnar, ciliated cells. During much of the endometrial cycle, the oval nuclei are situated in the lower portions of the cells but not so near the base as in the endocervix. The ciliated cells are located in discrete patches, whereas secretory activity appears to be limited to nonciliated cells. The ciliary current in both the fallopian tubes and the uterus is in the same direction and extends downward from the fimbriated end of the tubes toward the external os.

The tubular *uterine glands* are invaginations of the epithelium, which in the resting state are reminiscent of the fingers of a glove. The glands extend through the entire thickness of the endometrium to the myometrium, which is occasionally penetrated for a short distance. Histologically, the inner glands resemble the epithelium of the surface and are lined by a single layer of columnar, partially ciliated epithelium that rests upon a thin basement membrane. The glands secrete a thin, alkaline fluid.

In the classical monograph of [Hitschmann and Adler \(1908\)](#), the endometrium was described as undergoing constant, hormonally controlled changes during each ovarian cycle. These three fundamental phases—*menstrual*, *proliferative (follicular)*, and *secretory (luteal)*—are discussed in detail in [Chapter 4](#) in the section on menstruation. After menopause, the endometrium is atrophic and the epithelium flattens. The glands gradually disappear, and the interglandular tissue becomes more fibrous.

The connective tissue of the endometrium, between the surface epithelium and the myometrium, is a mesenchymal stroma. Immediately after menstruation, the stroma is composed of closely packed cells with oval- and spindle-shaped nuclei, around which there is very little cytoplasm. When separated by edema, the cells appear to be stellate, with cytoplasmic processes that branch to form anastomoses. These cells are packed more closely around the glands and blood vessels than elsewhere. Several days before menstruation, the stromal cells usually become larger and more vesicular, like decidual cells; and at the same time, there is a diffuse leukocytic infiltration.

The vascular architecture of the endometrium is of signal importance in the phenomena of menstruation and pregnancy. Arterial blood is transported to the uterus by way of the uterine and ovarian arteries. As the arterial branches penetrate the uterine wall obliquely inward and reach its middle third, these vessels ramify in a plane that is parallel to the surface; these vessels are therefore named the *arcuate arteries* ([DuBose and colleagues, 1985](#)). Radial branches extend from the arcuate arteries at right angles toward the endometrium. The endometrial arteries comprise *coiled or spiral arteries*, which are a continuation of the radial arteries, and *basal arteries*, which branch from the radial arteries at a sharp angle ([Figs. 3-11 and 3-12](#)). The coiled arteries supply most of the midportion and all of the superficial third of the endometrium. The walls of these vessels are responsive (sensitive) to the action of a number of hormones, especially by vasoconstriction, and thus probably serve an important role in the mechanism(s) of menstruation. The straight basal endometrial arteries are smaller in both caliber and length than are the coiled vessels. These vessels extend only into the basal layer of the endometrium, or at most a short distance into the middle layer, and are not responsive to hormonal action.

MYOMETRIUM. The myometrium, which makes up the major portion of the uterus, is composed of bundles of smooth muscle united by connective tissue in which there are many elastic fibers. According to [Schwalm and Dubrauszky \(1966\)](#), the number of muscle fibers of the uterus progressively diminishes caudally such that in the cervix, muscle comprises only 10 percent of the tissue mass. In the inner wall of the body of the uterus, there is relatively more muscle than in the outer layers; and in the anterior and posterior walls, there is more muscle than in the lateral walls. During pregnancy, the myometrium increases greatly via hypertrophy, with no significant change in the muscle content of the cervix ([Chap. 8, p. 168](#)).

LIGAMENTS. The *broad ligaments* are made up of two winglike structures that extend from the lateral margins of the uterus to the pelvic walls and thereby divide the pelvic cavity into anterior and posterior compartments. Each broad ligament consists of a fold of peritoneum, and there are superior, lateral, inferior, and medial margins. The inner two thirds of the superior margin form the *mesosalpinx*, to which the fallopian tubes are attached. The outer third of the superior margin of the broad ligament, which extends from the fimbriated end of the oviduct to the pelvic wall, forms the *infundibulopelvic ligament* (suspensory ligament of the ovary), through which the ovarian vessels traverse.

At the lateral margin of each broad ligament, the peritoneum is reflected onto the side of the pelvis. The base of the broad ligament, which is quite thick, is continuous with the connective tissue of the pelvic floor. The most dense portion—referred to as the *cardinal ligament*, transverse cervical ligament, or Mackenrodt ligament—is composed of connective tissue that medially is united firmly to the supravaginal portion of the cervix. In the base of the broad ligament, the uterine vessels and the lower portion of the ureter are enclosed.

A vertical section through the uterine end of the broad ligament is triangular, and the uterine vessels are found within its broad base ([Fig. 3-13](#)). In its lower part, it is widely attached to the connective tissues that are adjacent to the cervix, that is, the *parametrium*. The upper part is made up of three folds that nearly cover the oviduct, the utero-ovarian ligament, and the round ligament.

The *round ligaments* extend from the lateral portion of the uterus, arising somewhat below and anterior to that of the origin of the oviducts. Each round ligament is located in a fold of peritoneum that is continuous with the broad ligament and extends outward and downward to the inguinal canal, through which it passes to terminate in the upper portion of the labium majus. In nonpregnant women, the round ligament varies from 3 to 5 mm in diameter, and is comprised of smooth muscle cells that are continuous directly with those of the uterine wall and a certain amount of connective tissue. The round ligament corresponds, embryologically, to the gubernaculum testis of men. During pregnancy, the round ligaments undergo considerable hypertrophy and increase appreciably in both length and diameter.

Each *uterosacral ligament* extends from an attachment posterolaterally to the supravaginal portion of the cervix to encircle the rectum, and thence insert into the fascia over the second and third sacral vertebrae. The uterosacral ligaments are composed of connective tissue and some smooth muscle and are covered by peritoneum. These ligaments form the lateral boundaries of the rectouterine cul-de-sac, or pouch of Douglas.

POSITION. When a nonpregnant woman stands upright, the body of the uterus most often is almost horizontal, flexed somewhat anteriorly with the fundus resting upon the bladder, whereas the cervix is directed backward toward the tip of the sacrum with the external os approximately at the level of the ischial spines. The position of the body of the uterus is variable as a function of the degree of distension of the bladder, rectum, or both.

Normally, the uterus is a partially mobile organ; whereas the cervix is anchored, the body of the uterus is free to move in the anteroposterior plane. The posterior directed, or retroflexed uterus (that is, with the fundus resting on the rectum) is a normal variant and is encountered in many women.

BLOOD VESSELS. The vascular supply of the uterus is derived principally from the uterine and ovarian arteries. The uterine artery, a main branch of the internal iliac (hypogastric) artery, enters the base of the broad ligament, and makes its way medially to the side of the uterus. Immediately adjacent to the supravaginal portion of the cervix, the uterine artery is divided into two main branches. The smaller cervicovaginal artery supplies blood to the lower portion of the cervix and the upper portion of the vagina. The main branch turns abruptly upward and extends thereafter as a highly convoluted vessel that traverses along the margin of the uterus; a branch of considerable size extends to the upper portion of the cervix, and numerous other branches penetrate the body of the uterus. Just before the main branch of the uterine artery reaches the oviduct, it divides into three terminal branches: fundal, tubal, and ovarian. The ovarian branch of the uterine artery anastomoses with the terminal branch of the ovarian artery; the tubal branch makes its way through the mesosalpinx and supplies part of the oviduct; and the fundal branch is distributed to the uppermost portion of the uterus.

About 2 cm lateral to the cervix, the uterine artery crosses over the ureter ([Figs. 3-8 and 3-14](#)). The proximity of the uterine artery and uterine vein to the ureter at this point is of great surgical significance because, during hysterectomy, the ureter may be injured or ligated in the process of clamping and ligating the uterine vessels.

A major portion of the blood supply to the pelvis is via the branches of the internal iliac artery, as shown in the arteriogram in [Figure 3-15](#). In the past, this commonly was referred to as the hypogastric artery. Other branches of the anterior division of the internal iliac artery besides the uterine artery include the umbilical, middle and inferior vesical, middle rectal, obturator, internal pudendal, middle hemorrhoidal, vaginal, and inferior gluteal arteries. The branches of the posterior division of the internal iliac artery include the lateral sacral, superior gluteal, and iliolumbar arteries ([Table 3-1](#)).

The *ovarian artery*, a direct branch of the aorta, enters the broad ligament through the infundibulopelvic ligament. At the ovarian hilum, it is divided into a number of smaller branches that enter the ovary; whereas the main stem of the ovarian artery traverses the entire length of the broad ligament very near the mesosalpinx and makes its way to the upper portion of the lateral margin of the uterus, where it anastomoses with the ovarian branch of the uterine artery. There are numerous additional communications among the arteries on both sides of the uterus.

When the uterus is in a contracted state, its numerous venous lumens are collapsed; however, in injected specimens the greater part of the uterine wall appears to be occupied by dilated venous sinuses. On either side, the arcuate veins unite to form the *uterine vein*, which empties into the internal iliac vein and thence into the

common iliac vein.

Some of the blood from the upper part of the uterus and blood from the ovary and upper part of the broad ligament is collected by several veins that, within the broad ligament, form the large *pampiniform plexus*, the vessels that terminate in the ovarian vein. The right ovarian vein empties into the vena cava, whereas the left ovarian vein empties into the left renal vein.

During pregnancy, there is marked hypertrophy of the blood supply to the uterus ([Fig. 3-9](#)). This accommodates uteroplacental blood flow estimated at 500 to 700 mL/min ([Chap. 8, p. 169](#)).

LYMPHATICS. The endometrium is abundantly supplied with lymphatics, but true lymphatic vessels are confined largely to the basal layer. The lymphatics of the underlying myometrium are increased in number toward the serosal surface and form an abundant lymphatic plexus just beneath it, especially on the posterior wall of the uterus and, to a lesser extent, on the anterior wall.

The lymphatics from the various segments of the uterus drain into several sets of lymph nodes. Those from the cervix terminate mainly in the hypogastric nodes, which are situated near the bifurcation of the common iliac vessels. The lymphatics from the body of the uterus are distributed to two groups of nodes. One set of vessels drains into the internal iliac nodes; the other set, after joining certain lymphatics from the ovarian region, terminates in the periaortic lymph nodes.

INNERVATION. The nerve supply is derived principally from the sympathetic nervous system, but also partly from the cerebrospinal and parasympathetic systems. The parasympathetic system is represented on either side by the pelvic nerve, which is comprised of a few fibers that are derived from the second, third, and fourth sacral nerves; it loses its identity in the cervical ganglion of Frankenhauser. The sympathetic system enters the pelvis by way of the internal iliac plexus that arises from the aortic plexus just below the promontory of the sacrum. After descending on either side, it also enters the uterovaginal plexus of Frankenhauser, which is made up of ganglia of various sizes, but particularly of a large ganglionic plate that is situated on either side of the cervix and just above the posterior fornix in front of the rectum.

Branches from these plexuses supply the uterus, bladder, and upper vagina. Some of these fibers terminate freely between the muscular fibers, whereas others accompany the arteries into the endometrium.

In the 11th and 12th thoracic nerve roots, there are sensory fibers from the uterus that transmit the painful stimuli of uterine contractions to the central nervous system. The sensory nerves from the cervix and upper part of the birth canal pass through the pelvic nerves to the second, third, and fourth sacral nerves, whereas those from the lower portion of the birth canal pass primarily through the pudendal nerve.

OVIDUCTS

The oviducts, or fallopian tubes, vary from 8 to 14 cm in length and are covered by peritoneum; their lumen is lined by mucous membrane. Each fallopian tube is divided into an *interstitial portion*, *isthmus*, *ampulla*, and *infundibulum*. The interstitial portion is embodied within the muscular wall of the uterus. Its approximate course is obliquely upward and outward from the uterine cavity. The isthmus, or the narrow portion of the tube that adjoins the uterus, passes gradually into the wider, lateral portion, or *ampulla*. The *infundibulum*, or fimbriated extremity, is the funnel-shaped opening of the distal end of the fallopian tube ([Fig. 3-16](#)). The oviduct varies considerably in thickness; the narrowest portion of the isthmus measures from 2 to 3 mm in diameter, and the widest portion of the ampulla measures from 5 to 8 mm. The oviduct is surrounded completely by peritoneum except at the attachment of the mesosalpinx.

The fimbriated end of the infundibulum opens into the abdominal cavity. One projection, the *fimbria ovarica*, which is considerably longer than the other fimbriae, forms a shallow gutter that approaches or reaches the ovary.

The musculature of the fallopian tube is arranged in two layers, an inner circular and an outer longitudinal layer. In the distal portion of the oviduct, the two layers are less distinct and, near the fimbriated extremity, are replaced by an interlacing network of muscular fibers. The tubal musculature undergoes rhythmic contractions constantly, the rate of which varies with the hormonal changes of the ovarian cycle. The greatest frequency and intensity of contractions is reached during transport of ova. Contractions are slowest and weakest during pregnancy.

The fallopian tube is lined by a single layer of columnar cells, some of them ciliated and others secretory. The ciliated cells are most abundant at the fimbriated extremity; elsewhere, these cells are found in discrete patches. There are differences in the proportions of these two types of cells in different phases of the ovarian cycle. Because there is no submucosa, the epithelium is in close contact with the underlying muscle. In the tubal mucosa, there are cyclical histological changes similar to, but much less striking than, those of the endometrium. The postmenstrual phase is characterized by a low epithelium that rapidly increases in height. During the follicular phase, the cells are taller; the ciliated elements are broad, with nuclei near the margin; and the nonciliated cells are narrow, with nuclei nearer the base. During the luteal phase, the secretory cells enlarge, project beyond the ciliated cells, and the nuclei are extruded. During the menstrual phase, these changes are even more marked. Changes in the fallopian tubes during late pregnancy and in the puerperium include the development of a low mucosa, plugging of the capillaries with leukocytes, and a decidual reaction.

The mucosa of the oviducts is arranged in longitudinal folds that are more complex toward the fimbriated end. On cross sections through the uterine portion, four simple folds are found that form a figure that resembles a Maltese cross. The isthmus is more complex; in the ampulla, the lumen is occupied almost completely by the arborescent mucosa, which consists of very complicated folds ([Fig. 3-16](#)). The current produced by the tubal cilia is such that the direction of flow is toward the uterine cavity. Tubal peristalsis is believed to be an extraordinarily important factor in transport of the ovum.

The tubes are supplied richly with elastic tissue, blood vessels, and lymphatics. Sympathetic innervation of the tubes is extensive, in contrast to parasympathetic innervation. The role of these nerves in tubal function is poorly understood ([Hodgson and Eddy, 1975](#)).

Diverticula may extend occasionally from the lumen of the tube for a variable distance into the muscular wall and reach almost to the serosa. These diverticula may serve a role in the development of ectopic pregnancy ([Chap. 34, p. 884](#)). The gross anatomical, histological, and ultrastructural aspects of the human oviduct was summarized elegantly by [Woodruff and Pauerstein \(1969\)](#).

EMBRYOLOGICAL DEVELOPMENT OF THE UTERUS AND OVIDUCTS. The uterus and fallopian tubes arise from the mullerian ducts, which first appear near the upper pole of the urogenital ridge in the fifth week of embryonic development. This ridge is composed of the mesonephros, gonad, and associated ducts. The first indication of the development of the mullerian duct is a thickening of the coelomic epithelium at about the level of the fourth thoracic segment. This thickening becomes the fimbriated extremity of the fallopian tube, which invaginates and grows caudally to form a slender tube at the lateral edge of the urogenital ridge. In the sixth week of embryonic life, the growing tips of the two mullerian ducts approach each other in the midline and reach the sinus 1 week later. At that time, a fusion of the two mullerian ducts is begun at the level of the inguinal crest, or gubernaculum (primordium of the round ligament), to form a single canal. Thus, the upper ends of the mullerian ducts produce the oviducts and the fused parts give rise to the uterus. The uterine lumen from the fundus to the vagina is completed during the third month of fetal life. The vaginal canal is not patent throughout its entire length until the sixth month of fetal life ([Koff, 1933](#)).

OVARIES

The ovaries are almond-shaped organs, the functions of which are the development and extrusion of ova and the synthesis and secretion of steroid hormones. The ovaries vary considerably in size. During childbearing years, they are 2.5 to 5 cm in length, 1.5 to 3 cm in breadth, and 0.6 to 1.5 cm in thickness. After menopause, ovarian size diminishes remarkably.

Normally, the ovaries are situated in the upper part of the pelvic cavity and rest in a slight depression on the lateral wall of the pelvis between the divergent external and internal iliac vessels—the ovarian fossa of Waldeyer. The position of the ovaries is subject to marked variation, and it is rare to find both ovaries at exactly the same level.

The ovary is attached to the broad ligament by the *mesovarium*. The *utero-ovarian ligament* extends from the lateral and posterior portion of the uterus, just beneath the tubal insertion, to the uterine or lower pole of the ovary. Usually, it is several centimeters long and 3 to 4 mm in diameter. It is covered by peritoneum and is made up of muscle and connective tissue fibers that are continuous with those of the uterus. The *infundibulopelvic* or *suspensory ligament of the ovary* extends from the upper or tubal pole to the pelvic wall; through its course the ovarian vessels and nerves.

The exterior surface of the ovary varies in appearance with age. In young women, the organ is smooth, with a dull white surface through which glisten several small, clear follicles. As the woman grows older, the ovaries become more corrugated; in elderly women, the exterior surfaces may be convoluted markedly. BR>
The ovary consists of two portions, the *cortex* and *medulla*. The cortex, or outer layer, varies in thickness with age and becomes thinner with advancing years. It is in this layer that the ova and graafian follicles are located. The cortex of the ovary is composed of spindle-shaped connective tissue cells and fibers, among which there are scattered primordial and graafian follicles that are in various stages of development. As the woman ages, the follicles become less numerous. The outermost portion of the cortex, which is dull and whitish, is designated as the *tunica albuginea*; on its surface, there is a single layer of cuboidal epithelium, the germinal epithelium of Waldeyer.

The medulla, or central portion, of the ovary is composed of loose connective tissue that is continuous with that of the mesovarium. There are a large number of arteries and veins in the medulla and a small number of smooth muscle fibers that are continuous with those in the suspensory ligament; the muscle fibers may be functional in movements of the ovary.

Both sympathetic and parasympathetic nerves are supplied to the ovaries. The sympathetic nerves are derived, in large part, from the ovarian plexus that accompanies the ovarian vessels; a few are derived from the plexus that surrounds the ovarian branch of the uterine artery. The ovary is richly supplied with nonmyelinated nerve fibers, which for the most part accompany the blood vessels. These are merely vascular nerves, whereas others form wreaths around normal and atretic follicles, and these give off many minute branches that have been traced up to, but not through, the membrana granulosa.

EMBRYOLOGY. At first, the changes in the gonads are the same in both sexes. The earliest sign of a gonad is one that appears on the ventral surface of the embryonic kidney at a site between the eighth thoracic and fourth lumbar segments at about 4 weeks. As illustrated in [Figure 3-17](#), the coelomic epithelium is thickened, and clumps of cells are seen to bud off into the underlying mesenchyme. This circumscribed area of the coelomic epithelium often is called the *germinal epithelium*. By the fourth to sixth week, however, there are many large ameboid cells in this region that have migrated into the body of the embryo from the yolk sac; these cells have been recognized in this region as early as the third week. These *primordial germ cells* are distinguishable by a large size and certain morphological and cytochemical features. They react strongly in tests for alkaline phosphatase ([McKay and associates, 1949](#)), and are recognizable even after repeated divisions.

When the primordial germ cells reach the genital area, some enter the germinal epithelium and others mingle with the groups of cells that proliferate from it or lie in the mesenchyme. By the end of the fifth week, rapid division of all these types of cells results in development of a prominent *genital ridge*. The ridge projects into the body cavity medially to a fold in which there are the mesonephric (wolffian) and the mullerian ducts ([Fig. 3-18](#)). Because the growth of the gonad at the surface is more rapid, it enlarges centrifugally. By the seventh week ([Figs. 3-17 and 3-18](#)), it is separated from the mesonephros except at the narrow central zone, the future hilum, where the blood vessels enter. At this time, the sexes can be distinguished, because the testes can be recognized by well-defined radiating strands of cells (sex cords). These cords are separated from the germinal epithelium by mesenchyme that is to become the tunica albuginea. The sex cords, which consist of large germ cells and smaller epithelioid cells derived from the germinal epithelium, develop into the seminiferous tubules and tubuli rete. The rete, probably derived from mesonephric elements, establishes connection with the mesonephric tubules that develop into the epididymis ([Fig. 3-18](#)). The mesonephric ducts become the vas deferens.

In the female, the germinal epithelium continues to proliferate for a much longer time. The groups of cells thus formed lie at first in the region of the hilum. As connective tissue develops between them, these appear as sex cords. These give rise to the medullary cords and persist for variable times ([Forbes, 1942](#)). By the third month, medulla and cortex are defined ([Fig. 3-18](#)). The bulk of the organ is made up of cortex, a mass of crowded germ and epithelioid cells that show some signs of grouping, but there are no distinct cords as in the testis. Strands of cells extend from the germinal epithelium into the cortical mass, and mitoses are numerous. The rapid succession of mitoses soon reduces the size of the germ cells to the extent that these no longer are differentiated clearly from the neighboring cells; these cells are now called *oogonia*. Some of the oogonia in the medullary region are soon distinguishable by a series of peculiar nuclear changes. Large masses of nuclear chromatin appear, very different from the chromosomes of the oogonial divisions. This change marks the beginning of *synapsis*, which involves interactions between pairs of chromosomes that are derived originally from father and mother. Various stages of synapsis soon can be seen throughout the cortex; because similar changes occur in adjacent cells, groups or "nests" appear. During one stage of synapsis, the chromatin is massed at one side of the nucleus, and the cytoplasm becomes highly fluid. Unless the in vitro preservation is prompt and perfect, these cells appear to be degenerating.

By the fourth month, some germ cells, again in the medullary region, having passed through synapsis, begin to enlarge. These are called *primary oocytes* at the beginning of the phase of growth that continues until maturity is reached. During this period of cell growth, many oocytes undergo degeneration, both before and after birth. The primary oocytes soon become surrounded by a single layer of flattened *follicle* cells that were derived originally from the germinal epithelium. These structures are now called *primordial follicles* and are first seen in the medulla and later in the cortex. Some follicles begin to grow even before birth and some are believed to persist in the cortex almost unchanged until menopause.

By 8 months of gestation, the ovary has become a long, narrow, lobulated structure that is attached to the body wall along the line of the hilum by the *mesovarium*, in which lies the *epoophoron*. At that stage of development, the germinal epithelium has been separated for the most part from the cortex by a band of connective tissue (tunica albuginea), which is absent in many small areas where strands of cells, usually referred to as cords of Pfluger, are in contact with the germinal epithelium. Among these cords are cells believed by many investigators to be oogonia that have come to resemble the other epithelial cells as a result of repeated mitoses. In the underlying cortex, there are two distinct zones. Superficially, there are nests of germ cells in synapsis, interspersed with Pfluger cords and strands of connective tissue. In the deeper zone, there are many groups of germ cells in synapsis, as well as primary oocytes, prospective follicular cells, and a few primordial follicles.

At term, the various types of ovarian cells in the human female fetus may still be found. In some cases, there are vesicular follicles in the medulla, which are all doomed to early degeneration.

HISTOLOGY. From the first stages of its development until after the menopause, the ovary undergoes constant change. The number of oocytes at the onset of puberty has been estimated variously at 200,000 to 400,000. Because only one ovum ordinarily is cast off during each ovarian cycle, it is evident that a few hundred ova suffice for purposes of reproduction.

[Mossman and co-workers \(1964\)](#), in an attempt to clarify the terminology of glandular elements of ovaries of adult women, distinguished interstitial, thecal, and luteal cells. The interstitial glandular elements are formed from cells of the theca interna of degenerating or atretic follicles; the thecal glandular cells are formed from the theca interna of ripening follicles; and the true luteal cells are derived from the granulosa cells of ovulated follicles and from the undifferentiated stroma that surround them.

The huge store of primordial follicles at birth is exhausted gradually during the time of sexual maturation. [Block \(1952\)](#) found that there is a gradual decline from a mean of 439,000 oocytes in girls under 15 years to a mean of 34,000 in women over the age of 36.

In the young girl, the greater portion of the ovary is composed of the cortex, which is filled with large numbers of closely packed primordial follicles. Those nearest the central portion of the ovary are at the most advanced stages of development. In young women, the cortex is relatively thinner but still contains a large number of primordial follicles, which are separated by bands of connective tissue cells in which there are spindle-shaped or oval nuclei. Each primordial follicle is made up of an oocyte and its surrounding single layer of epithelial cells, which are small and flattened, spindle-shaped, and somewhat sharply differentiated from the still smaller and spindle cells of the surrounding stroma.

The oocyte is a large, spherical cell in which there is clear cytoplasm and a relatively large nucleus located near the center of the ovum. In the nucleus, there is one large and several smaller nucleoli, and numerous masses of chromatin. The diameter of the smallest oocytes in the ovaries of adult women averages 33 μm , and that of the nuclei, 20 μm .

EMBRYOLOGICAL REMNANTS

The *parovarium*, which can be found in the scant loose connective tissue within the broad ligament in the vicinity of the mesosalpinx, comprises a number of narrow vertical tubules that are lined by ciliated epithelium. These tubules connect at the upper ends with a longitudinal duct that extends just below the oviduct to the lateral margin of the uterus, where ordinarily it ends blindly near the internal os; infrequently, it may extend laterally down the vagina to the level of the hymen. This canal, the remnant of the wolffian (mesonephric) duct in women, is called the *Gartner duct*. The parovarium, also a remnant of the wolffian duct, is homologous, embryologically, with the caput epididymis in men. The cranial portion of the parovarium is the *epoophoron*, or organ of Rosenmuller; the caudal portion, or *paroophoron*, is a group of vestigial mesonephric tubules that lie in or around the broad ligament. It is homologous, embryologically, with the paradidymis of men. Usually the paroophoron in adult women disappears, but on occasion macroscopic cysts are formed from these remnants.

SURGICAL ANATOMY

Shown in [Figure 3-19](#) are illustrations of female pelvic surgical anatomy. The hysterectomy depicted is of a nonpregnant uterus. Refer to [Figure 3-9](#) of the pregnant uterus for anatomical differences.

THE BONY PELVIS

In both women and men the pelvis forms the bony ring through which body weight is transmitted to the lower extremities, but in women it has a special form that adapts it to childbearing ([Fig. 3-20](#)). The pelvis is composed of four bones: the sacrum, coccyx, and two innominate bones. Each innominate bone is formed by the fusion of the ilium, ischium, and pubis. The innominate bones are joined to the sacrum at the sacroiliac synchondroses and to one another at the symphysis pubis.

PELVIC ANATOMY

The false pelvis lies above the linea terminalis and the true pelvis below this anatomical boundary ([Fig. 3-20](#)). The false pelvis is bounded posteriorly by the lumbar vertebrae and laterally by the iliac fossae, and in front the boundary is formed by the lower portion of the anterior abdominal wall.

The true pelvis is the portion important in childbearing. It is bounded above by the promontory and alae of the sacrum, the linea terminalis, and the upper margins of the pubic bones, and below by the pelvic outlet. The cavity of the true pelvis can be described as an obliquely truncated, bent cylinder with its greatest height posteriorly, because its anterior wall at the symphysis pubis measures about 5 cm and its posterior wall about 10 cm ([Figs. 3-21](#) and [3-22](#)). With the woman upright, the upper portion of the pelvic canal is directed downward and backward, and its lower course curves and becomes directed downward and forward.

The walls of the true pelvis are partly bony and partly ligamentous. The posterior boundary is the anterior surface of the sacrum, and the lateral limits are formed by the inner surface of the ischial bones and the sacroscliac notches and ligaments. In front the true pelvis is bounded by the pubic bones, the ascending superior rami of the ischial bones, and the obturator foramina.

The sidewalls of the true pelvis of the normal adult woman converge somewhat; therefore, if the planes of the ischial bones were extended downward, they would meet near the knee. Extending from the middle of the posterior margin of each ischium are the ischial spines. The ischial spines are of great obstetrical importance because the distance between them usually represents the shortest diameter of the pelvic cavity. They also serve as valuable landmarks in assessing the level to which the presenting part of the fetus has descended into the true pelvis ([Chap. 12, p. 300](#)).

The sacrum forms the posterior wall of the pelvic cavity. Its upper anterior margin corresponds to the body of the first sacral vertebra and is designated as the promontory. The promontory may be felt on vaginal examination in small pelvises and can provide a landmark for clinical pelvimetry. Normally the sacrum has a marked vertical and a less pronounced horizontal concavity, which in abnormal pelvises may undergo important variations. A straight line drawn from the promontory to the tip of the sacrum usually measures 10 cm, whereas the distance along the concavity averages 12 cm.

The descending inferior rami of the pubic bones unite at an angle of 90 to 100 degrees to form a rounded arch under which the fetal head must pass.

PELVIC JOINTS

SYMPHYSIS PUBIS. Anteriorly, the pelvic bones are joined together by the symphysis pubis. This structure consists of fibrocartilage and the superior and inferior pubic ligaments; the latter is frequently designated the *arcuate ligament of the pubis* ([Fig. 3-23](#)). The symphysis has a certain degree of mobility, which increases during pregnancy. This fact was demonstrated by [Budin \(1897\)](#), who reported that if a finger was inserted into the vagina of a pregnant woman and she then walked, the ends of the pubic bones could be felt moving up and down with each step.

SACROILIAC JOINTS. Posteriorly the pelvic bones are joined by the articulations between the sacrum and the iliac portion of the innominate bones (sacroiliac joints). These joints also have a certain degree of mobility.

RELAXATION OF THE PELVIC JOINTS. During pregnancy, relaxation of these joints likely results from hormonal changes. [Abramson and co-workers \(1934\)](#) observed that relaxation of the symphysis pubis commenced in women in the first half of pregnancy and increased during the last 3 months. These investigators reported that regression of relaxation began immediately after parturition and was completed within 3 to 5 months. The symphysis pubis also increases in width during pregnancy (more in multiparas than in primigravidas), and returns to normal soon after delivery. By careful radiographic studies, [Borell and Fernstrom \(1957\)](#) demonstrated that the rather marked mobility of the pelvis of women at term was caused by an upward gliding movement of the sacroiliac joint. The displacement, which is greatest in the dorsal lithotomy position, may increase the diameter of the outlet by 1.5 to 2.0 cm. **This is the main justification for placing a woman in this position for a vaginal delivery.** It should be noted, however, that the increase in the diameter of the pelvic outlet occurs only if the sacrum is allowed to rotate posteriorly, that is, *only* if the sacrum is not forced anteriorly by the weight of the maternal pelvis against the delivery table or bed ([Russell, 1969, 1982](#)). This is likely the reason that the McRoberts maneuver often is successful in releasing an obstructed shoulder in a case of shoulder dystocia ([Chap. 19, p. 461](#)). [Gardosi and co-workers \(1989\)](#) reported in a randomized controlled trial that a modified squatting position in the second stage of labor resulted in a shorter second stage and fewer perineal lacerations. However, there was an increase in labial lacerations. The authors attributed the "success" of the method to increasing the interspinous diameter and the diameter of the pelvic outlet ([Russell, 1969, 1982](#)) as well as to improving the "pushing efforts" of the laboring woman. Although these observations are unconfirmed, such a squatting position is assumed by many primitive women as the usual position for birth ([Gardosi and associates, 1989](#); [Russell, 1982](#)).

PLANES AND DIAMETERS OF THE PELVIS

Because of its complex shape, it is difficult to describe the exact location of an object within the pelvis. For convenience, therefore, the pelvis is described as having four imaginary planes:

1. The plane of the pelvic inlet (superior strait).
2. The plane of the pelvic outlet (inferior strait).
3. The plane of the midpelvis (least pelvic dimensions).
4. The plane of greatest pelvic dimensions.

Because this last plane has no obstetrical significance, it is not considered further.

PELVIC INLET. The pelvic inlet (superior strait) is bounded posteriorly by the promontory and alae of the sacrum, laterally by the linea terminalis, and anteriorly by the horizontal rami of the pubic bones and symphysis pubis ([Figs. 3-21, 3-22, 3-24, and 3-25](#)). The configuration of the inlet of the human female pelvis typically is more nearly round than ovoid. [Caldwell and co-workers \(1934\)](#) identified radiographically a nearly round or *gynecoid* pelvic inlet in approximately 50 percent of the pelvises of white women.

Four diameters of the pelvic inlet are usually described: anteroposterior, transverse, and two obliques. The obstetrically important anteroposterior diameter is the shortest distance between the promontory of the sacrum and the symphysis pubis, and is designated the *obstetrical conjugate* ([Figs. 3-21, 3-22, and 3-24](#)). Normally, the obstetrical conjugate measures 10 cm or more, but it may be considerably shortened in abnormal pelvises.

The transverse diameter is constructed at right angles to the obstetrical conjugate and represents the greatest distance between the linea terminalis on either side. It usually intersects the obstetrical conjugate at a point about 4 cm in front of the promontory ([Fig. 3-22](#)). The segment of the obstetrical conjugate from the intersection of these two lines to the promontory is designated the *posterior sagittal* diameter of the inlet.

Each of the oblique diameters extends from one of the sacroiliac synchondroses to the iliopectineal eminence on the opposite side of the pelvis. They average just under 13 cm and are designated right and left, according to whether they originate at the right or left sacroiliac synchondrosis.

The anteroposterior diameter of the pelvic inlet that has been identified as the *true conjugate* does not represent the shortest distance between the promontory of the

sacrum and symphysis pubis (Fig. 3-24). The shortest distance is the *obstetrical conjugate*, which is the shortest anteroposterior diameter through which the head must pass in descending through the pelvic inlet (Figs. 3-21, 3-22, and 3-24).

The obstetrical conjugate cannot be measured directly with the examining fingers; therefore, various instruments have been designed in an effort to obtain such a measurement. Unfortunately, none of these instruments has proven to be reliable. For clinical purposes, it is sufficient to estimate the length of the obstetrical conjugate indirectly. This is accomplished by measuring the distance from the lower margin of the symphysis to promontory of the sacrum, that is, the *diagonal conjugate* (Fig. 3-24), and subtracting 1.5 to 2 cm from the result, according to the height and inclination of the symphysis pubis (see "Pelvic Size and Its Clinical Estimation" later in the chapter).

MIDPELVIS. The midpelvis at the level of the ischial spines (midplane, or plane of least pelvic dimensions) is of particular importance following engagement of the fetal head in obstructed labor. The interspinous diameter, 10 cm or somewhat more, is usually the smallest diameter of the pelvis. The anteroposterior diameter, through the level of the ischial spines, normally measures at least 11.5 cm. The posterior component (posterior sagittal diameter), between the sacrum and the line created by the interspinous diameter, is usually at least 4.5 cm.

PELVIC OUTLET. The outlet of the pelvis consists of two approximately triangular areas not in the same plane but having a common base, which is a line drawn between the two ischial tuberosities (Fig. 3-26). The apex of the posterior triangle is at the tip of the sacrum, and the lateral boundaries are the sacrosciatic ligaments and the ischial tuberosities. The anterior triangle is formed by the area under the pubic arch. Three diameters of the pelvic outlet usually are described: the anteroposterior, transverse, and posterior sagittal. The anteroposterior diameter (9.5 to 11.5 cm) extends from the lower margin of the symphysis pubis to the tip of the sacrum (Fig. 3-26). The transverse diameter (11 cm) is the distance between the inner edges of the ischial tuberosities. The posterior sagittal diameter extends from the tip of the sacrum to a right-angle intersection with a line between the ischial tuberosities. The normal *posterior sagittal diameter* of the outlet usually exceeds 7.5 cm (Fig. 3-26).

In obstructed labors caused by a narrowing of the midpelvis or pelvic outlet, the prognosis for vaginal delivery often depends on the length of the posterior sagittal diameter of the pelvic outlet (see Figs. 18-7 and 18-8).

PELVIC SHAPES

In the past, x-ray pelvimetry was used frequently in women with suspected cephalopelvic disproportion or fetal malpresentation. Pelvic radiography also was used as an aid in understanding the general architecture and configuration of the pelvis, as well as its size. [Caldwell and Moloy \(1933, 1934\)](#) developed a classification of the pelvis that is still used. The classification is based upon the shape of the pelvis, and familiarity with the classification helps the physician to understand the mechanisms of labor in normally and abnormally shaped pelvises.

CALDWELL-MOLOY CLASSIFICATION. A line drawn through the greatest transverse diameter of the inlet divides it into anterior and posterior segments. The shapes of these segments are important determinants in this method of classification (Fig. 3-27). The character of the posterior segment determines the type of pelvis, and the character of the anterior segment determines the tendency. Many pelvises are not pure but mixed types; for example, a gynecoid pelvis with an android tendency means that the posterior pelvis is gynecoid and the anterior pelvis is android in shape.

GYNECOID PELVIS. The posterior sagittal diameter of the inlet is only slightly shorter than the anterior sagittal. The sides of the posterior segment are well rounded and wide. Because the transverse diameter of the inlet is either slightly greater than or about the same as the anteroposterior diameter, the inlet is either slightly oval or round. The sidewalls of the pelvis are straight, the spines are not prominent, the pubic arch is wide, and the transverse diameter at the ischial spines is 10 cm or more. The sacrum is inclined neither anteriorly nor posteriorly. The sacrosiatic notch is well rounded and never narrow. [Caldwell and co-workers \(1939\)](#) ascertained the frequency of the four parent pelvic types by study of Todd's collection, and they reported that the gynecoid pelvis was found in almost 50 percent of women.

ANDROID PELVIS. The posterior sagittal diameter at the inlet is much shorter than the anterior sagittal, limiting the use of the posterior space by the fetal head. The sides of the posterior segment are not rounded but tend to form, with the corresponding sides of the anterior segment, a wedge at their point of junction. The anterior pelvis is narrow and triangular. The sidewalls are usually convergent, the ischial spines are prominent, and the subpubic arch is narrowed. The bones are characteristically heavy, and the sacrosiatic notches are narrow and highly arched. The sacrum is set forward in the pelvis and usually is straight, with little or no curvature, and the posterior sagittal diameter is decreased from inlet to outlet by the forward inclination of the sacrum. Not infrequently there is considerable forward inclination of the sacral tip.

The extreme android pelvis presages a poor prognosis for vaginal delivery. The frequency of difficult forceps operations increases substantively when there is a *small* android pelvis. Android-type pelvises made up one third of pure-type pelvises encountered in white women and one sixth in nonwhite women in the Todd collection.

ANTHROPOID PELVIS. The anteroposterior diameter of the inlet is greater than the transverse. This results in an oval anteroposteriorly, with the anterior segment somewhat narrow and pointed. The sacrosiatic notches are large, and the sidewalls often are convergent. The sacrum usually has six segments and is straight, making the anthropoid pelvis deeper than the other types.

The ischial spines are likely to be prominent. The subpubic arch frequently is narrowed but well shaped. Anthropoid-type pelvises make up one fourth of pure-type pelvises in white women and nearly one half of those in nonwhite women.

PLATYPelloID PELVIS. The platypelloid pelvis has a flattened gynecoid shape, with a short anteroposterior and a wide transverse diameter. The latter is set well in front of the sacrum, as in the typical gynecoid pelvis. The angle of the anterior pelvis is very wide, and the anterior puboiliac and posterior iliac portions of the iliopectineal lines are well curved. The sacrum usually is well curved and rotated backward. Thus, the sacrum is short and the pelvis shallow, creating wide sacrosiatic notches. The platypelloid pelvis is the rarest of the pure varieties and is found in less than 3 percent of women.

INTERMEDIATE-TYPE PELVES. Intermediate or mixed types of pelvises are much more frequent than pure types.

PELVIC SIZE AND ITS CLINICAL ESTIMATION

PELVIC INLET MEASUREMENTS DIAGONAL CONJUGATE. In many abnormal pelvises, the anteroposterior diameter of the pelvic inlet (the obstetrical conjugate) is considerably shortened. It is important therefore to determine its length, but this measurement can be obtained only by radiographic techniques. The distance from the sacral promontory to the lower margin of the symphysis pubis (the diagonal conjugate), however, can be measured clinically (Figs. 3-28 and 3-29). The examiner introduces two fingers into the vagina; before measuring the diagonal conjugate, the mobility of the coccyx is evaluated and the anterior surface of the sacrum is palpated. The mobility of the coccyx is tested by palpating it with the fingers in the vagina and attempting to move it to and fro. The anterior surface of the sacrum is then palpated from below upward, and its vertical and lateral curvatures are noted. In normal pelvises only the last three sacral vertebrae can be felt without indenting the perineum, whereas in markedly contracted pelvises the entire anterior surface of the sacrum usually is readily accessible. Occasionally, the mobility of the coccyx and the anatomical features of the lower sacrum may be defined more easily by rectal examination.

Except in extreme degrees of pelvic contraction, in order to reach the promontory of the sacrum, the examiner's elbow must be depressed and, unless the examiner's fingers are unusually long, the perineum forcibly indented by the knuckles of the examiner's third and fourth fingers. The index and the second fingers, held firmly together, are carried up and over the anterior surface of the sacrum. By sharply depressing the wrist, the promontory may be felt by the tip of the second finger as a projecting bony margin. With the finger closely applied to the most prominent portion of the upper sacrum, the vaginal hand is elevated until it contacts the pubic arch; and the immediately adjacent point on the index finger is marked, as shown in [Figure 3-28](#). The hand is withdrawn, and the distance between the mark and the tip of the second finger is measured. The diagonal conjugate is determined, and the obstetrical conjugate is computed by subtracting 1.5 to 2.0 cm, depending upon the height and inclination of the symphysis pubis, as illustrated in [Figure 3-29](#). If the diagonal conjugate is greater than 11.5 cm, it is justifiable to assume that the pelvic inlet is of adequate size for vaginal delivery of a normal-sized fetus.

Transverse contraction of the inlet can be measured only by imaging pelvimetry ([Chap. 18, p. 438](#)). Such a contraction is possible even in the presence of an adequate anteroposterior diameter.

ENGAGEMENT. This refers to the descent of the biparietal plane of the fetal head to a level below that of the pelvic inlet (Figs. 3-30 and 3-31). When the biparietal, or largest, diameter of the normally flexed fetal head has passed through the inlet, the head is engaged. Although engagement of the fetal head usually is regarded as a phenomenon of labor, in nulliparas it commonly occurs during the last few weeks of pregnancy. When it does so, it is confirmatory evidence that the pelvic inlet is

adequate for that fetal head. **With engagement, the fetal head serves as an internal pelvimeter to demonstrate that the pelvic inlet is ample for that fetus.**

Whether the head is engaged may be ascertained by rectal or vaginal examination or by abdominal palpation. After gaining experience with vaginal examination, it becomes relatively easy to locate the station of the lowermost part of the fetal head in relation to the level of the ischial spines. If the lowest part of the occiput is at or below the level of the spines, the head usually, but not always, is engaged, because the distance from the plane of the pelvic inlet to the level of the ischial spines is approximately 5 cm in most pelves, and the distance from the biparietal plane of the unmolded fetal head to the vertex is about 3 to 4 cm. Under these circumstances, the vertex cannot possibly reach the level of the spines unless the biparietal diameter has passed the inlet, or unless there has been considerable elongation of the fetal head because of molding and formation of a *caput succedaneum*.

Engagement may be ascertained less satisfactorily by abdominal examination. If the biparietal plane of a term-sized infant has descended through the inlet, the examining fingers cannot reach the lowermost part of the head. Thus, when pushed downward over the lower abdomen, the examining fingers will slide over that portion of the head proximal to the biparietal plane (nape of the neck) and diverge. Conversely, if the head is not engaged, the examining fingers can easily palpate the lower part of the head and will converge (the fourth Leopold maneuver; see [Chap. 12, p. 257](#)).

Fixation of the fetal head is its descent through the pelvic inlet to a depth that prevents its free movement in any direction when pushed by both hands placed over the lower abdomen. Fixation is not necessarily synonymous with engagement. Although a head that is freely movable on abdominal examination cannot be engaged, fixation of the head is sometimes seen when the biparietal plane is still 1 cm or more above the pelvic inlet, especially if the head is molded appreciably.

Although engagement is conclusive evidence of an adequate pelvic inlet for that fetal head, its absence is by no means always indicative of pelvic contraction.

PELVIC OUTLET MEASUREMENTS. An important dimension of the pelvic outlet that is accessible for clinical measurement is the diameter between the ischial tuberosities, variously called the *biischial diameter*, *intertuberous diameter*, and *transverse diameter of the outlet*. A measurement of over 8 cm is considered normal. The measurement of the transverse diameter of the outlet can be estimated by placing a closed fist against the perineum between the ischial tuberosities, after first measuring the width of the closed fist. Usually the closed fist is wider than 8 cm. The shape of the subpubic arch also can be evaluated at the same time by palpating the pubic rami from the subpubic region toward the ischial tuberosities.

MIDPELVIS ESTIMATION. Clinical estimation of midpelvis capacity by any direct form of measurement is not possible. If the ischial spines are quite prominent, the sidewalls are felt to converge, and the concavity of the sacrum is very shallow; if the biischial diameter of the outlet is less than 8 cm, then suspicion is aroused about a contraction in this region.

SECTION II - PHYSIOLOGY OF PREGNANCY

4. The Endometrium and Decidua: Menstruation and Pregnancy

Endometrium/decidua is the anatomical site of blastocyst apposition, implantation, and placental development. The endometrium is the mucosal lining of the uterine cavity and the decidua is the highly modified and specialized endometrium of pregnancy. From an evolutionary perspective, the human endometrium is highly developed in order to accommodate a hemochorioendothelial type of placentation. Endometrial development of a magnitude similar to that observed in women, that is with special spiral (or coiling) arteries, is restricted to only the catarrhine primates—such as humans, great apes, and Old World monkeys. Trophoblasts of the blastocyst invade these endometrial arteries during implantation and placentation to establish uteroplacental vessels.

The catarrhine primates are the only mammals that menstruate, a process of endometrial tissue shedding with hemorrhage that is dependent upon sex steroid hormone-directed changes in blood flow in the spiral arteries. With nonfertile, but ovulatory, ovarian cycles, menstruation effects desquamation of the endometrium. New endometrial growth and development must be initiated with each ovarian cycle, so that endometrial maturation corresponds rather precisely with the next pregnancy (implantation) opportunity. There seems to be a very narrow window of endometrial receptivity to blastocyst implantation in the human that corresponds approximately to menstrual cycle days 20 to 24.

MATERNAL TISSUES OF THE FETAL-MATERNAL COMMUNICATION SYSTEM

Direct cell-to-cell contact between blastocyst and maternal endometrium is first established 6 days after fertilization of the ovum. At this time, the blastocyst contacts the endometrial surface epithelium, a process called "blastocyst" apposition. For a brief time, the surface epithelium of the endometrium is the only maternal tissue in direct contact with the blastocyst; but even then, biological processes are occurring between the two. Soon after apposition, the blastocyst becomes adherent to the endometrium, and the process of implantation has begun. The fundamental components of immunological acceptance of the conceptus, maternal recognition of pregnancy, placental development, pregnancy maintenance, and fetal nutrition are quickly established.

THE CARDINAL FUNCTION OF THE UTERUS

Biologically, the single salutary function of the uterus is the accommodation of a conceptus (pregnancy). There is no known endocrine or other physiological function of the endometrium or myometrium, independent of pregnancy, that affects the metabolic homeostasis or the physical well-being of women. There is no evidence that the uncomplicated removal of the myometrium, endometrium, and cervix (hysterectomy) adversely affects the life span or general good health of women.

OVERVIEW OF ENDOMETRIAL FUNCTION

The growth and functional characteristics of the human endometrium are unique. The epithelial (glandular) cells, the stromal (mesenchymal) cells, and the blood vessels of the endometrium replicate cyclically in reproductive-age women at a rapid rate. The endometrium is regenerated during each endometrial (ovarian-menstrual) cycle. The superficial two thirds of the entire endometrium is shed and regenerated almost 500 times, on average, during the reproductive lifetime of most women. There is no other example in humans of the cyclical shedding and regrowth of an entire tissue.

To place repetitive menstruation in perspective, the lifetime cumulative blood loss associated with normal endometrial shedding is 10 to 20 liters or more, an amount of blood that contains at least three times the total body iron content of the average adult woman. The 38-year reproductive lifetime cumulative production of progesterone by corpora lutea and placenta in the woman who chooses two pregnancies but experiences 450 nonfertile ovarian cycles is about 150,000 mg (150 g), which is similar to the cumulative amount of cortisol secreted by the adrenal cortices during the same 38 years. This incredible investment in endometrial tissue growth provides for regular renewal of the functional portion of this tissue in preparation for the next pregnancy opportunity.

THE ACCOMMODATION OF PREGNANCY IS THE CARDINAL FUNCTION OF THE ENDOMETRIUM/DECIDUA. The single physiological and metabolic function of the endometrium/decidua is to serve as the maternal tissue interface of pregnancy. The endometrium is the optimal site for blastocyst implantation and embryo-fetal/placental development; but it cannot be claimed that this function of the endometrium/decidua is unique because of the known success, albeit limited, of ectopic pregnancies. "Decidualization" of tissues in which ectopic pregnancies implant is prominent.

There also may be a role for the endometrium in sperm capacitation; but again, it cannot be argued that this function is unique to this tissue, as evidenced by the success of sperm capacitation and fertilization of human ova in vitro.

The decidual cells are differentiated from the stromal cells of the endometrium under the influence of progesterone and other stimuli. In addition, there are many bone marrow-derived cells (a variety of lymphocytes and leukocytes) in normal endometrium and decidua. The unique spiral arteries persist in one portion of the decidua (parietalis), but these arteries are invaded and modified by trophoblasts in the decidua (basalis) underlying the implantation site.

The implantation of the blastocyst on the surface of the endometrial cavity provides an anatomical site from which the fetus can be born. The decidua is continuous with the birth canal, that is, there is access from the surface of the endometrium/decidua through the cervical canal to the vagina. This anatomical arrangement also provides for the expulsion of the fetus, by the contractions of the myometrium, which effect dilatation of the cervix and descent of the fetus with childbirth.

The endometrium and decidua are specialized tissues that carry out multiple functions.

1. The hormonal responsiveness and phenotypic changes of the endometrial/decidual cells facilitates apposition and implantation of the blastocyst.
2. The decidua serves as an immunologically specialized tissue.
3. The endometrium/decidua and the spiral arteries accept trophoblast invasion, providing for embryo-fetal nutrition.
4. The decidua contributes cytokines and growth factors that promote placental growth, function, and the inhibition of (trophoblast) apoptosis.

The decidua, with its bone marrow-derived cells, also serves first to accept and then to limit trophoblast invasion into maternal tissues. Lastly, the decidua is a highly versatile endocrine tissue, producing prolactin, 1,25-dihydroxy-vitamin D₃, corticotropin-releasing hormone, parathyroid hormone-related protein, relaxin, prorenin, somatostatin, oxytocin, activin, inhibin, corticosteroid-binding globulin, insulin-like growth factor-binding protein(s), and multiple pregnancy-specific proteins (Popovici and associates, 2000). These functions of the endometrium were reviewed by [Tang and co-workers \(1994\)](#).

The role of the decidua in promoting as well as accommodating placental growth and function is a topic of great research interest. Many investigations are directed toward a definition of the role of cytokines and growth factors, produced in the decidua, in trophoblast replication and differentiation, or in modifying growth factor receptors in the trophoblasts. It seems likely that trophoblasts secrete agents that induce the decidua to produce factors that incite further growth and differentiation of trophoblasts in a paracrine arrangement. The specifics of this coordinated process are not fully defined, but there seems to be little doubt that trophoblasts are capable of enlisting maternal decidual tissue support to ensure placental growth, development, and survival.

SPECIALIZED FUNCTIONS OF THE DECIDUA. The decidua likely is endowed with capacities to respond to microbiological challenges without simultaneously mounting an immunological response that results in abortion or preterm labor. The endometrial cavity is anatomically open, potentially and functionally patent to the external environment. The same is true of the decidua during pregnancy, at least at the juncture of the lower pole of the amniotic sac with the decidua parietalis. There is, however, functional closure of the cervical canal during pregnancy that is effected by a mucus "plug" that has antimicrobial properties. Therefore, the decidua must function in an exceptionally successful manner to limit bacterial colonization at the lower pole of the chorion laeve-decidual interface. Many investigators have suggested that infections that originate by ascending spread of microorganisms from the cervix of vaginal fluid may constitute one cause of the onset of preterm labor ([Chap. 11, p. 281](#)).

ESTROGEN ACTION. Estradiol-17 β , the biologically potent, naturally occurring estrogen, which is secreted by the granulosa cells of the dominant ovarian follicle, acts to promote responses of the endometrium in a manner that is classical for steroid hormone action. By use of estrogens of high specific radioactivity, [Jensen and Jacobson \(1962\)](#) demonstrated that nonmetabolized (radiolabeled) estradiol-17 β is sequestered in estrogen-responsive tissues, notably the uterus. These research

findings marked the beginning of the contemporary era of the study of the mechanisms of steroid action through specific steroid receptor proteins.

Estradiol-17 β enters cells from blood by simple diffusion; but in estrogen-responsive cells, estradiol-17 β is sequestered by binding to estrogen receptor protein molecules. The receptor is a macromolecule characterized by high affinity, but low capacity, for estradiol-17 β and other biologically active (synthetic) estrogens. The estradiol-17 β -receptor complex, after transformational changes, is a transcriptional factor that becomes associated with the estrogen response element of specific genes. This interaction brings about estrogen receptor-specific initiation of gene transcription, which promotes the synthesis of specific messenger RNAs, and thereafter the synthesis of specific proteins. Among the many proteins synthesized in most estrogen-responsive cells are additional estrogen receptors and other macromolecules characterized by high affinity for progesterone (progesterone receptors). Thus, estradiol-17 β acts in the endometrium and in other estrogen-responsive tissues to promote the perpetuation of estrogen action and to promote the responsiveness of that tissue to progesterone.

The endometrial epithelial (glandular) cells are estrogen responsive but do not necessarily replicate as a result of the direct action of estradiol-17 β on the epithelial cells. Estrogen, administered to castrate or postmenopausal women, promotes growth of the endometrium, especially the glandular epithelial cells. Replication of human endometrial epithelial cells in culture, however, is not increased appreciably, if at all, when estrogen is added to the medium. It seems more likely that estradiol-17 β and other bioactive estrogens in vivo cause replication of the epithelium indirectly (probably through actions on the stromal cells). It has been suggested that estrogen acts on the endometrial stromal cells to promote the synthesis of an endometrial epithelial cell growth factor, which functions in a paracrine manner to cause replication of the adjacent epithelial cells. This type of arrangement may be commonplace in epithelial-mesenchymal interactions in hormone-responsive tissues.

PROGESTERONE ACTION. This hormone also enters cells by diffusion and in responsive tissues becomes associated with progesterone receptors with high affinity, but low capacity, for progestins. Commonly, the cellular content of progesterone receptors is dependent on previous estrogen action. The progesterone-receptor complex also promotes gene transcription, but the response to progesterone is strikingly different from that evoked by the estradiol-17 β -estrogen receptor complex. Progesterone actions include a decrease in the synthesis of estrogen receptor molecules (Tseng and Gurpide, 1975). This is one means by which progesterone (and synthetic progestins) attenuates estrogen action. Tseng and Gurpide (1974) also found that progesterone acts to increase the rate of enzymatic inactivation of estradiol-17 β through an increase in the activity of the enzyme, estradiol dehydrogenase. Progesterone also acts to increase sulfurylation of estrogens (estrogen sulfotransferase), another means of estrogen inactivation (Tseng and Liu, 1981).

Steroid hormones also may act by mechanisms other than the receptor-mediated, genomic process just described. For example, progesterone and some of its metabolites induce profound biological (cellular) responses through receptor-independent, nongenomic processes.

THE ENDOMETRIAL CYCLE OF OVULATORY WOMEN

In 1937, Rock and Bartlett suggested that the histological features of the endometrium were sufficiently characteristic to permit "dating" of the ovarian cycle of the woman from whom the endometrial tissue was obtained. The histological changes that occur in the endometrium during the nonfertile (but ovulatory) menstrual cycle are summarized in Figure 4-1 and Table 4-1.

HORMONE-INDUCED MORPHOLOGICAL CHANGES OF THE ENDOMETRIUM. The cyclical changes in endometrial histology are faithfully reproduced during each ovulatory ovarian cycle. These sex steroid hormone-induced modifications can be summarized as follows.

1. During the preovulatory, or follicular, phase of the cycle, estradiol-17 β is secreted—principally by a single dominant follicle of one ovary—in increasing quantities until just before ovulation.
2. During the postovulatory, or luteal, phase of the cycle, progesterone is secreted by the corpus luteum in increasing amounts (up to 40 to 50 mg per day) until the midluteal phase.
3. Beginning about 7 to 8 days after ovulation, the rates of progesterone (and estrogen) secretion by the corpus luteum begin to decline and diminish progressively before menstruation.

In response to these cyclical changes in the rates of ovarian sex steroid hormone secretion, there are five main stages of the corresponding endometrial cycle:

1. Menstrual/postmenstrual reepithelialization.
2. Endometrial proliferation in response to stimulation (directly or indirectly) by estradiol.
3. Abundant glandular secretion, in response to the combined action of estrogen and progesterone.
4. Premenstrual ischemia, the result of endometrial tissue volume involution, which causes stasis of blood in the spiral arteries.
5. Menstruation, which is preceded and accompanied by severe vasoconstriction of the endometrial spiral arteries and collapse and desquamation of all but the deepest layer of the endometrium.

In the final analysis, menstruation is the consequence of the withdrawal of factors that maintain endometrial growth.

Commonly, the initiation of menstruation is attributed to "progesterone withdrawal," but this is probably a very oversimplified explanation. It is true that the administration of estrogen to castrate women and then treatment/withdrawal with progesterone will effect menstruation, even with continued estrogen treatment. Nonetheless, the heretofore dominant role attributed to progesterone in promoting pregnancy-favorable phenomena and the physiological importance of progesterone withdrawal in the initiation of menstruation seem to have been overestimated. Progesterone facilitates and permits decidualization of the endometrium and the maintenance of pregnancy; progesterone withdrawal may favor the initiation of menstruation, lactation, and parturition. There are, however, multiple other coordinated, interactive processes that are operative and essential for the success of each of these events (Chap. 11, p. 262).

The follicular (preovulatory or proliferative) phase, and the postovulatory (luteal or secretory) phase of the ovarian/endometrial cycles, are customarily divided into early and late stages. The normal secretory phase of the endometrial (menstrual) cycle can be subdivided rather finely (almost day by day), by histological criteria, from shortly after ovulation until the onset of menstruation.

EARLY PROLIFERATIVE PHASE ENDOMETRIUM. About two thirds of the functional endometrium is fragmented and shed during menstruation; but, reepithelialization is in progress even before menstrual bleeding has ceased. By the fifth day of the endometrial cycle (first day of menses equals day 1), the epithelial surface of the endometrium has been restored and revascularization of the endometrium is in progress. During the early part of the proliferative phase, the endometrium is thin, usually less than 2 mm in thickness. The glands at this stage are narrow, tubular structures that pursue almost a straight and parallel course (one with the other) from the basal layer toward the surface of the endometrial cavity. Mitotic figures, especially in the glandular epithelium, are identified by the fifth day after the commencement of menstruation, and mitotic activity in both epithelium and stroma persists until 2 to 3 days after ovulation. Although blood vessels are numerous and prominent, there is no extravasated blood or leukocyte infiltration in the endometrium at this stage. Clearly, reepithelialization and angiogenesis are important to the cessation of endometrial bleeding at the end of menstruation, and these processes are dependent upon tissue regrowth.

LATE PROLIFERATIVE PHASE ENDOMETRIUM. In the late proliferative phase, the endometrium has become thicker, the result of both glandular hyperplasia and an increase in stromal ground substance (edema and proteinaceous material). The loose stroma is especially prominent, and the glands in the superficial portions of the endometrium (functional zone) are widely separated compared with those of the deeper zone, where the glands are crowded and tortuous and the stroma is more dense. At midcycle, as the time of ovulation is approached, the glandular epithelium has become taller and pseudostratified.

Day-by-day dating of the endometrium by histological criteria is not possible during the proliferative phase because of the considerable variation among women in the length of the follicular (preovulatory) phase of the cycle. The luteal or secretory (postovulatory) phase of the cycle among women is remarkably constant in duration (12 to 14 days), but the length of the proliferative or follicular (preovulatory) phase varies greatly. In apparently normal, fertile women, the follicular phase may be as short as 5 to 7 or as long as 21 to 30 days.

SPIRAL (COILED) ARTERIES OF THE ENDOMETRIUM AND DECIDUA. Boyd and Hamilton (1970) emphasized the extraordinary importance of the spiraling or

coiled arteries of the human endometrium, pointing out that William Hunter in 1774 referred to these vessels as the "curling" arteries. The endometrial spiral arteries arise from the arcuate arteries, which are branches of the uterine vessels ([Chap. 3, p. 42](#)). The morphological and functional properties of these vessels are unique and essential for establishing the changes in blood flow that permit menstruation. An important characteristic of the secretory-phase endometrium is the striking growth and development of these coiled arteries, which become much more tortuous at this time. Ovarian/endometrial cycle-specific modifications in the rate of blood flow in the spiral arteries are essential for:

1. The initiation of menstruation.
2. The limitation of blood loss with menses.

Pregnancy-induced modifications of these vessels result in the establishment of maternal blood flow to the syncytiotrophoblast, that is, the delivery of maternal blood to the intervillous space of the placenta. The spiral arteries branch, and the arterioles break up into capillaries within the compact layer of endometrium. Superficially, a capillary network forms near the endometrial surface, and these are the first vessels invaded by cytotrophoblasts of the implanting blastocyst.

POSTOVULATORY ENDOMETRIUM. In the catarrhine primates the midluteal/secretory phase of the ovarian/endometrial cycle is a critical branch point in the development and differentiation of the endometrium ([Fig. 4-2](#)). This is the time of biochemical transition when (with blastocyst implantation) full decidualization commences, or else (in the absence of blastocyst implantation) the multiple changes in endometrium begin that are preparatory to menstruation (including predecidualization of stromal cells). It has been suggested that transforming growth factor- β acts in an autocrine/paracrine fashion to define the functional destiny of the endometrium at this critical branch point of development ([Casey and McDonald, 1996](#)).

With rescue of the corpus luteum and continued progesterone secretion after implantation, transforming growth factor- β facilitates decidualization. In the absence of implantation and a decline in progesterone secretion, transforming growth factor- β facilitates the complete abandonment of progesterone action, resulting in menstruation. The possibility that uterine leukocytes are instrumental in the decidualization/menstruation branch point has been reviewed by [King \(2000\)](#).

CHANGES IN ENDOMETRIAL SPIRAL ARTERY BLOOD FLOW. From observations made in a classical study, [Markee \(1940\)](#) described the tissue and vascular changes that occur in endometrium before menstruation. He observed cyclical alterations in endometrial tissue explants that he had transplanted to the anterior chamber of the eye of rhesus monkeys. At magnifications up to 150 \times , Markee studied 432 separate cycles (2 to 72 per animal) in pieces of endometrial tissue in each of 41 monkeys during an intense 9-year investigation, including each menstrual cycle of one monkey for 6 years! From many thousands of detailed observations, Markee deduced that the vascular changes that occur in endometrium are in response to growth cycles. He concluded that menstruation occurred during a phase of regression of endometrial growth (as estrogen and progesterone secretion by the corpus luteum decline).

Markee also surmised that there were marked changes in blood flow to the endometrium during the time of growth regression, and that these changes are essential for menstruation, that is, endometrial shedding with bleeding. He emphasized that the endometrium is supplied with blood by two types of vessels:

1. Straight arteries, which supply the basal one third of endometrium.
2. Coiled or spiral (curling) arteries, which supply the superficial two thirds of this tissue.

During and preceding menstruation, the straight arteries do not contract.

During the phase of endometrial growth, the spiral arteries lengthen at a rate that is appreciably greater than the rate of increase in endometrial tissue height or thickness ([Fig. 4-3](#)). This discordance in growth between the two tissues obliges even greater coiling of the already spiraling vessels. [Perrot-Applanat and associates \(1988\)](#) described progesterone and estrogen receptors in the smooth muscle cells of the uterine arteries, including the spiral arteries. It is likely, however, that specific angiogenic agents are produced by endometrial stromal (and epithelial) cells in response to estrogen ([Zhang and colleagues, 1995](#)).

As endometrial growth regresses, commencing concomitantly with the decline in corpus luteum function during nonfertile ovarian cycles, an even greater coiling of the spiral arteries is obliged. When the coiling of the spiral arteries becomes sufficiently severe, the resistance to blood flow in these vessels is increased strikingly, becoming so marked that profound stasis develops, causing hypoxia of the endometrium. Perhaps in response to hypoxia, vasodilatation at this time was sometimes observed (45 percent of cycles). Somewhat later, at 4 to 24 hours before bleeding into the endometrium began, there was, invariably, a period of intense vasoconstriction of the spiral arteries. Markee emphasized that the anemic appearance of the functional zone of the endometrium that results during this time of spiral artery vasoconstriction may be striking.

Markee also emphasized that the period of vasoconstriction preceding the onset of menstruation is the most striking and constant event of the menstrual cycle. Based on the sequence of vascular changes in endometrium, Markee reasoned that the intense vasoconstriction of the spiral arteries served to limit blood loss during menstruation. The reduction in spiral artery blood flow and resultant stasis before the time of vasoconstriction, however, was the primary cause of endometrial ischemia and then tissue degeneration.

Markee hypothesized that, immediately preceding menstruation, a substance is produced in the hypoxic endometrium that acts to induce severe vasospasm of the spiral arteries. His observations led him to surmise that what is now referred to as a paracrine mechanism was involved in the induction of the characteristic premenstrual vasoconstriction of the spiral arteries. Namely, he deduced that a vasoconstrictor was produced by endometrial stromal cells. Endothelin-1 is one candidate for the stromal cell vasoconstrictor that Markee predicted ([Casey and MacDonald, 1993, 1996](#); [Economos and colleagues, 1992](#)).

Markee also noted that when an individual coiled artery relaxed, after a period of constriction, hemorrhage occurred from that artery or its branches. Thereafter, in sequence, the arterioles of these constricted arteries relax and bleed; the succession of small hemorrhages from individual arterioles or capillaries continues for a variable but very short time (seconds to a few minutes). Although this sequence of vasoconstriction, relaxation, and hemorrhage appears to be well established, the mechanism(s) that actually brings about the escape of blood from the vessels is not certain. Perhaps damage to the walls of these vessels occurs during the period of intense vasoconstriction, favoring the rupture of these vessels once the constricted segment relaxes and blood flow is resumed.

LEUKOCYTE INFILTRATION OF ENDOMETRIUM. Another notable histological characteristic of the late premenstrual phase endometrium is the infiltration of the stroma by polymorphonuclear leukocytes, giving a pseudoinflammatory appearance to the tissue. The infiltration of neutrophils occurs primarily on the day or two immediately preceding the onset of menstruation. The endometrial stromal and epithelial cells produce interleukin-8 (IL-8), a chemotactic/activating factor for neutrophils ([Arici and associates, 1993](#)). IL-8¹ may be one of the agents that serves to recruit neutrophils to the endometrium just prior to the onset of menstruation. Similarly, the endometrium is capable of synthesizing monocyte chemotactic protein-1 (MCP-1), a potent chemoattractant for monocytes ([Arici and colleagues, 1995](#)). The rates of synthesis of IL-8 and MCP-1² in endometrial stromal cells appears to be modulated, in part, by sex steroid hormones and transforming growth factor- β ([Arici and associates, 1996a, b](#)).

Interleukin-15 (IL-15) is also expressed in endometrium and preferentially during the secretory phase ([Okada and associates, 2000](#)). [Verma and associates \(2000\)](#) demonstrated that IL-15³ acts to induce proliferation of decidual natural killer cells. These findings are suggestive that IL-15 produced in situ may be involved in replication of natural killer cells that occurs in secretory endometrium.

VASOACTIVE AGENTS PRODUCED IN THE ENDOMETRIUM. Blood flow in the endometrium (spiral arteries) appears to be regulated in an endocrine manner by sex steroid hormone-induced modifications of a local (paracrine-mediated) vasoactive/peptide system.

PROSTAGLANDINS. These bioactive tissue autacoids are most commonly synthesized in the same cells in which these substances act or else in nearby cells. Thus, prostaglandins usually are autocrine- or paracrine-acting agents rather than endocrine (or humoral) hormones. Prostaglandins act through a host of separate but specific plasma membrane G-protein-linked receptors that also facilitate some degree of specificity of the actions of various prostaglandins. Prostaglandins are degraded rapidly in the tissues of origin such as endometrium, or in nearby tissues, and in more remote sites such as the lungs, in a reaction catalyzed by the enzyme prostaglandin dehydrogenase ([Casey and associates, 1980, 1989](#)).

A role for prostaglandins, especially PGF₂ (a vasoconstrictor), in the initiation of menstruation has been suggested by many investigators ([Abel, 1985](#)). Large amounts of prostaglandins are present in menstrual blood, and the administration of PGF_{2a} to women also gives rise to symptoms that mimic those of dysmenorrhea, which is commonly associated with normal ovulatory menses (menstruation after progesterone withdrawal), and likely caused by myometrial contractions and uterine

ischemia. The administration of PGF_{2a} to nonpregnant women also will cause menstruation; this response is believed to be mediated by PGF_{2a}-induced vasoconstriction of the endometrial spiral arteries.

An alternative explanation is that prostaglandins are produced in endometrium at the time of menstruation in an accelerated fashion in response to inflammation, hypoxia, and trauma. Membrane glycerophospholipid hydrolysis is accelerated with tissue insult, causing the release of arachidonic acid, the precursor of prostaglandins, a major route by which arachidonic acid is metabolized. Prostaglandin formation in endometrium is obliged with hypoxia caused by stasis of blood in the highly coiled spiral arteries with regression of endometrial growth. Prostaglandin formation also may account, in part, for Markee's observation that vasodilatation oftentimes accompanied the stasis of blood flow in the spiral arteries. PGE₂ and PGI₂ (prostacyclin) both act to effect vasodilation. Consequently, accelerated prostaglandin formation in endometrium is most likely the result of, and not the cause of, tissue hypoxia and menstruation.

Prostaglandin dehydrogenase activity also is greater in early secretory endometrium than in endometrium before ovulation ([Fig. 4-4](#)). This enzyme activity, however, is localized primarily in the glandular epithelium and may be involved more intimately in implantation processes rather than in the initiation of menstruation ([Casey and co-workers, 1980](#)).

VASOACTIVE PEPTIDES. The actions of a number of peptides may explain a hormone-responsive paracrine system in the endometrium to regulate spiral artery blood flow. One is the endothelin/enkephalinase system ([Casey and MacDonald, 1996](#)). The endothelins (endothelin-1, -2, and -3) are small (21 amino acids) peptides. Endothelin-1 is a very potent vasoconstrictor, which was first identified as a product of vascular endothelial cells ([Yanagisawa and colleagues, 1988](#)).

The endothelins are degraded by the enzyme enkephalinase (membrane metalloendopeptidase), which also inactivates the enkephalins in brain cells; atrial natriuretic peptide in kidney; substance P in bronchial epithelium and intestine; and the endothelins in endometrium. Enkephalinase is localized in endometrial stromal cells, and its specific activity in these cells increases strikingly and in parallel with the increase in blood levels of progesterone after ovulation. As shown in [Figure 4-4](#), the specific activity of enkephalinase in endometrium is highest during the midluteal phase of the ovarian cycle and declines steadily thereafter as the plasma levels of progesterone decrease with regression of the corpus luteum ([Casey and associates, 1991](#)).

Parathyroid hormone-related protein (PTH-rP) is another vasoactive peptide demonstrated in human endometrial stromal cells ([Casey and colleagues, 1992](#)). PTH-rP⁴ and parathyroid hormone (PTH) act as vasorelaxants. Thus, an endothelin-1/enkephalinase/PTH-rP system may be operative in endometrial stroma cells to modulate endometrial spiral arterial blood flow in a local but hormonally responsive manner. The potential roles of PTH-rP in other reproductive processes and in placental function and fetal life are discussed in [Chapters 6, 7, and 11](#).

ORIGIN OF MENSTRUAL BLOOD. Menstrual bleeding is of both arterial and venous origin, but arterial bleeding is, quantitatively, appreciably greater than venous. Endometrial bleeding appears to begin by rhexis of an arteriole of a coiled artery with consequent formation of a hematoma. On occasion, however, bleeding takes place by leakage through a spiral artery. When a hematoma forms, the superficial endometrium is distended and then ruptures. Subsequently, fissures develop in the adjacent functional layers, and blood, as well as fragments of tissue of various sizes, are detached. Although some tissue autolysis occurs, as a rule, fragments of endometrium can be identified in menstrual discharge collected from the vagina. Hemorrhage stops when the arterioles are again constricted. The changes that accompany partial tissue necrosis also serve to seal off the tip of the vessel; and in the superficial portion, often only the endothelium remains. The surface of the endometrium is restored, according to [Markee \(1940\)](#), by growth of the flanges, or collars, that form the everted free ends of the uterine glands. These flanges increase in diameter very rapidly, and the continuity of the epithelium is reestablished by the fusion of the edges of these sheets of thin, migrating cells.

The correlations of ovarian hormonal and endometrial morphological events are summarized in [Table 4-1](#).

CLINICAL ASPECTS OF MENSTRUATION

Menstruation is the periodic discharge of blood, mucus, and cellular debris from the uterine mucosa. Menses occur at more or less regular, cyclical, and predictable intervals from menarche to menopause except during pregnancy, lactation, anovulation, or pharmacological intervention. It is convenient and more descriptive to use the term menstruation to refer to the bleeding that accompanies progesterone withdrawal after ovulation with nonfertile cycles, and to refer to other episodes of endometrial hemorrhage in nonpregnant women as uterine or endometrial bleeding.

MENARCHE AND PUBERTY. During the past two centuries, the age at which menstruation begins during puberty, menarche, has declined steadily until recent years (see [Fig. 2-1](#)). This decline in age of menarche in girls living in the United States, however, seems to have ceased. The average time at which menstruation begins is now between 12 and 13 years of age, but in a small proportion of apparently normal girls, menarche may occur as early as the 10th or as late as the 16th year. The term menarche refers specifically to the first menstruation, whereas puberty is a more general term that encompasses the entire process of sexual maturation in the transition from childhood to maturity. Menarche is just one sign of puberty; but when menarche is the consequence of ovulation (and attendant hormonal secretion), the fundamental physiological events of puberty have been completed.

INTERVAL BETWEEN MENSES. The modal interval at which menstruation recurs is considered to be 28 days, but there is considerable variation among women in general, as well as in the cycle lengths of a given woman. Marked variation in the intervals between menstrual cycles is not necessarily indicative of infertility.

[Arey \(1939\)](#), who analyzed the findings of 12 separate studies comprising about 20,000 calendar records from 1500 women, concluded that there is no evidence of perfect menstrual cycle regularity. [Gunn and co-workers \(1937\)](#), in a study of 479 normal British women, found that the typical difference between the shortest and the longest cycle was 8 or 9 days. In 30 percent of women, it was more than 13 days, but it was never fewer than 2 days in any woman. Arey found that among average adult women, one third of menstrual cycles departed by more than 2 days from the mean of the lengths of all cycles. In Arey's analysis of 5322 cycles in 485 normal women, an average interval of 28.4 days was estimated; his finding for the average cycle length in pubertal girls was longer, 33.9 days. [Chiazze and associates \(1968\)](#) analyzed the intervals between 30,655 menstrual cycles of 2316 women. The mean for all cycles was 29.1 days. For cycle intervals that ranged from 15 to 45 days, the average length was 28.1 days. The degree of variability was such that only 13 percent of the women experienced cycles that varied by less than 6 days. [Haman \(1942\)](#) surveyed 2460 cycles in 150 housewives who attended a clinic where special attention was directed to recording accurately the length of the menstrual cycles. Arey's data and those of Haman, which are similar, and the distribution curve computed from averages of these data, are shown in [Figure 4-5](#).

DURATION OF MENSTRUAL BLEEDING. The duration of menstrual flow also is variable, most commonly 4 to 6 days. Bleeding for 2 to 8 days may be normal for a given woman, but the duration of the menstrual flow is usually reasonably similar from cycle to cycle in the same woman.

MENSTRUAL BLOOD. Menstruation in ovulatory women (after progesterone withdrawal) is characterized by the extrusion of shed fragments of endometrium mixed with a variable quantity of blood. Usually the blood is liquid; but if the rate of hemorrhage is excessive, clots of various sizes may appear. The extrusion of clots with uterine bleeding, especially if bleeding is not cyclical or predictable, is suggestive of anovulation, that is, bleeding that occurs without benefit of progesterone action and withdrawal ([Hahn, 1980](#)).

Considerable research has been conducted to understand the incoagulability of menstrual blood. The most logical explanation is consistent with the conclusions of [Whitehouse \(1914\)](#) that the blood is coagulated as it is shed, but thereafter is liquefied by fibrinolytic activity. There are potent thromboplastic properties of endometrium that promptly initiate clotting, but there also are potent fibrinolytic properties that effect prompt lysis of the fibrin clots that are formed.

TISSUE FACTOR AND MENSTRUAL BLOOD CLOTTING. Tissue factor is a plasma membrane-bound protein that is involved in the extrinsic coagulation pathway, which serves to effect clotting after vascular disruption. Ultimately, tissue factor is important in promoting the conversion of prothrombin to thrombin in the initiation of clotting. [Lockwood and colleagues \(1994\)](#) have shown that tissue factor is expressed in human endometrial stromal cells, and that progesterone acts indirectly to increase tissue factor (and plasminogen activator inhibitor 1) expression in these cells. This effect of progesterone requires activation of the epidermal growth factor receptor by epidermal growth factor or transforming growth factor- β . Plasminogen activator inhibitors act to inhibit plasminogen activator action directly, and therefore prevent fibrinolysis ([Lockwood and associates, 1999](#)).

FIBRINOLYSIS OF MENSTRUAL BLOOD CLOTS. Serine proteinases (and their inhibitors) also are produced in endometrium in a cyclical manner suggestive of hormonal regulation. Among the proteinases, plasminogen activator is the enzyme believed to be important in the promotion of fibrinolysis. Plasmin is formed through the action of plasminogen activator (e.g., urokinase) produced in endometrium on blood-borne plasminogen.

BLOOD LOSS WITH MENSES. The amount of blood lost during individual normal menstrual periods has been quantified by several groups of investigators who found the range to be from about 25 to 60 mL ([Baldwin and associates, 1961](#); [Hallberg and co-workers, 1966](#); [Hyttén and associates, 1964](#)). With a normal hemoglobin concentration of 14 g per dL and a hemoglobin iron content of 3.4 mg per g, these volumes of blood contain from 12 to 29 mg of iron and represent blood

loss equivalent to 0.4 to 1.0 mg of iron for every day of the cycle, or from 150 to 400 mg per year. Because the amount of iron that is absorbed from the diet usually is quite limited, this seemingly negligible iron loss is quantitatively important because it contributes further to the low iron stores of the majority of women ([Scott and Pritchard, 1967](#)).

The volume of blood lost with each menstruation is relatively small, especially considering that the surface area of the endometrium of normal uteri of nonpregnant women is 10 to 45 cm² ([Chimbira and colleagues, 1980](#)). Therefore, there must be an effective means of hemostasis in endometrium during menstruation. The control of blood loss likely is not induced by myometrial contractions to compress uterine vessels, as is the case after delivery of the fetus and placenta. Excessive blood loss with menstruation is common, however, in women with coagulation or platelet disorders. It is likely that hemo-stasis in endometrium is effected by:

1. Hemostatic plug formation as in other tissues ([Christiaens and associates, 1985](#)).
2. The intense vasoconstriction of the spiral arteries that commences immediately before and continues during menstruation ([Markee, 1940](#)).

PREMENSTRUAL SYNDROMES

A variety of maladies, sometimes disabling, beset many ovulatory women in a recurrent manner during the luteal phase of each ovarian cycle. Although the biological basis for this association is not defined, evidence points to a causal relationship between progesterone secretion and withdrawal and the development of these premenstrual syndromes (PMS). As reviewed by [MacDonald and associates \(1991\)](#), symptoms include disorders in mood, behavior, and physical well-being. Commonly, there is a characteristic cluster of the same symptoms in a given woman month after month.

RECURRENT PROGESTERONE SECRETION: AN ENDOCRINOPATHY? It is important to recognize that the cyclical recurrence of PMS symptoms is restricted to women in whom endogenous progesterone is secreted in large amounts and then withdrawn, and that these symptoms recur but are limited to the time of progesterone secretion and withdrawal. Specifically, these symptoms do not recur predictably in prepubertal, postmenopausal, anovulatory, or castrate women. Also, PMS-like symptoms do not recur in hypogonadal women treated with estrogen, whether given continuously or cyclically. Moreover, the symptoms of PMS can be relieved by treatment with gonadotropin-releasing hormone (GnRH) agonists, which arrest ovarian function, and by oophorectomy. All of these correlates are indicative of the obligatory involvement of ovulation and the secretion and withdrawal of progesterone in the biogenesis of PMS.

It has been generally assumed that (aside from pregnancy) cyclical ovulation and menstruation is the pinnacle of endocrinological normality in reproductive-age women. In several previous editions of this book, we emphasized, with great conviction, that such a history is highly suggestive of recurrent ovulation, corpus luteum formation, and progesterone secretion. Therefore, from the perspective of ovarian function, recurrent, cyclical, spontaneous menstruation is evidence of normal ovarian function.

Indisputably, the brain-pituitary-ovarian cycle that culminates in ovulation is a normal physiological event. Moreover, the sex hormone-induced biochemical and morphological antecedents of menstruation, eventuating in intense vasospasm of the endometrial spiral arteries, and culminating in the near-complete shedding of the endometrium, provide a unique physiological finale to this cycle. Nonetheless, and even though ovulation is the penultimate in ovarian physiological achievement, the repetition of this process at approximately monthly intervals (followed by menstruation) may not be considered the **evolutionary norm**, however universal these phenomena may be among young women ([Chap. 2, p. 16](#)).

PROGESTERONE AND PMS. Except for pregnancy, progesterone is produced in large amounts only during the luteal phase of each ovarian cycle. The rate of progesterone secretion at these times is greater, by a large margin, than that of any other steroid hormone produced in men or nonpregnant women ([Fig. 4-6](#)).

But, how can progesterone bring about PMS in some but not all women? There is no apparent difference in the rates of progesterone secretion by the corpus luteum in women who do and those who do not suffer from PMS. Until relatively recently, it was believed that progesterone action was mediated singularly by way of the progesterone receptor acting via the progesterone response element in selected genes. Based on this presumption, there were no known actions of progesterone that would clearly implicate this steroid in the biogenesis of PMS, let alone explain the striking differences among women in the spectrum or severity of the multiple symptoms that characterize this disorder(s).

It has now been demonstrated that some of the bioactions of progesterone and its metabolites are mediated by progesterone receptor-independent cellular mechanisms. Progesterone acts at the level of the plasma membrane of selected cells by a nongenomic mechanism to inhibit the activation of adenylate cyclase, for example, in oocytes and in spermatozoa. Progesterone is metabolized, by extraadrenal 21-hydroxylation, to deoxycorticosterone, which acts by way of the mineralocorticosteroid receptor. Another metabolite, 5 α -pregnan-3 α -ol-20-one, acts in brain as an anesthetic/anxiolytic agent by binding to the gamma-aminobutyric acid (GABA)_A receptor. [GABA⁵](#) is an inhibitory neurotransmitter, an endogenously produced anxiolytic-like compound. The anesthetic/anxiolytic steroids act to increase GABA action.

To explain the role of progesterone in the development of PMS, the suggestion was made that (1) the extent of extrahepatic metabolism of progesterone to selected bioactive metabolites may be dissimilar among women, and (2) there may be a close correlation between the metabolic fate of progesterone in a given woman and the recurrence of luteal phase disabilities ([MacDonald and associates, 1991](#)). This theory evolved from the findings that (1) the fractional conversion of progesterone to deoxycorticosterone varies by 30-fold among women (but is constant in the same woman from time to time), and (2) selected 5 α -reduced metabolites of progesterone are bioactive as anxiolytic/anesthetic agents.

The wide variation in the conversion of plasma progesterone to deoxycorticosterone among women is the reason for wide variations in the production rate of deoxycorticosterone during the luteal phase of the ovarian cycle. Deoxycorticosterone is produced from plasma progesterone in a manner that is not regulated by adrenocorticotrophic hormone (ACTH) or angiotensin II.

It has been known for more than 50 years that selected metabolites of progesterone, administered to experimental animals or to humans, cause anesthesia. [GABA⁶](#)-producing neurons and GABA_A receptors are widely distributed in brain. Apparently the conformational change of the GABA_A receptor after anxiolytic steroid binding increases the affinity of GABA for this receptor. These steroids, therefore, are active only in the presence of GABA. The benzodiazepine class of drugs also act at the GABA_A receptor in a manner analogous to that of the 5 α -reduced metabolites of progesterone, namely to increase the affinity of the GABA_A receptor for GABA.

Steroidal anesthetics were synthesized for use in humans; and many hundreds of cesarean deliveries have been performed in women in Great Britain with the steroid anesthetic *althesin*, or 11-keto-5 α -pregnan-3 α -ol-20-one. The endogenously produced anxiolytic metabolite of progesterone, 5 α -pregnan-3 α -ol-20-one (allopregnanolone), is formed in women during the luteal phase of the cycle when progesterone levels are high. A role for progesterone metabolite formation and withdrawal in the biogenesis of postpartum depression, a severe emotional disorder that develops during the early puerperium in some women has also been proposed ([Chap. 53, p. 1420](#)). [Monteleone and associates \(2000\)](#) found that the plasma levels of allopregnanolone in women with premenstrual syndrome are decreased. Given the benzodiazepine-like action of allopregnanolone, lower levels of this metabolite could lead to some symptoms of premenstrual syndrome.

PROGESTERONE METABOLISM. The potential importance of these bioactive progesterone metabolites in the biogenesis of PMS likely resides in the stereospecificity of their actions and in the potential for differences among women in the rates of formation of these compounds in extrahepatic tissues. It is now known that the majority (50 to 60 percent) of plasma progesterone is metabolized by initial 5 α -reduction, and much of this metabolism occurs in extrahepatic tissues ([Chantilis and colleagues, 1996](#)). Ultimately, the 5 α -reduced metabolites of progesterone are transported to liver and there are preferentially sulfoconjugated and excreted in bile. In the intestine, these sulfoconjugates are acted upon by enzymes in intestinal bacteria to give products that have not been readily identifiable.

SAFE CONTRACEPTION, WITHOUT MENSTRUATION. It therefore may be that recurrent, cyclical progesterone secretion by the corpus luteum of women who choose not to be pregnant is not the **evolutionary norm**. In an evolutionary sense, menstruation may be viewed as the fail-safe, end result of fertility failure, whether the infertility was purposefully chosen or naturally occurring.

The development of safe and effective contraceptive agents, according to [Baird \(1985\)](#), who also referred to the writings of his father, Sir Dugald Baird, "has relieved [women] from the tyranny of excessive fertility—the fifth freedom.' Because the social and physical demands of continuous [pregnancy and] breast-feeding, are unlikely to be acceptable to women of the 20th century," they have chosen menstruation as an alternative, "in the absence of a simple, safe means of inducing amenorrhea pharmacologically."

Clearly, it is vitally important to search for more acceptable means of effective and safe human contraception. As an intermediate goal, women should be able to choose an infertility-promoting method that may not oblige a possible endocrinopathy induced by recurrent secretion and withdrawal of progesterone. Safe, effective contraception that does not cause uterine bleeding or loss of the metabolic benefits of estrogen likely will be developed for use by women who would select such an alternative.

THE DECIDUA

This tissue is the specialized, highly modified endometrium of pregnancy. The transformation of secretory endometrium to decidua is dependent upon the action of estrogen and progesterone and other stimuli provided by the implanting blastocyst (or maternal platelets) during trophoblast invasion of the endometrium and its blood vessels. The special relationship that exists between the endometrium/decidua and the invading trophoblast seemingly defies the laws of transplantation immunology. The success of this unique autograft is not only a scientific curiosity but may involve processes that harbor insights into more successful transplantation surgery and perhaps the control of neoplasia as well. Some of the processes that appear to be fundamentally important in the immunological acceptance of the conceptus are considered in [Chapter 5 \(p. 89\)](#).

STRUCTURE

William Hunter, 19th-century British gynecologist, provided the first scientific description of the *membrana decidua*. According to [Damjanov \(1985\)](#), the term was coined in the best tradition of formal logic applied to scientific writing—*membrana*, denoting its gross appearance, while the qualifier, *decidua*, was added in analogy with deciduous leaves to indicate its ephemeral nature and the fact that it is shed from the rest of the uterus after childbirth. [Wewer and associates \(1985\)](#) provided evidence that decidua indeed qualifies to be called a membrane, not only because of its gross appearance but because it contains most if not all of the major basement membrane components.

Moreover, each mature decidual cell becomes surrounded by a membrane, indeed a pericellular membrane. Thus, the human decidual cells clearly build walls around themselves and possibly around the fetus. In fact, the pericellular matrix surrounding the decidual cells may provide for attachment of cytotrophoblasts through cellular adhesion molecules. This would provide the scaffolding for trophoblast attachment. The pericellular decidual cell membrane also may provide for protection of the decidual cell against selected proteinases of the cytotrophoblasts.

DECIDUAL REACTION

In human pregnancy, the decidual reaction is completed only with blastocyst implantation. Predecidual changes, however, commence first in endometrial stromal cells adjacent to the spiral arteries and arterioles, spreading thereafter in waves throughout the mucosa of the uterus and then from the site of implantation. The endometrial stromal cells enlarge to form polygonal or round, decidual cells. The nuclei become round and vesicular, and the cytoplasm becomes clear, slightly basophilic, and surrounded by a translucent membrane. In early pregnancy, the decidua begins to thicken, eventually attaining a depth of 5 to 10 mm. With magnification, furrows and numerous small openings, representing the mouths of uterine glands, can be detected. Later in pregnancy, as the fetus grows and the amniotic fluid expands, the thickness of the decidua decreases, presumably because of the pressure exerted by the expanding uterine contents.

The portion of the decidua directly beneath the site of blastocyst implantation is modified by trophoblast invasion and becomes the *decidua basalis*; that portion overlying the enlarging blastocyst, and initially separating it from the rest of the uterine cavity, is the *decidua capsularis* ([Fig. 4-7](#)). The decidua capsularis is most prominent during the second month of pregnancy, consisting of decidual cells covered by a single layer of flattened epithelial cells without traces of glands. Internally, this portion of the decidua contacts the avascular, extraembryonic fetal membrane, the *chorion laeve*. The remainder of the uterus is lined by *decidua parietalis*, sometimes called the *decidua vera* when decidua capsularis and decidua parietalis are joined.

During the early weeks of pregnancy, there is a space between the decidua capsularis and decidua parietalis because the gestational sac does not fill the entire uterine cavity. By 14 to 16 weeks, the expanding sac has enlarged enough to fill the uterine cavity; and with fusion of the decidua capsularis and parietalis, the uterine cavity is functionally obliterated.

The decidua parietalis and the decidua basalis, like the secretory endometrium, are each composed of three layers: a surface, or compact zone (*zona compacta*); a middle portion, or spongy zone (*zona spongiosa*), with remnants of glands and numerous small blood vessels; and a basal zone (*zona basalis*). The *zona compacta* and *spongiosa* together form the functional zone (*zona functionalis*). The basal zone remains after delivery and gives rise to new endometrium.

BLOOD SUPPLY

This is changed as a consequence of implantation. The blood supply to the decidua capsularis is lost as the embryo-fetus grows and expands into the uterine cavity. The blood supply to the decidua parietalis through the spiral arteries persists, as in the endometrium during the luteal phase of the cycle. The spiral arteries in the decidua parietalis retain a smooth muscle wall and endothelium and thereby remain responsive to vasoactive agents that act upon the smooth muscle or endothelial cells of these vessels.

The (spiral) arterial system supplying the decidua basalis directly beneath the implanting blastocyst, and ultimately the intervillous space surrounding the syncytiotrophoblast, however, are altered remarkably. These spiral arterioles and arteries are invaded by the cytotrophoblasts; during this process, the walls of these vessels are destroyed, leaving only a shell without smooth muscle or endothelial cells. In consequence, these vascular conduits of maternal blood—which become the uteroplacental vessels—are not responsive to vasoactive agents ([Chap. 5, p. 92](#)). By contrast, the fetal chorionic vessels, which transport blood between the placenta and the fetus, contain smooth muscle and do respond to vasoactive agents, as do the maternal spiral arteries.

HISTOLOGY

The compact layer of the decidua consists of large, closely packed, epithelioid, polygonal, lightly staining cells with round vesicular nuclei. Many stromal cells appear stellate (particularly when the decidua is edematous) with long protoplasmic processes that anastomose with those of adjacent cells. Numerous small round cells, which contain very little cytoplasm, are scattered among the decidual cells, especially in early pregnancy. These are a particular type of natural-killer lymphocytes and are referred to as **uterine large granular lymphocytes**, in which a special and unusual phenotype has been defined. These are bone marrow-derived cells that at one time entered endometrium from peripheral blood; but thereafter, these large granular lymphocytes arise primarily by replication in the endometrium in situ at specific times in the cycle ([Chap. 5, p. 90](#)).

Early in pregnancy, the spongy layer of the decidua consists of large distended glands, often exhibiting marked hyperplasia but separated by minimal stroma. At first, the glands are lined by typical cylindrical uterine epithelium with abundant secretory activity. Presumably, the glandular secretion contributes to the nourishment of the blastocyst during its histotrophic phase, before the establishment of a placental circulation. As pregnancy progresses, the epithelium gradually becomes cuboidal or even flattened, later degenerating and sloughing to a greater extent into the lumens of the glands. Later in pregnancy, the glandular elements of the decidua largely disappear.

In comparing the decidua parietalis at 16 weeks' gestation with the early proliferative endometrium of a nonpregnant woman, it is clear that there is marked hypertrophy but only slight hyperplasia of the endometrial stroma during decidual transformation.

The decidua basalis contributes to the formation of the basal plate of the placenta, and differs histologically from the decidua parietalis in two important respects ([Fig. 4-8](#)). First, the spongy zone of the decidua basalis consists mainly of arteries and widely dilated veins; by term, the glands have virtually disappeared. Second, the decidua basalis is invaded by trophoblastic giant cells, which appear at the time of implantation. The number and depth of endometrial penetration of the giant cells varies greatly. Although generally confined to the decidua, these cells may penetrate the myometrium. In such circumstances, their number and invasiveness may be so extensive as to be suggestive of choriocarcinoma to the inexperienced observer.

AGING OF THE DECIDUA

Where invading trophoblasts meet the decidua, there is a zone of fibrinoid degeneration, **Nitabuch layer**. Whenever the decidua is defective, as in placenta accreta ([Chap. 25, p. 632](#)), the Nitabuch layer is usually absent. There also is an inconstant deposition of fibrin, **Rohr stria**, at the bottom of the intervillous space and surrounding the fastening villi. [McCombs and Craig \(1964\)](#) found that decidual necrosis is a normal phenomenon in the first and probably the second trimester. The presence of necrotic decidua obtained through curettage after spontaneous abortion in the first trimester should not, therefore, necessarily be interpreted as either a

cause or an effect of the abortion.

PROLACTIN IN THE DECIDUA

Convincing evidence was presented by [Riddick and co-workers \(1979\)](#) and [Golander and associates \(1978\)](#) that the decidua is a source of prolactin, which is present in enormous amounts in the amniotic fluid during human pregnancy. Decidual prolactin is not to be confused with placental lactogen (hPL), which is produced only by the syncytiotrophoblast ([Chap. 6, p. 113](#)). Rather, decidual prolactin is a product of the same gene that encodes for prolactin that is secreted by the anterior pituitary.

The levels of prolactin in amniotic fluid during the 20th to 24th week of pregnancy may reach 10,000 ng per mL ([Tyson and co-workers, 1972](#)). As described in [Chapter 8 \(p. 191\)](#), the concentration of prolactin in amniotic fluid is extraordinarily high compared with the highest levels of prolactin in fetal (up to about 350 ng/mL) or maternal plasma (up to about 150 to 200 ng/mL). Prolactin produced in decidua preferentially enters amniotic fluid and little or none enters maternal blood. This is the classical example of the peculiar trafficking of molecules between maternal and fetal tissues of the paracrine arm of the fetal-maternal communication system.

The factors that regulate prolactin secretion in decidua are not clearly defined. Most of the agents known to affect, either negatively or positively, the rate of secretion of prolactin by the anterior, pituitary—for example, dopamine and dopamine agonists and thyrotropin-releasing hormone—do not alter the rate of decidual prolactin secretion (either in vivo or in vitro). [Brosens and colleagues \(2000\)](#) demonstrated that progestin (namely, medroxyprogesterone acetate) acts synergistically with cyclic AMP on human endometrial stromal cells in culture to increase the expression of prolactin. The findings of these investigators are indicative that the decidualization process, as marked by prolactin production, is determined by the level of progesterone receptor. It has been reported that arachidonic acid, but not PGF_{2a} or PGE₂, attenuates the rate of decidual prolactin secretion ([Handwerger and colleagues, 1981](#)). In addition, a variety of cytokines, including interleukin-1 and interleukin-2, act to decrease decidual prolactin secretion, as does endothelin-1 ([Chao and colleagues, 1994](#); [Frank and co-workers, 1995](#); [Kanda and colleagues, 1999](#)). [Blithe and associates \(1991\)](#) found that "free alpha" molecules stimulate prolactin synthesis and the secretion of prolactin by human decidual cells. By "free" alpha is meant the common α -subunit of several glycoprotein hormones including hCG, follicle-stimulating hormone (FSH), luteinizing hormone (LH), and thyroid-stimulating hormone (TSH). Free α -subunit is produced by placenta ([Chap. 6, p. 111](#)), and the levels of free α -subunit in maternal blood increase as pregnancy advances. In part, this is the case because the synthesis of the β -subunit of hCG (but not the α -subunit) is limiting in the syncytiotrophoblast formation of complete hCG.

The physiological role of prolactin produced in decidua is not known. Because all (or most) of prolactin produced in decidua enters amniotic fluid, it has been speculated that there may be a role for this hormone in solute and water transport across the chorioamnion, and thus in the maintenance of amniotic fluid volume homeostasis. It also has been shown, however, that prolactin receptors are present in a number of bone marrow-derived immune cells, and that prolactin acts on bone cells to modify selected immune functions ([Pellegrini and colleagues, 1992](#)). Recall that many bone marrow-derived lymphocytes are present in endometrium and decidua throughout pregnancy, and the function of these immune cells is modified appreciably in this tissue site. Therefore, prolactin produced in decidua may act in regulating immunological functions in this tissue during pregnancy. Various other roles for prolactin have been suggested, but presently these must be considered as speculative.

TABLE 4-1. Important Milestones in the Correlation of Ovarian and Endometrial (Menstrual) Cycles (Idealized 28-Day Cycle)

	Phase				
<i>Menstrual (1-5 days)</i>	<i>Early Follicular (6-8 days)</i>	<i>Advanced Follicular (9-13 days)</i>	<i>Ovulation (14 days)</i>	<i>Early Luteal (15-19 days)</i>	<i>Advanced Luteal (20-25 days)</i>
Ovary					
Formation of corpus albicans from corpus luteum of preceding cycle. Recruitment of follicles.	Follicular maturation and development of the chosen or dominant follicle.		Ovulation and luteinization of granulosa cells in the ruptured follicle.	Vascularization of granulosa lutein cells and formation of corpus luteum. Follicular atresia.	Mature corpus luteum continued follicular atresia.
Estrogen					
Low; derived principally from extraglandularly produced estrone; little estradiol-17 β secretion by the ovary.	Estradiol-17 β secretion, principally by granulosa cells of the dominant follicle, increases strikingly, maximal rates being attained just prior to the LH surge.		Immediately after, or coincident with, ovulation, there is an abrupt, indeed, precipitous decline in estradiol-17 β secretion.	Gradual and progressive postovulatory rise in estradiol-17 β secretion by the corpus luteum.	Maximal rates of postovulatory estradiol-17 β secretion are attained; luteal phase estradiol-17 β secretion, however, are not nearly as great as those observed immediately preovulatory.
Progesterone					
Low secretion; there is little secretion of progesterone by the adrenal cortex and the corpus luteum of the preceding ovarian cycle has regressed.	During the follicular phase of the ovarian cycle, progesterone levels remain low. This is due to the fact that human granulosa cells cannot synthesize cholesterol, the obligate precursor of progesterone, but are dependent upon LDL cholesterol that can be obtained only from the blood after vascularization of the granulosa cells after ovulation.		Progesterone secretion increases steadily as the consequence of the availability of LDL and LH action to effect cholesterol side-chain cleavage.	Progesterone secretion remains high until the end of the advanced luteal phase.	
Endometrium					
Menstrual desquamation and early reorganization of endometrial glandular epithelium.	Proliferation of glandular epithelium with many mitoses.	Pseudostratification of nuclei—no secretion, early stromal changes.	Appearance of subnuclear vacuoles that are rich in glycogen.	Migration of vacuoles to the luminal surface; cessation of mitosis. The endometrial glands become very tortuous.	Vacuoles have been seen and decidualization commences. Stromal edema and enlargement of stromal cells is prominent.
Pituitary Secretion: FSH					
Continuing decline in FSH levels that had become modestly increased coincident with the decline in steroid secretion by the regressing corpus luteum of the preceding cycle.	FSH secretion is at all times pulsatile in nature, but during the proliferative phase of the ovarian cycle, prior to the time of the LH surge at midcycle, FSH levels remain low.		There is a significant surge of FSH secretion, albeit less prominent than that of LH, that heralds the commencement of the ovulatory process.	After the midcycle gonadotropin surge, FSH levels fall to levels similar to those found during the preovulatory phase of the cycle.	
Pituitary Secretion: LH					
The levels of LH are low and reasonably constant until just prior to ovulation.			Coincident with, or just after, the striking increase in estradiol-17 β secretion by the dominant follicle, there is a striking increase in LH secretion—the "LH surge."	The levels of LH are low and reasonably constant until just prior to ovulation.	

FSH = follicle-stimulating hormone; LDL = low-density lipoprotein; LH = luteinizing hormone.

5. The Placenta and Fetal Membranes

The development of the human placenta is as uniquely intriguing as the embryology of the fetus. The placenta is a fascinating organ, especially when its function is considered. During its brief intrauterine existence, the fetus is dependent upon the placenta as its lung, liver, and kidneys. The organ serves these purposes until sufficient maturation of the fetus allows it to survive ex utero as an air-breathing organism.

Despite its unassailable role in human fetal development, study of the placenta has lagged behind that of the fetus. A number of anatomists and embryologists worked through the 1980s to provide some basic knowledge. It has not been until recently that clinicians have appreciated the plethora of knowledge that can be gained by microscopic study of the placenta. This latter enlightenment has transposed through the efforts of placental pathologists such as Benirschke, Driscoll, Fox, and Naeye. Their work, as well as that of many of their colleagues, has shown that careful examination of the placenta may frequently shed light on the etiopatho-genesis of a number of maternal-fetal disorders ([Benirschke, 2000](#); [Benirschke and Kauffman, 2000](#)). Abnormal placentation, placental pathology, and their effects on pregnancy outcome, as well as adverse placental effects from maternal diseases, are considered in [Chapters 31](#) and [32](#).

[Boyd and Hamilton \(1970\)](#) presented a marvelous account of the history of placental research. A summary of this history was presented in [Chapter 5](#) (p. 95) of the 20th edition of *Williams Obstetrics*. The interested reader is referred to this summary or to the treatise of [Boyd and Hamilton \(1970\)](#).

FETAL TISSUES OF THE FETAL-MATERNAL COMMUNICATION SYSTEM

The two arms of the fetal-maternal communication system of human pregnancy were described in [Chapters 2](#) and [4](#) (see [Fig. 5-2](#)). The extravillous and villous trophoblasts are the embryonic-fetal tissues of the anatomical interface of the placental arm; the avascular fetal membranes—the amnion and chorion laeve—are the fetal tissues of the anatomical interface of the paracrine arm of this system.

The placental arm of this system links the mother and fetus as follows: maternal blood (spurting out of the uteroplacental vessels) directly bathes the syncytiotrophoblast, the outer surface of the trophoblastic villi; fetal blood is contained within fetal capillaries, which traverse within the intravillous spaces of the villi. This is a hemochorioendothelial type of placenta. The paracrine arm of this system links the mother and fetus through the anatomical and biochemical juxtaposition of (extraembryonic) chorion laeve and (maternal uterine) decidua parietalis tissue.

Therefore, at all sites of direct cell-to-cell contact, maternal tissues (decidua and blood) are juxtaposed to extraembryonic cells (trophoblasts) and not to embryonic cells or fetal blood. This is an extraordinarily important arrangement for communication between fetus and mother and for maternal (immunological) acceptance of the conceptus.

The role of the placenta in nidation and in the transfer of nutrients from mother to embryo-fetus has longed fueled interest in this unique organ. Subsequently, the enormous diversity of form and function of the placenta was recognized as the incredible metabolic, endocrine, and immunological properties of its trophoblasts were discovered.

EARLY HUMAN DEVELOPMENT

The definitions that follow are taken from [Moore \(1973, 1988\)](#).

- **Zygote:** The cell that results from the fertilization of the ovum by a spermatozoan.
- **Blastomeres:** Mitotic division of the zygote (cleavage) yields daughter cells called blastomeres.
- **Morula:** The solid ball of cells formed by 16 or so blastomeres.
- **Blastocyst:** After the morula reaches the uterus, a fluid-filled cavity is formed, converting the morula to a blastocyst.
- **Embryo:** The embryo-forming cells, grouped together as an inner cell mass, give rise to the embryo, which usually is so designated when the bilaminar embryonic disc forms. The embryonic period extends until the end of the seventh week, at which time the major structures are present.
- **Fetus:** After the embryonic period, the developing conceptus is referred to as the fetus.
- **Conceptus:** This term is used to refer to all tissue products of conception—embryo (fetus), fetal membranes, and placenta. The conceptus includes all tissues, both embryonic and extraembryonic, that develop from the zygote.

FERTILIZATION OF THE OVUM AND CLEAVAGE OF THE ZYGOTE

Few, if any, naturally occurring phenomena are of greater importance to humankind than the union of egg and sperm. Fertilization occurs in the fallopian tube; and it is generally agreed that fertilization of the ovum must occur within minutes or no more than a few hours after ovulation. Consequently, spermatozoa must be present in the fallopian tube at the time of ovulation. Most all pregnancies occur when intercourse occurs during the 2 days preceding or on the day of ovulation. If intercourse takes place on the day after ovulation, pregnancy probably will not result.

After fertilization in the fallopian tube, the mature ovum becomes a zygote—a diploid cell with 46 chromosomes—that then undergoes segmentation, or cleavage, into blastomeres. The first typical mitotic division of the segmentation nucleus of the zygote results in the formation of two blastomeres ([Fig. 5-1](#)). The zygote undergoes slow cleavage for 3 days while still within the fallopian tube; fertilized human ova that are recovered from the uterine cavity may be composed of only 12 to 16 blastomeres. As the blastomeres continue to divide, a solid mulberry-like ball of cells, referred to as the *morula*, is produced. The morula enters the uterine cavity about 3 days after fertilization. The gradual accumulation of fluid between blastomeres within the morula results in the formation of the *blastocyst* ([Fig. 5-2](#)). The compact mass of cells at one pole of the blastocyst, called the *inner cell mass*, is destined to be the embryo. The outer mass of cells is destined to be the trophoblasts.

THE EARLY HUMAN ZYGOTE. [Hertig and co-workers \(1954\)](#) found in the two-cell zygote that the blastomeres and the polar body are free in the perivitelline fluid and are surrounded by a thick zona pellucida ([Fig. 5-1A](#)). In a 58-cell blastocyst, the outer cells which are progenitors of the trophoblasts can be distinguished from the inner cells that form the embryo ([Fig. 5-2B](#)). The 107-cell blastocyst was found to be no larger than the earlier cleavage stages, despite the accumulated fluid ([Fig. 5-1C](#)). It measured 0.153 by 0.155 mm in diameter before fixation and after the disappearance of the zona pellucida. The eight formative or embryo-producing cells were surrounded by 99 trophoblastic cells.

IMPLANTATION

Just before implantation, the zona pellucida disappears and the blastocyst touches the endometrial surface; at this time of apposition, the blastocyst is composed of 107 to 256 cells. The blastocyst adheres to the endometrial epithelium, and implantation occurs most commonly on the endometrium of the upper part and on the posterior wall of the uterus. After gentle erosion between epithelial cells of the surface endometrium, the invading trophoblasts burrow deeper into the endometrium, and the blastocyst becomes totally encased within the endometrium, being covered over by the endometrium.

BIOLOGY OF THE TROPHOBLAST

Of all placental components, the trophoblast is the most variable in structure, function, and development. Its invasiveness provides for attachment of the blastocyst to the decidua of the uterine cavity; its role in nutrition of the conceptus is reflected in its name; and its function as an endocrine organ in human pregnancy is essential to maternal physiological adaptations and to the maintenance of pregnancy.

DIFFERENTIATION. Morphologically, trophoblasts are either **cellular** or **syncytial**, and may appear as uni-nuclear cells or multinuclear giant cells. At implantation, some of the innermost cytotrophoblasts or *Langhans cells* that are contiguous with and invading the endometrium, coalesce to become an amorphous, multinucleated,

continuous membrane that is uninterrupted by intercellular spaces, the syncytium. There are no individual cells, only a continuous lining; therefore it is the singular "syncytiotrophoblast" or syncytium. The true syncytial nature of the human syncytiotrophoblast has been confirmed by electron microscopy. The mechanism of syncytial growth, however, was a mystery in view of the discrepancy between an increase in the number of nuclei in the syncytiotrophoblast and equivocal evidence (at best) of intrinsic nuclear replication. Mitotic figures are completely absent from the syncytium, being confined to the cytotrophoblasts.

FORMATION OF THE SYNCYTIUM. [Ulloa-Aguirre and co-workers \(1987\)](#) elegantly demonstrated the conversion of cytotrophoblasts to a morphologically and functionally characteristic syncytium in vitro. They established that at least part of this differentiation process involves the action of cyclic adenosine monophosphate (cAMP). Based on their methods of isolation and characterization of human cytotrophoblasts, others developed systems to evaluate blastocyst implantation in vitro ([Kliman and associates, 1986](#); [Ringler and Strauss, 1990](#)). Isolated cytotrophoblasts, placed in serum-containing medium, migrate toward one another and form aggregates. Ultimately, the aggregates fuse and syncytium is produced during 3 to 4 days. The syncytium also is formed in the absence of serum, provided that extracellular matrix components are present to serve as a lattice for cytotrophoblast migration. The syncytium produced in vitro is covered by microvilli, as it is in vivo. Cytotrophoblast aggregation is dependent upon protein synthesis, and involves a calcium-dependent cell adhesion molecule, *E-cadherin*, for aggregation. Desmosomes develop between the cells; and as the cytotrophoblasts fuse, the expression of E-cadherin diminishes.

The cytotrophoblast is the germinal cell; the syncytium, or the secretory component, is derived from cytotrophoblasts. Therefore, the cytotrophoblasts are the cellular progenitors of the syncytiotrophoblast. Well-demarcated borders and a single, distinct nucleus characterize each cytotrophoblast; and there are frequent mitoses among the cytotrophoblasts. These characteristics are lacking, however, in the syncytium, in which the cytoplasm is amorphous, without cell borders, and the nuclei are multiple and diverse in size and shape. The absence of cell borders in the syncytium obliges transport across this structure. Hence, the control of transport is not dependent on the participation of individual cells.

[Coutifaris and Coukos \(1994\)](#) presented a succinct and informative review of the processes of human implantation. They point out that after apposition and adherence of the trophoblast of the blastocyst to the endometrial epithelial cells, implantation commences by intrusion of cytotrophoblasts between endometrial epithelial cells. This process of trophoblast invasion is facilitated by degradation of the extracellular matrix of the endometrium/decidua, catalyzed by urokinase-type plasminogen activator, urokinase plasminogen activator receptor, and metalloproteinases that are produced by selected cytotrophoblasts at various stages of implantation/placentation. **These functions of cytotrophoblasts invading the endometrium are indistinguishable from those of metastasizing malignant cells.** As the cytotrophoblasts move through the decidua, selected populations of these cells bind to various extracellular matrix components of the decidual stromal cells. This facilitates migration and thence the establishment of placental anchors to the decidua.

IMMUNOLOGICAL ACCEPTANCE OF THE CONCEPTUS

Over the last half century, many attempts to explain the survival of the semiallogenic fetal graft have been proposed. One of the earliest explanations was based on the theory of antigenic immaturity of the embryo-fetus. This was disproved by [Billingham \(1964\)](#) who showed that transplantation (HLA) antigens are demonstrable very early in embryonic life. The trophoblasts are the only cells of the conceptus in direct contact with maternal tissues or blood and these tissues are genetically identical with fetal tissues. Another explanation was based on diminished immunological responsiveness of the pregnant woman. There is, however, no evidence for this to be other than an ancillary factor. In a third explanation, the uterus (decidua) is proposed as an immunologically privileged tissue site. This would preclude well-documented advanced ectopic pregnancies discussed in [Chapter 34](#). Clearly, transplantation immunity can be evoked and expressed in the uterus as in other tissues. Therefore, the acceptance and the survival of the conceptus in the maternal uterus must be attributed to an immunological peculiarity of the trophoblasts, not the decidua.

CURRENT STATUS OF RESEARCH

It still is enigmatic that maternal tissues accept and tolerate the grafted conceptus. Moreover, the placenta likely expresses "novel" genes ([Dizon-Townson and colleagues, 2000](#)). Several novel aspects of the expression of the HLA system in trophoblasts, together with a unique set of lymphocytes, may provide an explanation for this.

IMMUNOCOMPETENCY OF THE TROPHOBLASTS. Almost 50 years ago, Sir Peter [Medawar \(1953\)](#) suggested that the solution to the riddle of the fetal allograft might be explained by *immunological neutrality*. As early as 1932, Witebsky and Reich found that blood group antigens are lacking in human trophoblasts. Subsequently, many researchers focused on defining the expression of the *major histocompatibility complex (MHC)* antigens in trophoblasts. *Human leukocyte antigens*, or *HLA*, by international agreement, are the human analogue of the major histocompatibility complex (see also [Chap. 52, p. 1384](#)).

MHC class II antigens are absent from trophoblasts at all stages of gestation ([Weetman, 1999](#)). Before blastocyst implantation in the mouse, MHC class I antigens on the trophoblast are expressed in low levels, but these antigens disappear at the time of implantation, not to reappear except later in selected subpopulations of trophoblasts in the mature placenta.

TROPHOBLAST HLA CLASS I EXPRESSION. [King and Loke \(1991\)](#) reasoned that normal implantation is dependent upon controlled trophoblastic invasion of maternal endometrium/decidua and the spiral arteries—a mechanism for permitting and then limiting trophoblast invasion. They suggested that such a system involves the uterine large granular lymphocytes (LGLs) and the unique expression (or absence thereof) of a specific monomeric HLA class I gene in trophoblasts.

HLA-I GENE EXPRESSION. The HLA genes are the products of multiple genetic loci of the MHC located within the short arm of chromosome 6 ([Hunt and Orr, 1992](#)). There are 17 HLA class I genes, which include three classical genes. The three classical genes—HLA-A, -B, and -C—which encode the major class I(a) transplantation antigens. Three other class I(b) genes, designated HLA-E, -F, and -G also encode class I HLA antigens. The remaining DNA sequences appear to be pseudogenes or partial gene fragments.

Class I antigen(s) in cytotrophoblasts is accounted for by the expression of a single gene for HLA-G. As HLA-G is monomorphic (or nearly so), this antigen is recognized as "self" and therefore should not evoke an immunological response by maternal immune cells against fetal trophoblasts expressing HLA-G ([Kilburn and associates, 2000](#); [Weetman, 1999](#)). Its expression may be stimulated by hypoxias ([Kilburn and associates, 2000](#)). To elucidate HLA-G expression, it is important to understand the nature of the unusual lymphocyte population of the human decidua.

UTERINE LARGE GRANULAR LYMPHOCYTES (LGLs)¹. These distinctive cells are believed to be lymphoid and of bone marrow origin and natural killer (NK) cell lineage. They are present in large numbers only at the midluteal phase of the cycle—at the expected time of implantation ([Johnson and colleagues, 1999](#)). These [LGLs¹](#) have a distinct phenotype characterized by a high surface density of CD56 or *neural cell adhesion molecule* ([Loke and King, 1995](#)).

Near the end of the luteal phase of nonfertile ovulatory cycles, the nuclei of the uterine [LGLs¹](#) begin to disintegrate. With blastocyst implantation, these cells persist in the decidua during the early weeks of pregnancy. At term, however, there are relatively few LGLs in decidua. It is speculated that LGLs are involved in the regulation of trophoblast invasion. They secrete large amounts of granulocyte/macrophage-colony stimulating factor (GM-CSF), suggestive that the LGLs in first trimester decidua are in an activated state. This has led [Jokhi and co-workers \(1994\)](#) to speculate that [GM-CSF²](#) may function primarily not to promote trophoblast replication but rather to forestall trophoblast apoptosis. According to this theory, LGLs rather than the T lymphocytes would bear the primary responsibility for immunosurveillance in decidua.

HLA-G EXPRESSION IN HUMAN TROPHOBLASTS. This hypothesis involves developmental modifications in HLA-G class I antigen expression on trophoblasts. HLA-G is expressed only in the human. Indeed, HLA-G antigen is identified only in extravillous cytotrophoblasts in the decidua basalis and in the chorion laeve ([McMaster and colleagues, 1995](#)). HLA-G is not present in villous trophoblasts, either in the syncytium or in the cytotrophoblasts. HLA-G is expressed in cytotrophoblasts that are contiguous with maternal tissues (decidual cells). A soluble major isoform, HLA-G2, is increased during pregnancy ([Hunt and associates, 2000](#)). It is hypothesized that HLA-G is immunologically permissive of the antigen mismatch between mother and fetus ([LeBouteiller and co-workers, 1999](#)). Indeed, [Goldman-Wohl and colleagues \(2000\)](#) have provided evidence for abnormal HLA-G expression in extravillous trophoblasts from women with preeclampsia.

HLA EXPRESSION IN THE HUMAN EMBRYO. As gestation progresses, cells from the inner cell mass of the blastocyst (those that form the embryo) gradually develop both class I and class II HLA antigens. Importantly, these tissues are not in direct contact with maternal tissues or blood.

IMPLANTATION AND INTEGRIN SWITCHING. The attachment of the trophoblast of the blastocyst to the endometrial surface by apposition and adherence and then the intrusion and invasion of the endometrium/decidua by cytotrophoblasts (implantation) appears to be dependent upon two factors:

1. Trophoblast elaboration of specific proteinases that degrade selected extracellular matrix proteins of the endometrium/decidua.
2. A coordinated and alternating process referred to as *integrin switching*, which facilitates migration and then attachment of trophoblasts in the decidua.

The integrins, one of four families of cell adhesion molecules (CAMs), are cell-surface receptors that mediate the adhesion of cells to extracellular matrix proteins ([Frenette and Wagner, 1996](#)). Great diversity of cell binding to a host of different extracellular matrix proteins is possible by way of the integrin system.

Recall that the decidual cell becomes completely encased by a pericellular (extracellular matrix) membrane. This "wall" around the decidual cell provides the scaffolding for the attachment of the extravillous trophoblasts, the *anchoring cytotrophoblasts* ([Chap. 4, p. 79](#)). These cells first elaborate selected proteinases that degrade the extracellular matrix of decidua. Thereafter, the expression of a specific group of integrins enables the docking of these cells. By alternating between these two processes and by "integrin switching," the movement of cytotrophoblasts into the decidua is aggressive, but regulated. Specific decidual localization of the cytotrophoblasts to establish attachment of the placenta to the wall of the uterine cavity results. [Craven and colleagues \(2000\)](#) have provided evidence that a similar process is operative for trophoblastic invasion of uterine veins.

TROPHOBLAST ATTACHMENT IN DECIDUA: ONCOFETAL FIBRONECTIN. As described by [Feinberg and colleagues \(1991\)](#), oncofetal fibronectin (onfFN) molecules are characterized by a unique glycopeptide of the fibronectin molecule. They refer to onfFN as *trophouteronectin* or *trophoblast glue* to suggest a critical role for this protein in the migration and attachment of trophoblasts to maternal decidua. They localized onfFN to the junction of cytotrophoblast with extracellular matrix. Importantly, onfFN was localized to the extracellular matrix connecting extravillous cytotrophoblasts and cytotrophoblastic cell columns to the uterine decidua. As onfFN is formed by extravillous trophoblasts, including those of the chorion laeve, these investigators suggest that it may function to facilitate separation of the extraembryonic tissues from the uterus at delivery. More recently, [Feinberg and associates \(1994\)](#) have shown that transforming growth factor- β (TGF- β) promotes the synthesis of onfFN. This is consistent with the proposition that TGF- β ³ is intimately involved in multiple aspects of implantation and decidualization.

[Lockwood and colleagues \(1991\)](#) and others evaluated cervical and vaginal secretions for the presence of onfFN in association with term and preterm labor. Their findings are discussed further in [Chapter 27](#) (p. 702) concerning the usefulness of the identification of onfFN to predict preterm labor. Clearly the levels of onfFN are increased in cervical/vaginal fluids that are obtained during labor. One possibility is that this represents some type of separation (chemical, mechanical, or both) of chorion laeve (trophoblasts) from decidua parietalis. Feinberg and associates speculate that the "leakage" of onfFN is the result of enzymatic action to release the onfFN. This putative enzyme activity may be part of the parturitional process. Alternatively, separation of chorion laeve and decidua could be a mechanical consequence of labor, that is, the chorion laeve is pulled away from decidua by shear stress as labor progresses. Recent evidence is suggestive that digital cervical examination affects fetal fibronectin levels ([McKenna and associates, 1999](#)).

EMBRYONIC AND PLACENTAL DEVELOPMENT

EARLY BLASTOCYSTS

In a description of the earliest stages of the human blastocyst, the wall of the primitive blastodermic vesicle was characterized as consisting of a single layer of ectoderm ([Fig. 5-1](#)). As early as 72 hours after ovum fertilization, the 58-cell blastula had differentiated into 5 embryo-producing cells and 53 cells destined to form trophoblasts ([Hertig, 1962](#)). Although trophoblasts have not been distinguished before blastocyst implantation, both cytotrophoblasts and syncytiotrophoblast are present in the earliest implanted blastocyst of the monkey. Indeed, evidence has been presented that chorionic gonadotropin (hCG) is secreted by cells of the human blastocyst at the time of implantation ([Chap. 6, p. 110](#)).

Soon after blastocyst adherence to the endometrial epithelium, the cytotrophoblasts proliferate rapidly and begin to invade the surrounding decidua. The extravillous cytotrophoblasts that ultimately form the anchoring cells in the decidua remain as individual cells or cytotrophoblasts. As the blastocyst and its surrounding trophoblasts, which are completely covered by decidua, grow and expand, one pole of this mass extends toward the endometrial cavity and the other pole remains buried in the endometrium/decidua. The innermost pole enters into the formation of the placenta, that is, the anchoring cytotrophoblasts and the villous trophoblasts. The trophoblasts of the villus are the outer layer of syncytium and an inner layer of cytotrophoblasts. The pole developing toward the endometrial cavity is covered by the chorion frondosum, which at this time is covered by decidua (capsularis). As the growth of embryonic and extraembryonic tissues continues, the blood supply of the chorion facing the endometrial cavity is restricted, and consequently the villous nature of this tissue and its blood supply are lost. This portion of the chorion becomes the avascular fetal membrane that touches the decidua parietalis, that is, the chorion laeve or smooth chorion. With continued expansion of the embryo-fetus, the chorion laeve becomes contiguous with the entire maternal decidua (parietalis) that is not occupied by the placenta. The chorion laeve is comprised of cytotrophoblasts and fetal mesodermal (mesenchymal) cells that survive in a relatively low oxygen atmosphere.

As the fetus grows, the decidua capsularis merges with the decidua parietalis. The decidua capsularis, however, is largely lost by pressure and the attendant loss of blood supply. The area of decidua where decidua capsularis and decidua parietalis merge, is referred to as the decidua vera.

One of the earliest implanting blastocysts discovered by [Hertig and Rock \(1944\)](#) is shown in [Figure 5-3](#). It measured only 0.36 by 0.31 mm, and it was believed to have been in the process of penetrating the endometrium, with the thin outer wall of the blastocyst still within the uterine cavity. An implanting blastocyst at a similar stage of development, 9 days after fertilization, is shown in [Figure 5-4](#). It appears to have been flattened in the process of penetrating the uterine epithelium; the enlargement and multiplication of the trophoblasts in contact with the endometrium are alone responsible for the increase in size of the implanted blastocyst as compared with the free blastocyst.

EMBRYONIC DEVELOPMENT AFTER IMPLANTATION

At 9 days of development ([Fig. 5-4](#)), the wall of the blastocyst that faces toward the uterine lumen is a single layer of flattened cells. The opposite, thicker wall comprises two zones, the trophoblasts and the embryo-forming inner cell mass. As early as 7 1/2 days after fertilization, the inner cell mass, referred to as the embryonic disc, is differentiated into a thick plate of primitive ectoderm and an underlying layer of endoderm. Some small cells appear between the embryonic disc and the trophoblast, and enclose a space that will become the amniotic cavity.

As the embryo enlarges, more maternal tissue (decidua basalis) is invaded, and the walls of the superficial decidual capillaries are eroded. As a consequence, maternal blood leaks into the lacunae. With deeper burrowing and blastocyst invasion into the decidua, the strands of trophoblasts branch to form the solid primitive villi that traverse the lacunae. The villi that were located over the entire blastocyst surface later disappear except over the most deeply implanted portion, the site destined to form the placenta.

The embryonic mesenchyme first appears as isolated cells within the cavity of the blastocyst. When the cavity is completely lined with mesoderm, it is termed the chorionic vesicle, and its membrane, now called the chorion, is composed of trophoblasts and mesenchyme. The mesenchymal cells within the cavity are most numerous about the embryo, where these eventually condense to form the body stalk, which serves to join the embryo to the nutrient chorion and later develops into the umbilical cord.

The syncytiotrophoblast of the chorionic shell is permeated by a system of intercommunicating channels of trophoblastic lacunae that contain maternal blood. At the same time, the decidual reaction intensifies in the surrounding stroma, which is characterized by enlargement of the decidual stromal cells and glycogen storage.

CYTOTROPHOBLAST INVASION OF DECIDUAL VESSELS

The capillary network of the most superficial portion of the endometrium is invaded by cytotrophoblasts. Subsequently, the arterioles and then the spiral arteries are invaded, and the walls of these vessels are destroyed. This phenomenon will be considered in some detail because of its special importance to an understanding of human uteroplacental blood flow. [Hamilton and Boyd \(1966\)](#) give credit to Friedlander (1870) for the first description of the striking structural changes of the spiral arteries of the decidua basalis during human placentation. During implantation, the spiral arteries acquire a lining of cells within the endothelium that is derived from the invading cytotrophoblasts. During this vascular invasion, degenerative changes occur in the arterial wall, affecting all layers of these vessels. The most striking change involves the vascular smooth muscle, which becomes nonrecognizable.

The cytotrophoblasts that invade the spiral arteries can pass several centimeters along the vessel lumen; indeed, Hamilton and Boyd observed cytotrophoblasts in myometrial portions of these vessels. They also emphasize that these vascular changes are not observed in the decidua parietalis—that is, in decidual sites removed from the invading cytotrophoblasts. The intraluminal trophoblastic cells diminish in number near term. In midtrimester pregnancy, however, trophoblasts are present in all of the spiral arteries of the decidua at the placental site.

Hamilton and Boyd took special notice of several curious features of these observations:

1. The cytotrophoblasts in the vessel lumens do not appear to replicate.
2. Oddly, these cells are not readily dislodged by the flow of blood.
3. In fact, these cytotrophoblasts appear to migrate against arterial flow and pressure.
4. There is no obvious adhesion of these cells one to the other.
5. The invasion of maternal vascular tissues by trophoblasts involves only the decidual spiral arteries, not the decidual veins.

Maternal blood enters the intervillous space from the spiral arteries in fountain-like bursts. Thus, maternal blood that is propelled outside of the maternal vessels sweeps over and directly bathes the syncytio-trophoblast. The maternal surface of the syncytio-trophoblast consists of a complex microvillus structure that undergoes continual shedding and reformation during pregnancy.

As endometrial invasion by trophoblasts progresses, decidual spiral arteries are tapped to form lacunae, which are soon filled with maternal blood. The term **hemochorioendothelial** used to describe human placentation is derived as follows: *hemo* refers to maternal blood, which directly bathes the syncytiotrophoblast; *chorio* is for chorion-placenta, which in turn is separated from fetal blood by the *endothelial* wall of the fetal capillaries that traverse the intervillous space. The characteristics of this type of placentation are illustrated in [Figures 5-5 and 5-6](#). As the lacunae join, a complicated labyrinth is formed that is partitioned by solid cytotrophoblastic columns. The trophoblast-lined labyrinthine channels and the solid cellular columns form the intervillous space and primary villous stalks, respectively.

GERM LAYERS

The amnion and yolk sac, with both epithelial and mesenchymal components, are illustrated in [Figures 5-5 and 5-6](#). The body stalk, from which the caudal end of the embryo arises, can also be recognized at this stage.

ORGANIZATION OF PLACENTA

TROPHOBLAST ULTRASTRUCTURE

From the electron microscopic studies of [Wislocki and Dempsey \(1955\)](#), data were provided that permitted a functional interpretation of the fine structure of the placenta. There are prominent microvilli on the syncytial surface, corresponding to the "brush border" described by light microscopy ([Fig. 5-7](#)). Associated pinocytotic vacuoles and vesicles are related to the absorptive and secretory placental functions. The inner layer of the villi—the cytotrophoblasts—persists to term, although often compressed against the trophoblastic basal lamina, and retains its ultrastructural simplicity ([Fig. 5-8](#)).

CHORIONIC VILLI

Villi can first be distinguished easily in the human placenta on about the 12th day after fertilization. When a mesenchymal cord, presumably derived from cytotrophoblasts, invades the solid trophoblast column secondary villi are formed. After angiogenesis occurs from the mesenchymal cores in situ, the resulting villi are termed tertiary. Maternal venous sinuses are tapped early in the implantation process, but until the 14th or 15th day after fertilization, maternal arterial blood does not enter the intervillous space. By about the 17th day, fetal blood vessels are functional, and a placental circulation is established. The fetal-placental circulation is completed when the blood vessels of the embryo are connected with the chorionic blood vessels. Some villi, in which failure of angiogenesis results in a lack of circulation, become distended with fluid and form vesicles. A striking exaggeration of this process is characteristic of the development of hydatidiform mole ([Chap. 32, 836](#)).

Proliferation of cellular cytotrophoblasts at the tips of the villi produces the trophoblastic cell columns, which are not invaded by fetal mesenchyme but are anchored to the decidua at the basal plate. Thus, the floor of the intervillous space (maternal-facing side) consists of cytotrophoblasts from the cell columns, the peripheral syncytium of the trophoblastic shell, and decidua of the basal plate. The floor of the chorionic plate, consisting of the two layers of trophoblasts externally and fibrous mesoderm internally, forms the roof of the intervillous space.

In early pregnancy, the villi are distributed over the entire periphery of the chorionic membrane. A blastocyst dislodged from the endometrium at this stage of development appears shaggy ([Fig. 5-9](#)). The villi in contact with the decidua basalis proliferate to form the leafy chorion, or chorion frondosum, the fetal component of the placenta; the villi in contact with the decidua capsularis cease to grow and degenerate to form the chorion laeve. The chorion laeve is generally more nearly translucent than the amnion even though rarely exceeding 1 mm in thickness. The chorion laeve contains ghost villi, and decidua clings to its surface.

Until near the end of the third month, the chorion laeve is separated from the amnion by the exocoelomic cavity. Thereafter, the amnion and chorion are in intimate contact. In the human, the chorion laeve and amnion form an avascular amniochorion, but these two structures are important sites of molecular transfer and metabolic activity. They constitute the paracrine arm of the fetal-maternal communication system.

PLACENTAL COTYLEDONS

Certain villi of the chorion frondosum extend from the chorionic plate to the decidua and serve as *anchoring villi*. Most villi, however, arboresce and end freely in the intervillous space without reaching the decidua ([Fig. 5-10](#)). As the placenta matures, the short, thick, early stem villi branch repeatedly, forming progressively finer subdivisions and greater numbers of increasingly small villi ([Fig. 5-11](#)). Each of the main stem (truncal) villi and their ramifications (rami) constitute a placental cotyledon (lobe). Each cotyledon is supplied with a branch (truncal) of the chorionic artery; and for each cotyledon, there is a vein, constituting a 1:1:1 ratio of artery to vein to cotyledon.

BREAKS IN THE PLACENTAL "BARRIER"

The placenta does not maintain absolute integrity of the fetal and maternal circulations. This is evidenced by numerous findings of the passage of cells between mother and fetus in both directions. This situation is best exemplified clinically by erythrocyte *D*-antigen isoimmunization and the occurrence of *erythroblastosis fetalis* ([Chap. 39, p. 1061](#)). Typically, a few fetal blood cells are found in maternal blood; but on extremely rare occasions, the fetus exsanguinates into the maternal circulation. Fetal leukocytes may replicate in the mother and leukocytes bearing a Y chromosome have been identified in women for up to 5 years after giving birth to a son ([Ciaranfi and colleagues, 1977](#)). [Desai and Creger \(1963\)](#) labeled maternal leukocytes and platelets with atabrine and found that the atabrine-labeled cells crossed the placenta from mother to fetus.

PLACENTAL SIZE AND WEIGHT

[Crawford \(1959\)](#) suggested that the total number of cotyledons remains the same throughout gestation. Individual cotyledons continue to grow, although less actively in the final weeks. Placental weights vary considerably, depending upon how the placenta is prepared. If the fetal membranes and most of the cord are left attached and adherent maternal blood clot is not removed, the weight may be greater by nearly 50 percent ([Thomson and co-workers, 1969](#)).

THE PLACENTA AT TERM

According to [Boyd and Hamilton \(1970\)](#), the placenta at term is, on average, 185 mm in diameter and 23 mm in thickness, with an average volume of 497 mL, and weight of 508 g; but these measurements vary widely. There are multiple shapes and forms of the human placenta and a variety of types of umbilical cord insertions, which are discussed in [Chapter 32](#). Viewed from the maternal surface, the number of slightly elevated convex areas called lobes (or if small, lobules) varies from 10 to 38. These lobes are separated, albeit incompletely, by grooves of variable depth, the *placental septa*. The lobes are also referred to as *cotyledons*.

PLACENTAL AGING

As the villi continue to branch and the terminal ramifications become more numerous and smaller, the volume and prominence of cytotrophoblasts decrease. As the syncytium thins and forms knots, the vessels become more prominent and lie closer to the surface. The stroma of the villi also exhibits changes associated with aging. In placentas of early pregnancy, the branching connective tissue cells are separated by an abundant loose intercellular matrix. Later, the stroma becomes denser and the cells more spindly and more closely packed.

Another change in the stroma involves the *Hofbauer cells*, which likely are fetal macrophages. These cells are nearly round with vesicular, often eccentric nuclei and very granular or vacuolated cytoplasm. These cells are characterized histochemically by intracytoplasmic lipid and are readily distinguished from plasma cells.

Certain of the histological changes that accompany placental growth and aging are suggestive of an increase in the efficiency of transport and exchange to meet increasing fetal metabolic requirements. Among these changes are a decrease in thickness of the syncytium, partial reduction of cytotrophoblastic cells, decrease in the stroma, and an increase in the number of capillaries and the approximation of these vessels to the syncytial surface. By 4 months, the apparent continuity of the cytotrophoblasts is broken, and the syncytium forms knots on the more numerous smaller villi. At term, the covering of the villi may be focally reduced to a thin layer of syncytium with minimal connective tissue; and the fetal capillaries seem to abut the trophoblast. The villous stroma, Hofbauer cells, and cytotrophoblasts are markedly reduced, and the villi appear filled with thin-walled capillaries.

Other changes, however, are suggestive of a decrease in the efficiency for placental exchange. These changes include thickening of the basement membranes of the trophoblast capillaries, obliteration of certain fetal vessels, and fibrin deposition on the surface of the villi in the basal and chorionic plates as well as elsewhere in the intervillous space.

BLOOD CIRCULATION IN THE MATURE PLACENTA

Because the placenta functionally represents a rather intimate association of the fetal capillary bed to maternal blood, its gross anatomy primarily concerns vascular relations. The fetal surface of the placenta is covered by the transparent amnion beneath which the fetal chorionic vessels course. A section through the placenta in situ ([Figure 5-12](#), [Figure 5-13](#), and [Figure 5-14](#)) includes amnion, chorion, chorionic villi and intervillous spaces, decidua, and myometrium. The maternal surface of the placenta ([Fig. 5-15](#)) is divided into irregular lobes by furrows produced by septa, which consist of fibrous tissue with sparse vessels confined mainly to their bases. The broad-based septa ordinarily do not reach the chorionic plate, thus providing only incomplete partitions.

FETAL CIRCULATION

Fetal deoxygenated, or "venous-like," blood flows to the placenta through the two umbilical arteries. At the juncture of the umbilical cord with the placenta, the umbilical vessels branch repeatedly beneath the amnion and again within the dividing villi, finally forming capillary networks in the terminal divisions ([Fig. 5-16](#)). Blood, with significantly higher oxygen content, returns from the placenta to the fetus through a single umbilical vein.

The branches of the umbilical vessels that traverse along the fetal surface of the placenta (the chorionic plate) are referred to as the placental surface or chorionic vessels. These vessels are responsive to vasoactive substances; but anatomically, morphologically, histologically, and functionally, these are curious vessels. The chorionic arteries always cross over the chorionic veins. Identification of chorionic artery and vein is most readily recognized by this interesting relationship because, as Benirschke points out, it is nearly impossible to distinguish the two by histological criteria. Immediately before or just after entering the chorionic plate, the two umbilical arteries are joined by a transverse connection, the *Hyrtl anastomosis*, which is rarely missing. The two umbilical arteries separate at the chorionic plate to supply branches to the cotyledons. There are two different patterns of chorionic artery branching: disperse (63 percent) and magistral (37 percent). The pattern of distribution in the disperse type is that of a fine network of vessels that traverse from the site of insertion of the umbilical cord to the various cotyledons. The magistral pattern is characterized by arteries that traverse to the edge of the placenta without an appreciable decrease in the diameter of the vessel. The arteries are end arteries, supplying one cotyledon, as the branch turns downward to pierce the chorionic plate.

The truncal arteries are the perforating branches of the surface arteries that pass through the chorionic plate. Each truncal artery supplies one cotyledon. There is a decrease in smooth muscle of the vessel wall and an increase in the caliber of the vessel as it penetrates through the basal plate; the loss in smooth muscle continues as the truncal arteries branch into the rami; the same is true of the vein walls.

At about 10 postconceptional weeks, the pattern of umbilical blood velocity waveforms changes abruptly ([Fisk and colleagues, 1988](#); [Loquet and associates, 1988](#)). Before this time, there are no "end-diastolic frequencies." Later in gestation, this finding would be considered abnormal. [Maulik \(1996\)](#) provided an excellent review of these findings.

The "definitive" chorionic plate also is formed by 8 to 10 weeks as the amnionic and primary chorionic plate mesenchyme fuse with each other. This is accomplished by expansion of the amnionic sac, which also surrounds the connective stalk and the allantois and joins these structures to form the umbilical cord ([Kaufmann and Scheffen, 1992](#)). There is another curious feature of the chorionic vessels; the thickness of the wall of these vessels is asymmetric, being much thinner on the side contiguous with the amnion (the fetal side).

MATERNAL CIRCULATION

Fetal homeostasis is dependent on an efficient maternal-placental circulation. Consequently investigators have sought to define the factors that regulate the flow of blood into and from the intervillous space. An adequate theory must explain how (1) blood can leave the maternal circulation; (2) flow into an amorphous space (lined by trophoblast syncytium, rather than capillary endothelium; and (3) return through maternal veins without producing arteriovenous-like shunts that would prevent maternal blood from remaining in contact with the villi long enough for adequate exchange. It was not until the studies of [Ramsey and co-workers \(1963, 1966\)](#) that a physiological explanation of the placental circulation, consistent with both experimental and clinical findings, was available ([Fig. 5-16](#)). These investigators discarded the crude corrosion technique of previous researchers, and proved, by careful, slow injections of radiocontrast material under low pressure, which avoided disruption of the circulation, that the arterial entrances as well as the venous exits are scattered at random over the entire base of the placenta.

The physiological particulars of the maternal-placental circulation are as follows. Maternal blood enters through the basal plate and is driven high up toward the chorionic plate by the head of maternal arterial pressure before lateral dispersion occurs ([Fig. 5-16](#)). After bathing the external microvillus surface of chorionic villi, the maternal blood drains back through venous orifices in the basal plate and enters the uterine veins. Therefore, maternal blood traverses the placenta randomly without performed channels, propelled by the maternal arterial pressure. Generally the spiral arteries are perpendicular to, but the veins are parallel to, the uterine wall, an arrangement that facilitates closure of the veins during a uterine contraction and prevents squeezing of essential maternal blood from the intervillous space. According to [Brosens and Dixon \(1963\)](#), there are about 120 spiral arterial entries into the intervillous space of the human placenta at term, discharging blood in spurts that displace the adjacent villi, as described by [Borell and co-workers \(1958\)](#).

Ramsey's concept is supported by the findings of numerous arteriographic studies. Clearly, the spiral arterial spurts are associated with the "lakes," and the closure of uteroplacental veins is affected by pressure produced at the beginning of uterine contractions. She found that with myometrial contractions there is a slight delay in the appearance of contrast medium in the veins of the uterine wall with injection during a strong contraction. The pressure in the intervillous space may be decreased sufficiently so that blood cannot be expressed against the prevailing myometrial pressure. Ramsey provided further evidence of independent activity of the uteroplacental (spiral) arteries, as indicated by the appearance of spurts in different locations even when injections were performed under conditions of minimal myometrial pressure. Not all endometrial spiral arteries are continuously patent, nor do all spiral arteries necessarily discharge blood into the intervillous space simultaneously.

In summary, Ramsey found that maternal blood enters the intervillous space in spurts produced by the maternal blood pressure. The *vis a tergo* forces blood in discrete streams toward the chorionic plate until the head of pressure is reduced. Lateral spread then occurs. The continuing influx of arterial blood exerts pressure on the contents of the intervillous space, pushing the blood toward exits in the basal plate, from which it is drained through uterine veins. During uterine contractions, both inflow and outflow are curtailed, although the volume of blood in the intervillous space is maintained, thus providing for continual, albeit reduced, exchange.

[Bleker and associates \(1975\)](#) used serial sonography during normal labor and found that the length, thickness, and surface of the placenta increased during contractions. They attributed these changes to distension of the intervillous spaces by blood as the consequence of relatively greater impairment of venous outflow compared with arterial inflow. During contractions, therefore, a somewhat larger volume of blood is available for exchange even though the rate of flow is decreased. Subsequently, by use of Doppler velocimetry, it was shown that diastolic flow velocity in spiral arteries is diminished during uterine contractions. Therefore, the principal factors regulating blood flow in the intervillous space are arterial blood pressure, intrauterine pressure, the pattern of uterine contractions, and factors that

act specifically upon the arteriolar walls.

[Ramsey and Donner \(1980\)](#) presented a summary of anatomical studies of the uteroplacental vasculature. Cytotrophoblastic elements are initially confined to the terminal portions of the uteroplacental arteries. By the 16th week, cytotrophoblasts are found in many of the arteries of the inner layer of myometrium. The accumulation of trophoblasts may ultimately stop circulation through some of these vessels. The number of arterial openings into the intervillous space is gradually reduced by cytotrophoblasts and by breaching of the walls of the more proximal parts of the arteries by deeply penetrating trophoblasts. After the 30th week, a prominent venous plexus separates the decidua basalis from the myometrium ([Fig. 5-16](#)), thus participating in providing a plane of cleavage for placental separation.

THE AMNION

The amnion at term is a tough and tenacious but pliable membrane. It is the innermost fetal membrane and is contiguous with the amniotic fluid. This particular avascular structure occupies a role of incredible importance in human pregnancy. In many obstetrical populations, preterm premature rupture of the fetal membranes is the single most common antecedent of preterm delivery ([Chap. 11, p. 281](#)). The amnion is the tissue that provides almost all of the tensile strength of the fetal membranes. Therefore, the development of the component(s) of the amnion that protects against rupture or tearing is vitally important to successful pregnancy outcome.

STRUCTURE

[Bourne \(1962\)](#) described five separate layers of amnion tissue. The inner surface, which is bathed by the amniotic fluid, is an uninterrupted, single layer of cuboidal epithelial cells, believed to be derived from embryonic ectoderm. This epithelium is attached firmly to a distinct basement membrane that is connected to the acellular compact layer, which is composed primarily of interstitial collagens I, III, and V. On the outer side of the compact layer, there is a row of fibroblast-like mesenchymal cells (which are widely dispersed at term). These cells are probably derived from mesoderm of the embryonic disc. There also are a few fetal macrophages in the amnion. The outermost layer of amnion is the relatively acellular zona spongiosa, which is contiguous with the second fetal membrane, the chorion laeve. The important "missing" elements of human amnion are smooth muscle cells, nerves, lymphatics, and importantly, blood vessels.

DEVELOPMENT

Early in the process of implantation, a space develops between the embryonic cell mass and adjacent trophoblasts ([Fig. 5-5](#)). Small cells that line this inner surface of trophoblasts have been called amniogenic cells, the precursors of the amniotic epithelium. The human amnion is first identifiable about the seventh or eighth day of embryo development. Initially, a minute vesicle ([Fig. 5-5](#)), the amnion, develops into a small sac that covers the dorsal surface of the embryo. As the amnion enlarges, it gradually engulfs the growing embryo, which prolapses into its cavity ([Benirschke and Kaufman, 2000](#)).

Distension of the amniotic sac eventually brings it into contact with the interior surface of the chorion laeve. Apposition of the mesoblasts of chorion laeve and amnion near the end of the first trimester then causes an obliteration of the extraembryonic coelom. The amnion and chorion laeve, though slightly adherent, are never intimately connected, and usually can be separated easily, even at term.

AMNION CELL HISTOGENESIS

It is now generally accepted that the epithelial cells of the amnion are derived from fetal ectoderm of the embryonic disc. They do not arise by delamination from trophoblasts. This is an important consideration from both the embryological and the functional perspectives. For example, HLA class I gene expression in amnion is more akin to that in cells of the embryo than that in trophoblasts.

In addition to the epithelial cells that line the innermost (amniotic fluid) side of the amnion, there is a layer of fibroblast-like (mesenchymal) cells, which also are likely derived from embryonic mesoderm. Early in human embryogenesis, the mesenchymal cells of the amnion lie immediately adjacent to the basilar surface of the epithelium. At this time, therefore, the amnion surface is a two cell-layer structure with approximately equal numbers of epithelial and mesenchymal cells. Simultaneously with growth and development, interstitial collagens are deposited between these two layers of cells. This marks the commencement of the formation of the compact layer of the amnion, which also brings about a distinct separation of the two layers of amnion cells. As the amniotic sac expands to envelop the placenta and then the chorion frondosum at about 10 to 14 weeks, there is a progressive reduction in the compactness of the mesenchymal cells. These cells continue to separate and in the process become rather sparsely distributed. It appears that early in pregnancy the epithelial cells of the amnion replicate at a rate appreciably faster than the mesenchymal cells. At term, the epithelial cells form a continuous uninterrupted epithelium on the fetal surface of the amnion. The mesenchymal cells, however, are widely dispersed, being connected by a fine lattice network of extracellular matrix with the appearance of long slender fibrils.

AMNION EPITHELIAL CELLS. Epithelial cells line the entire inner (amniotic fluid) side of all portions of the amniotic membrane. These are the cells usually referred to and those studied most commonly in investigations of amnion function. The apical surface of the epithelial cells is replete with highly developed microvilli, consistent with a major site of transfer between amniotic fluid and amnion ([Fig. 5-17](#)). They also are active metabolically; for example, these epithelial cells of amnion are the site of preferential synthesis of tissue inhibitor of metalloproteinase-1 ([Rowe and associates, 1997](#)).

AMNION MESENCHYMAL CELLS. The mesenchymal cells of the fibroblast layer of amnion are responsible for major amnion functions. The synthesis of interstitial collagens that make up the compact layer of the amnion, the source of the majority of tensile strength of this membrane, takes place in mesenchymal cells ([Casey and MacDonald, 1996](#)). These cells also are highly capable of synthesizing cytokines to include interleukin (IL)-6, IL-4-8, and monocyte chemoattractant protein-1 (MCP-1). Their synthesis is increased in response to bacterial toxins and interleukin-1. This functional capacity of amnion mesenchymal cells is an important consideration in the study of amniotic fluid for evidence of labor-associated accumulation of inflammatory mediators ([Garcia-Velasco and Arici, 1999](#)).

ANATOMY

Reflected amnion is fused to the chorion laeve. Placental amnion covers the fetal surface of the placenta, and thereby is in contact with the adventitial surface of the chorionic vessels, which traverse the chorionic plate and branch into the cotyledons. Umbilical amnion covers the umbilical cord. In the conjoined portion of the membranes of diamniotic-dichorionic twin placentae, the fused amnions are separated by fused chorion laeve; and aside from the small area of the fetal membranes immediately over the cervical os, this is the only site at which the reflected chorion laeve is not contiguous with decidua. With diamniotic-monochorionic placentae, there is no intervening tissue between the fused amnions of each twin.

TENSILE STRENGTH

More than 125 years ago, Matthew Duncan (1868) examined the nature of the forces involved in fetal membrane rupture. During tests of tensile strength—resistance to tearing and rupture—he found that the decidua and then the chorion laeve gave way long before the amnion ruptured. Indeed, the membranes are quite elastic and can expand to twice normal size during pregnancy ([Benirschke and Kauffman, 2000](#)). The amnion provides the major strength of the membranes. Moreover, the tensile strength of amnion resides almost exclusively in the compact layer, which is comprised of cross-linked interstitial collagens I, III, and lesser amounts of V and VI.

INTERSTITIAL COLLAGENS. Collagens are the major macromolecules of most connective tissues and the most abundant proteins in the body. Collagen I is the major interstitial collagen in tissues characterized by great tensile strength such as bone and tendon. In other tissues, collagen III is believed to make a unique contribution to tissues integrity, serving to increase tissue extensibility as well as tensile strength. For example, the ratio of collagen III to collagen I in the walls of a number of highly extensible tissues—amniotic sac, blood vessels, urinary bladder, bile ducts, intestine, and gravid uterus—is greater than that in nonelastic tissues. There is a high percentage of collagen III relative to collagen I in fetal skin, and as the proportion of collagen III decreases with fetal and newborn age, there is a parallel decrease in skin extensibility. Because there is little elastin in amnion, it is likely that collagen III provides the extensibility of this membrane. Another unique structural feature of interstitial collagens important to amnion integrity is resistance to proteolytic degradation ([Jeffrey, 1991](#)).

COLLAGEN SYNTHESIS IN AMNION. Interstitial amniotic collagens—types I and III—are produced primarily in mesenchymal cells ([Casey and MacDonald, 1996, 1997](#)). Epithelial cells, conversely, produce primarily basement membrane proteins such as procollagen IV, fibronectin, and laminin. The finding that metallothionein, a protein with high affinity for Cu²⁺, is expressed in high amounts in amnion epithelial cells led to the hypothesis that decreased collagen synthesis may occur in women who smoke ([King and colleagues, 1997](#)). This is the proposed mechanism leading to the increased risk for prematurely ruptured membranes. Cadmium, inhaled in cigarette smoke, enters amniotic fluid and will act on amnion epithelial cells to induce high levels of metallothionein. As a result, Cu²⁺ deficiency may limit the activity of lysyl oxidase and hence the capacity of mesenchymal cells to form cross-linked collagens.

[McLaren and associates \(1999\)](#) and [McParland and colleagues \(2000\)](#) have identified unique changes in the morphology of the fetal membranes at the site of rupture. They found that modifications in the differentiation of cells in the chorion laeve in this specific area may weaken the fetal membranes. Whether these changes involve interstitial collagen content is not known.

METABOLIC FUNCTIONS

The amnion is clearly more than a simple avascular membrane that functions to contain amniotic fluid. It is metabolically active, involved in solute and water transport to maintain amniotic fluid homeostasis, and produces a variety of interesting bioactive compounds, including vasoactive peptides, growth factors, and cytokines.

VASOACTIVE PEPTIDES. A number of investigators have demonstrated the capacity of amnion to synthesize the vasoconstrictor endothelin-1 as well as vasorelaxant parathyroid hormone-related protein ([Casey and associates, 1991, 1992](#); [Germain and co-workers, 1992](#)). Amnion epithelium also produces brain natriuretic peptide (BNP) and corticotropin-releasing hormone (CRH), and these two peptides also are smooth muscle relaxants ([Itoh and associates, 1993, 1994](#); [Riley and co-workers, 1991](#); [Warren and Silverman, 1995](#)). Thus, the vasoactive peptides produced in amnion may gain access to the adventitial surface of the chorionic vessels. These findings suggest that the placental amnion could become involved in modulating chorionic vessel tone and blood flow.

The amnion vasoactive peptides also function in other tissues in diverse physiological processes, including the promotion of cell replication and calcium metabolism. After secretion from the amnion, these bioactive agents can enter amniotic fluid and thereby are available to the fetus by swallowing and fetal thoracic movements.

AMNIOTIC FLUID. The normally clear fluid that collects within the amniotic cavity increases in quantity as pregnancy progresses until near term, when there is a decrease in amniotic fluid volume in many normal pregnancies. An average volume of about 1000 mL is found at term, although this may vary widely from a few milliliters to many liters in abnormal conditions (oligohydramnios and polyhydramnios or hydramnios). The origin, composition, circulation, and function of the amniotic fluid are discussed further in [Chapters 11](#) and [31](#).

UMBILICAL CORD AND RELATED STRUCTURES

DEVELOPMENT

The yolk sac and the umbilical vesicle into which it develops are quite prominent early in pregnancy. At first, the embryo is a flattened disc interposed between amnion and yolk sac ([Fig. 5-6](#)). Because the dorsal surface grows faster than the ventral surface, in association with the elongation of the neural tube, the embryo bulges into the amniotic sac and the dorsal part of the yolk sac is incorporated into the body of the embryo to form the gut. The allantois projects into the base of the body stalk from the caudal wall of the yolk sac or, later, from the anterior wall of the hindgut.

As pregnancy advances, the yolk sac becomes smaller and its pedicle relatively longer. By about the middle of the third month, the expanding amnion obliterates the exocoelom, fuses with the chorion laeve, and covers the bulging placental disc and the lateral surface of the body stalk, which is then called the umbilical cord, or funis. Remnants of the exocoelom in the anterior portion of the cord may contain loops of intestine, which continue to develop outside the embryo. Although the loops are later withdrawn, the apex of the midgut loop retains its connection with the attenuated vitelline duct. The duct terminates in a crumpled, highly vascular sac 3 to 5 cm in diameter lying on the surface of the placenta between amnion and chorion or in the membranes just beyond the placental margin, where occasionally it may be identified at term.

The cord at term normally has two arteries and one vein. The right umbilical vein usually disappears early during fetal development, leaving only the original left vein. Sections of any portion of the cord frequently reveal, near the center, the small duct of the umbilical vesicle, lined by a single layer of flattened or cuboid epithelial cells. In sections just beyond the umbilicus, but never at the maternal end of the cord, another duct representing the allantoic remnant is occasionally found. The intra-abdominal portion of the duct of the umbilical vesicle, which extends from umbilicus to intestine, usually atrophies and disappears, but occasionally it remains patent, forming a Meckel diverticulum. The most common vascular anomaly is the absence of one umbilical artery ([Chap. 32, p. 832](#)).

STRUCTURE AND FUNCTION

The umbilical cord, or funis, extends from the fetal umbilicus to the fetal surface of the placenta or chorionic plate. Its exterior is dull white, moist, and covered by amnion, through which three umbilical vessels may be seen. Its diameter is 0.8 to 2.0 cm, with an average length of 55 cm and a range of 30 to 100 cm. Generally, cord length less than 30 cm is considered abnormally short ([Benirschke and Kauffman, 2000](#)). Folding and tortuosity of the vessels, which are longer than the cord itself, frequently create nodulations on the surface, or false knots, which are essentially varices. The extracellular matrix, which is a specialized connective tissue, consists of Wharton jelly ([Figs. 5-18](#) and [5-19](#)). After fixation, the umbilical vessels appear empty, but [Figure 5-19](#) more accurately is representative of the situation in vivo, when the vessels are not emptied of blood. The two arteries are smaller in diameter than the vein. When fixed in their normally distended state, the umbilical arteries exhibit transverse intimal *folds of Hoboken* across part of their lumens ([Chacko and Reynolds, 1954](#)). The mesoderm of the cord, which is of allantoic origin, fuses with that of the amnion.

Blood flows from the umbilical vein by two routes—the ductus venosus, which empties directly into the inferior vena cava, and numerous smaller openings into the fetal hepatic circulation—and then into the inferior vena cava by the hepatic vein. The blood takes the path of least resistance through these alternate routes. Resistance in the ductus venosus is controlled by a sphincter situated at the origin of the ductus at the umbilical recess and innervated by a branch of the vagus nerve.

Anatomically, the umbilical cord can be regarded as a fetal membrane. The vessels contained in the cord are characterized by spiraling or twisting. The spiraling may occur in a clockwise (dextral) or anticlockwise (sinistral) direction. The anticlockwise spiral is present in 50 to 90 percent of cases. It is believed that the spiraling serves to attenuate "snarling," which occurs in all hollow cylinders subjected to torsion. [Boyd and Hamilton \(1970\)](#) note that these twists are not really spirals, but rather they are cylindrical helices in which a constant curvatures is maintained equidistant from the central axis. [Benirschke and Kauffman \(2000\)](#) reported that 11 is the average number of helices in the cord.

6. The Placental Hormones

The production of steroid and protein hormones by human trophoblasts is greater in amount and diversity than that of any endocrine tissue known in all of mammalian physiology. In a few species, for example, the horse, during pregnancy, estrogen but not progesterone formation, is high. In others, for example, rat and mouse, progesterone production is relatively high but estrogen is not. A variety of protein hormones of the prolactin-growth hormone-placental lactogen family are synthesized in the placenta of most mammals, including humans. But incredible amounts of chorionic gonadotropin are produced in the syncytium only in primates and equids.

A unique and obligatory relationship was discovered between the incredible hyperestrogenic state of human pregnancy and the fetal adrenal secretion of very large quantities of C₁₉-steroids which serve as plasma-borne precursors for estrogen synthesis. An interactive system also has been identified by which human syncytio-trophoblast takes up maternal plasma low-density lipoprotein (LDL)-cholesterol for use in progesterone biosynthesis.

A compendium of the average production rates for various steroid hormones in nonpregnant and in near-term pregnant women is given in [Table 6-1](#). It is readily apparent that the alterations in steroid hormone production that accompany normal human pregnancy are incredible.

The human placenta also synthesizes an enormous amount of protein and peptide hormones: approximately 1 gram of placental lactogen ([hPL](#)¹) each 24 hours, massive quantities of chorionic gonadotropin (hCG), chorionic adrenocorticotropin ([ACTH](#)²) as well as other products of proopiomelanocortin, chorionic thyrotropin, growth hormone variant, parathyroid hormone-related protein (PTH-rP), calcitonin, and relaxin; and a variety of hypothalamic-like releasing and inhibiting hormones, including thyrotropin-releasing hormone (TRH), gonadotropin-releasing hormone (GnRH), corticotropin-releasing hormone (CRH), somatostatin, and growth hormone-releasing hormone (GHRH). The human placenta also produces inhibins, activins, and atrial natriuretic peptide.

It is understandable, therefore, that yet another remarkable feature of human pregnancy is the success of the physiological adaptations of pregnant women to a most unusual endocrine milieu ([Chap. 8](#)). The anatomical parts of the endocrine system of the placental arm of the fetal-maternal communication system are illustrated in [Figure 6-1](#).

HUMAN CHORIONIC GONADOTROPIN (hCG)

The "pregnancy hormone" is a glycoprotein with biological activity very similar to luteinizing hormone (LH), both of which act via the plasma membrane [LH](#)³/hCG receptor. HCG is produced almost exclusively in the placenta, but is synthesized in fetal kidney, and a number of fetal tissues produce the β-subunit or intact hCG molecule ([McGregor and associates, 1981, 1983](#)).

A variety of malignant tumors also produce hCG, sometimes in reasonably large amounts—especially neoplastic trophoblasts. HCG is produced in very small amounts in tissues of men and nonpregnant women, perhaps primarily in the anterior pituitary gland. Nonetheless, the detection of hCG in blood or urine is almost always indicative of pregnancy ([Chap. 2, p. 26](#)).

CHEMICAL CHARACTERISTICS. HCG is a glycoprotein (M_r about 36,700) with the highest carbohydrate (30 percent) content of any human hormone. The carbohydrate component, and especially the terminal sialic acid, protects the molecule from catabolism. The plasma half-life of intact hCG (24 hours) is much longer than that of [LH](#)³ (2 hours).

The hCG molecule is composed of two dissimilar subunits, designated α (92 amino acids) and β (145 amino acids), which are noncovalently linked. They are held together by electrostatic and hydrophobic forces that can be separated in vitro. There is no intrinsic [LH](#)³-like biological activity of either separated subunit because neither subunit binds to the LH receptor.

HCG is related structurally to three other glyco-protein hormones—[LH](#)³, follicle-stimulating hormone (FSH), and thyroid-stimulating hormone (TSH). The amino acid sequence of the α-subunits of these four glycoproteins is identical; but the β-subunits of [FSH](#)⁴ and [TSH](#)⁵, as well as those of hCG and LH, while sharing certain similarities, are characterized by distinctly different amino acid sequences. Recombination of an α- and a β-subunit of the four glycoprotein hormones gives a molecule with biological activity characteristic of the hormone from which the β-subunit was derived.

BIOSYNTHESIS. The synthesis of the α- and β-chains of hCG is regulated separately. A single gene—on chromosome 6 at q12-q21—codes for the α-subunit of all four glycoprotein hormones. There are eight separate genes on chromosome 19 for the β-hCG/β-[LH](#)³ family. Seven of these genes code for β-hCG and one for β-LH, but only three of the β-hCG genes are expressed. Both the α- and β-subunits of hCG are synthesized as larger molecular weight precursors which are cleaved by microsomal endopeptidases. Once intact hCG is assembled, the molecule is rapidly released from the cell but its regulation is not understood.

The rate of synthesis of the β-subunit of hCG is believed to be limiting in the formation of the complete molecule. Trophoblasts of normal placenta and those of hydatidiform mole and choriocarcinoma tissues secrete free α- and β-subunits as well as intact hCG; but there is an excess of hCG α-subunits in placenta and in plasma. The hCG free β-subunit, however, is present in plasma in only small quantities.

CELLULAR SITES OF ORIGIN. The complete hCG molecule is synthesized primarily in the syncytiotrophoblast. It has been demonstrated, however, that immunoreactive hCG is present in cytotrophoblasts before 6 weeks. Thereafter, hCG is localized almost exclusively in the syncytium. A similar cellular distribution for immunoreactive [hPL](#)¹ in early pregnancy also has been reported ([Maruo and associates, 1992](#)).

REGULATION OF hCG SUBUNIT BIOSYNTHESIS. The amounts of mRNA for both the α- and β-subunits of hCG in syncytiotrophoblast from the first trimester are greater than at term. This may be an important consideration in the measurement of hCG in plasma as a screening procedure to identify abnormal fetuses. The finding of mRNA for the α- and β-subunits of hCG in cyto-trophoblasts or in intermediate trophoblasts is suggestive that the genes for hCG are expressed before full differentiation of the trophoblasts. Cytotrophoblasts begin to disappear from the placenta at the end of the first trimester; but in some abnormal pregnancies in which there is a reappearance of cytotrophoblasts, as with D-antigen isoimmunization and gestational diabetes, plasma levels of hCG may be increased.

MOLECULAR FORMS OF hCG IN PLASMA AND URINE. There are multiple forms of hCG in maternal plasma and urine. Some of these arise as the result of enzymatic degradation, and others are accounted for by modifications during the normal cellular sequence of synthesis/processing of the hCG molecule. The multiple forms of hCG vary enormously in bioactivity and immunoreactivity.

FREE SUBUNIT. As cited, the levels of the β-subunit in plasma are very low or undetectable throughout human pregnancy (see [Fig. 2-6](#)). In part, this finding is the result of the rate-limiting synthesis of the β-subunit. Free α-subunits that do not combine with the β-subunit are found in placenta and maternal plasma. The increased size of the oligosaccharides of free α-subunits prevent dimerization with β-hCG. The plasma levels of free α-subunits increase gradually, but steadily, until about 36 weeks, when a plateau is attained that is maintained for the remainder of pregnancy. This pattern is similar to that of [hPL](#)¹ in plasma (see [Fig. 2-6](#)). Thus, the secretion of α-hCG roughly corresponds to placental mass, whereas the rate of secretion of the complete hCG molecule is maximal at 8 to 10 weeks. The plasma concentration of α-hCG, however, is always much less (10 percent or less) than that of intact hCG.

NICKS IN THE hCG MOLECULE. During the past 10 years, it has been shown that many of the hCG molecules in serum and urine contain nicks, or missing peptide linkages. This is true of purified standard preparations and of individual samples from serum and urine as well. These nicks occur primarily between β-subunit amino acids 44-45 and 47-48. The extent of nicking in standard preparations from pooled urine is 10 to 20 percent, but in individual samples it varies from 0 to 100 percent. The origin of these nicks is believed to be through enzymatic action on the molecule that occurs near the cellular site of synthesis of the β-subunit. One example is that these reactions are catalyzed by leukocyte elastase. The biological importance of these nicked molecules is unknown, but the bioactivity of nicked hCG is diminished to about 20 percent and the immunoreactivity to monoclonal antibodies may be severely attenuated but variable ([Cole and associates, 1991](#)). This can be an issue of some concern when monitoring changes in the hCG levels if assays are conducted with different antibodies.

CONCENTRATIONS OF hCG IN SERUM AND URINE. The intact hCG molecule is detectable in plasma of pregnant women about 7 1/2 to 9 1/2 days after the midcycle surge of [LH](#)³ that precedes ovulation. Thus, it is likely that hCG enters maternal blood at the time of blastocyst implantation ([Chap. 2, p. 27](#)). Blood levels increase rapidly thereafter, with maximal levels being attained at about 8 to 10 weeks. Appreciable fluctuations in the levels of plasma hCG are observed on the same day, and evidence has accrued that the trophoblast secretion of protein hormones is episodic.

Maternal urine concentration is closely parallel to that in plasma, which is approximately 1 IU/mL by 6 weeks after the commencement of the last menstrual period, increasing to an average value of about 100 IU/mL between the 60th and 80th days after the last menses (see [Fig. 2-6](#)). The levels of hCG in plasma of pregnant women may reach 15 mg/mL. Beginning at about 10 to 12 weeks, the levels of hCG in maternal plasma begin to decline, a nadir being reached by about 20 weeks. The levels of hCG in plasma are maintained at this lower level for the remainder of pregnancy.

The pattern of appearance of hCG in fetal blood (as a function of gestational age) is similar to that in the mother, but the levels of hCG in fetal plasma are only about 3 percent of those in maternal plasma. The concentration of hCG in amniotic fluid early in pregnancy is similar to that in maternal plasma; but as pregnancy progresses, the concentration of hCG in amniotic fluid declines, so that near term, the levels are only a fifth those in maternal plasma.

ELEVATED OR DEPRESSED hCG LEVELS IN MATERNAL PLASMA OR URINE. Significantly higher plasma levels of hCG are sometimes found in pregnancies with multiple fetuses, and with a single erythroblastotic fetus resulting from maternal D-antigen isoimmunization. The levels of hCG in plasma and urine may be increased strikingly in women with hydatidiform mole or choriocarcinoma. Relatively higher levels of plasma hCG may be found at midtrimester with Down syndrome. The reason for this is not clear, but it has been speculated that the placenta in these pregnancies is less mature compared with those with normal fetuses. Relatively lower levels of hCG in plasma are found with ectopic pregnancies and impending spontaneous abortion.

REGULATION OF hCG SYNTHESIS. Placental GnRH⁶ is likely involved in the regulation of hCG formation. A role for placental inhibin in regulation of hCG also has been proposed. A large number of compounds act to increase hCG secretion by trophoblasts in vitro. Among these are derivatives of cyclic AMP, hypothalamic-like hormones (GnRH, CRH⁷), some cytokines, various growth factors, colony-stimulating factors, and thyroid hormones. From this brief compilation, it is evident that the in vivo regulation of hCG synthesis is not yet clearly understood.

METABOLIC CLEARANCE OF hCG. The renal clearance of hCG accounts for 30 percent of metabolic clearance and the remainder is cleared by other pathways, likely by metabolism in liver and kidney ([Nishula and Wehmann, 1980](#)). Clearances of β -subunit and α -subunit are about 10-fold and 30-fold, respectively, greater than that of intact hCG. By contrast, renal clearance of subunits is considerably lower than that of dimeric hCG.

ASSAY OF hCG. The methods for detecting hCG in urine or blood are of considerable importance, because these assays form the basis for the vast majority of pregnancy tests ([Chap. 2, p. 27](#)).

BIOLOGICAL FUNCTIONS OF hCG. Both subunits of hCG are required for normal binding to the LH³/hCG receptor. There are LH/hCG receptors in a variety of tissues other than the corpus luteum and the testis ([Chap. 11, p. 272](#)).

RESCUE OF THE CORPUS LUTEUM. The best known biological function of hCG is the "rescue" and maintenance of function of the corpus luteum—that is, continued progesterone production. [Bradbury and colleagues \(1950\)](#) found that the progesterone-producing life span of the corpus luteum of menstruation could be prolonged perhaps for 2 weeks by the administration of hCG to nonpregnant women. This action provides only an incomplete explanation for the physiological role of hCG in pregnancy. The maximum plasma hCG concentrations are attained at a time in gestation that is well after hCG-stimulated corpus luteum secretion of progesterone has ceased. Specifically, progesterone synthesis by the corpus luteum begins to decline at about 6 weeks despite continued and increasing hCG production.

HCG STIMULATION OF FETAL TESTIS. Fetal testicular secretion of testosterone is maximum at approximately the same time in gestation when the maximal levels of hCG are attained. Thus, at a critical time in sexual differentiation of the male fetus, hCG, entering fetal plasma from syncytiotrophoblast, acts as an LH³ surrogate, stimulating the replication of fetal testicular Leydig cells and testosterone synthesis to promote male sexual differentiation ([Chap. 7, p. 158](#)). Before about 110 days of human pregnancy, there is no vascularization of the fetal anterior pituitary from the hypothalamus, and thus little LH secretion from the pituitary. HCG acts as LH before this time. Thereafter, as hCG levels fall, pituitary LH maintains a lower level of fetal testicular stimulation.

HCG STIMULATION OF THE MATERNAL THYROID. In many women with hydatidiform mole or choriocarcinoma, biochemical and clinical evidence of hyperthyroidism sometimes develops ([Chap. 32, p. 840](#)). For a time it was believed that the formation of chorionic thyrotropins by the neoplastic trophoblasts was the cause of the hyperthyroid-like findings in these women. Later, however, it was shown that some forms of hCG bind to the TSH⁵ receptors of thyroid cells. Treatment of normal men with hCG increases thyroid activity. The thyroid-stimulatory activity in plasma of first-trimester pregnant women varies appreciably from sample to sample. Modifications in the oligosaccharides of hCG seem to be important in establishing the capacity of hCG to stimulate thyroid function. Some of the acidic isoforms of hCG stimulate thyroid activity, and some more basic forms also stimulate iodine uptake ([Kraiem and co-workers, 1994](#); [Tsuruta and colleagues, 1995](#); [Yoshimura and associates, 1994](#)). There also is preliminary evidence that the LH³/hCG receptor is expressed in the thyroid ([Tomer and co-workers, 1992](#)). Thus, the possibility exists that hCG stimulates thyroid activity via the LH/hCG receptor and by the TSH receptor as well.

OTHER PROPOSED FUNCTIONS. HCG acts in vivo to promote relaxin secretion by the corpus luteum. LH³/hCG receptors are found in myometrium and in uterine vascular tissue, and it has been hypothesized that hCG may act to promote uterine vascular vaso-dilation and myometrial smooth muscle relaxation ([Chap. 11](#)).

HUMAN PLACENTAL LACTOGEN

Prolactin-like activity in the human placenta was first described by Ehrhardt in 1936. The protein responsible for this activity was isolated from extracts of human placenta and retroplacental blood and partially purified by [Ito and Higashi \(1961\)](#) and by [Josimovich and MacLaren \(1962\)](#). Because of the potent lactogenic and growth hormone-like bioactivity (and an immunochemical resemblance to human growth hormone), it was first called human placental lactogen or chorionic growth hormone. This hormone also has been referred to as chorionic somatomammotropin. Recently, most authors have used the original name, human placental lactogen (hPL). [Grumbach and Kaplan \(1964\)](#) found, by immunofluorescence studies, that this hormone, like hCG, was concentrated in the syncytiotrophoblast. hPL is detected in the trophoblast as early as the second or third week after fertilization of the ovum. It was originally believed that hPL¹ in placenta was localized exclusively in the syncytiotrophoblast, indicating that the genes for hPL are expressed only in the fully differentiated trophoblast. This, however, does not appear to be the case; as with hCG, hPL is identified in cytotrophoblasts from before 6 weeks in pregnancy ([Maruo and associates, 1992](#)).

CHEMICAL CHARACTERISTICS. hPL is a single nonglycosylated polypeptide chain with a molecular weight of 22,279 d, which is derived from a precursor of 25,000 d that contains a 26 amino-acid signal sequence. There are 191 amino acid residues in placental lactogen, compared with 188 in human growth hormone; the amino acid sequence in each hormone is strikingly similar, with 96 percent homology. hPL also is structurally similar to human prolactin (hPRL), with about 67 percent amino-acid sequence homology. For these reasons, it has been suggested that the genes for hPL¹, hPRL, and hGH evolved from a common ancestral gene (probably PRL) by repeated gene duplication ([Ogren and Talamantes, 1994](#)).

hPL production is not restricted to the trophoblast. The hormone has been detected by direct radioimmunoassay in sera from men and women with various malignancies other than those originating in trophoblast or gonad, including bronchogenic carcinoma, hepatoma, lymphoma, and pheochromocytoma ([Weintraub and Rosen, 1970](#)).

GENE STRUCTURE AND EXPRESSION. There are five genes in the prolactin-growth hormone-placental lac-togen gene family; these genes are linked and located on chromosome 17. Two of these genes, hCS-A and hCS-B, both code for hPL¹, and the amount of mRNA in the term placenta is similar for each. The gene for hPRL (prolactin) is located on chromosome 6 ([Owerbach and co-workers, 1980, 1981](#)).

SECRETION AND METABOLISM. hPL accounts for 7 to 10 percent of the proteins synthesized by placental ribosomes at term. In fact, 5 percent of the mRNA of term placenta is hPL¹ mRNA. The production rate of hPL near term, about 1 g/day, is the greatest (by far) of any known hormone in humans.

SERUM CONCENTRATION. hPL is demonstrable in placenta within 5 to 10 days after conception and hPL¹ can be detected in serum as early as 3 weeks after fertilization. Maternal plasma concentration rises steadily until about 34 to 36 weeks, it is approximately proportional to placental mass. The serum concentration reaches higher levels in late pregnancy (5 to 15 ug/mL) than those of any other known protein hormone (see [Fig. 2-6](#)). The half-life of hPL in maternal plasma is between 10 and 30 minutes ([Walker and associates, 1991](#)).

Very little hPL¹ is detected in fetal blood or in the urine of the mother or newborn; the concentration of hPL in amniotic fluid is somewhat lower than that in maternal plasma. Because hPL is secreted primarily into the maternal circulation, with only very small amounts in cord blood, it appears that the role of the hormone in

pregnancy, if any, is mediated through actions in maternal rather than in fetal tissues. Nonetheless, there is continuing interest in the possibility that hPL in the fetus serves select functions in fetal growth.

REGULATION OF hPL BIOSYNTHESIS. The levels of mRNA for [hPL¹](#) in syncytiotrophoblast remain relatively constant throughout pregnancy. This finding is supportive of the idea that the rate of hPL secretion is proportional to placental mass. There are very high levels of hCG in the blood of women with neoplastic trophoblastic disease, but only low levels of hPL in these same women.

Prolonged maternal starvation in the first half of pregnancy leads to an increase in the plasma concentration of [hPL¹](#). Short-term changes in plasma glucose or insulin, however, have relatively little effect on plasma levels of hPL. The synthesis of hPL is stimulated by insulin and cAMP. PGE₂ and PGF_{2a} seem to inhibit the secretion of hPL.

METABOLIC ACTIONS. HPL has putative actions in a number of important metabolic processes. These include:

1. Lipolysis and an increase in the levels of circulating free fatty acids—thereby providing a source of energy for maternal metabolism and fetal nutrition.
2. An anti-insulin action, leading to an increase in maternal levels of insulin, which favors protein synthesis and provides a mobilizable source of amino acids for transport to the fetus.

OTHER PLACENTAL PROTEIN HORMONES

CHORIONIC ADRENOCORTICOTROPIN

A protein similar to adrenocorticotrophic hormone ([ACTH⁸](#)) has been isolated from placental tissue. [Odagiri and colleagues \(1979\)](#) found that ACTH, lipotropin, and β -endorphin are recovered in placental extracts and presumably are derived from the same or a similar 31-kd precursor molecule, proopiomelanocortin (POMC). [Liotta and colleagues \(1977\)](#) also found that ACTH is produced by dispersed placental cells. Dexamethasone treatment of pregnant women does not alter the levels of bioactive or immunoreactive ACTH in placental tissue. Finally, evidence comes from radiolabeled amino acid uptake into peptides that characterize ACTH.

The physiological role of placental [ACTH⁹](#) is unclear. ACTH plasma levels at all times in pregnancy (before labor) are lower than those in men and nonpregnant women; nonetheless, the concentration increases as pregnancy advances ([Carr and colleagues, 1981](#)). The placenta may produce ACTH that is secreted into the mother or fetus during pregnancy, but ACTH does not cross the placenta (i.e., from mother to fetus). The administration of dexamethasone to pregnant women does not cause suppression of urinary free cortisol levels as effectively as it does in men and nonpregnant women.

Corticotropin-releasing hormone stimulates the synthesis and release of chorionic [ACTH¹⁰](#) in vitro (p. 115).

CHORIONIC THYROTROPIN

There is evidence that the placenta produces a chorionic thyrotropin, but a significant biological role for this peptide in normal human pregnancy has not been established. The neoplastic trophoblasts of hydatidiform mole and choriocarcinoma may produce a family of chorionic thyrotropins, but the increased thyroid-stimulating activity in women with neoplastic trophoblastic disease is believed to be attributable primarily to the thyroid-stimulating properties of hCG (p. 113).

RELAXIN

Expression of relaxin has been demonstrated in human corpus luteum, decidua, and placenta ([Bogic and colleagues, 1995](#)). This peptide is synthesized as a single 105 amino-acid preprorelaxin molecule that gives rise to two chains (A and B) by cleavage of the preprorelaxin. Relaxin is structurally similar to insulin and nerve growth factor. There are two relaxin genes (H1 and H2), but only H2 is transcribed in the corpus luteum. Other tissues, including decidua, placenta, and fetal membranes, also express H1. Relaxin acts on myometrial smooth muscle to stimulate adenyl cyclase and to promote uterine relaxation ([Chap. 11, p. 272](#)). An understanding of relaxin synthesis and action, however, is far from complete.

PARATHYROID HORMONE-RELATED PROTEIN (PTH-rP¹¹)

The chemical relationships between PTH and [PTH-rP¹²](#) were described in [Chapters 4 and 5](#). Since PTH-rP was identified, many potential functions have been suggested. The synthesis of PTH-rP has been demonstrated in a number of normal adult tissues, especially in reproductive organs of men and women, including the uterus (myometrium and endometrium), corpus luteum, and lactating mammary tissue. Recall that PTH-rP is not produced in the parathyroid glands of normal adults.

A number of fetal tissues also synthesize [PTH-rP¹³](#), including the fetal parathyroid, kidney, and placenta. Because immunoreactive PTH is not readily detected in fetal blood, and because PTH-rP is produced by several fetal tissues, it has been suggested that PTH-rP may serve as the parathyroid of the fetus. The findings of recently conducted studies are supportive of this view. The rate of PTH secretion by the adult parathyroid is modulated by plasma Ca²⁺ concentration. PTH-rP secretion from other tissues is not regulated by calcium concentration except in the placenta. [Hellman and associates \(1992\)](#) found that PTH-rP secretion by trophoblasts is responsive to extracellular Ca²⁺.

GROWTH HORMONE-VARIANT (hGH-V)

There is a gene which encodes a growth hormone variant that is expressed in the placenta, but not in the pituitary. The gene is located in the growth hormone-prolactin gene cluster. The variant of hGH, sometimes referred to as placental growth hormone, is a 191-amino acid protein that differs in 15 amino acid positions from the sequence for hGH. hGH-V is synthesized in placenta, presumably in the syncytium, but the pattern of synthesis of hGH-V secretion with gestation is not precisely known because antibodies available against hGH-V cross-react with hGH. It is believed that hGH-V is present in maternal plasma by 21 to 26 weeks, increasing in concentration to about 36 weeks, and remaining relatively constant thereafter. There is a correlation between the levels of hGH-V in maternal plasma and those of insulin growth factor-1, and the secretion of hGH-V by trophoblasts in vitro is inhibited by glucose in a dose-dependent manner ([Patel and colleagues, 1995](#)). The biological activity profile of hGH-V is similar to that of [hPL¹](#).

HYPOTHALAMIC-LIKE RELEASING HORMONES

For each of the known hypothalamic-releasing or-inhibiting hormones described—[GnRH¹⁴](#), [TRH¹⁵](#), [CRH¹⁶](#), [GHRH¹⁷](#), and somatostatin—there is an analogous hormone produced in human placenta ([Petraglia and colleagues, 1992](#); [Siler-Khodr, 1988](#)). Their role in trophoblasts, however, has not been completely resolved. Many investigators have proposed that the presence of these substances in placental tissue is indicative of a hierarchy of control of the synthesis of chorionic trophic agents.

GONADOTROPIN-RELEASING HORMONE (GnRH)

There is a reasonably large amount of immunoreactive gonadotropin-releasing hormone ([GnRH¹⁸](#)) in placenta ([Siler-Khodr, 1988](#); [Siler-Khodr and Khodr, 1978](#)). Interestingly, these investigators also found that immunoreactive GnRH was present in cytotrophoblasts, but not in the syncytiotrophoblast. [Siler-Khodr \(1983\)](#) has referred to chorionic GnRH as hCG-releasing hormone. [Gibbons and co-workers \(1975\)](#) and [Khodr and Siler-Khodr \(1980\)](#) demonstrated that the human placenta can synthesize both GnRH and [TRH¹⁵](#) (thyrotropin-releasing hormone) in vitro.

CORTICOTROPIN-RELEASING HORMONE (CRH¹⁹)

Attempts to isolate and identify corticotropin-releasing hormone ([CRH²⁰](#)) from the hypothalamus took some 40 years. The same CRH gene (long arm of chromosome 8) expressed in hypothalamic tissues is also expressed in trophoblasts, amnion, chorion laeve, and decidua. In nonpregnant women, the plasma level of CRH is about 15 pg/mL. This increases to about 250 pg/mL in the early third trimester and to 1000 to 2000 pg/mL abruptly during the last 5 to 6 weeks ([Goland and associates, 1988](#)). After labor begins, maternal plasma levels of CRH increase further by about two- to threefold ([Petraglia and colleagues, 1989, 1990](#)).

The biological function of CRH²¹ synthesized in placenta (and fetal membranes/decidua) is not so clear. Receptors for CRH are present in many tissues: placenta, adrenal, sympathetic ganglia, lymphocytes, gastrointestinal tract, pancreas, gonads, and myometrium. The finding that only very small amounts of placental CRH enter the fetal umbilical circulation mitigates against a role for placental CRH in fetal adrenal steroidogenesis. Large amounts of CRH from trophoblast enter the maternal blood, but there also is a large concentration of a specific CRH-binding protein in maternal plasma, and the bound CRH seems to be biologically inactive and targeted for degradation. Other proposed biological roles include the induction of smooth muscle relaxation (vascular and myometrial) and immunosuppression. The physiological reverse, the induction of myometrial contractions (i.e., the initiation of parturition by CRH) has also been suggested ([Wadhwa and associates, 1998](#)). Prostaglandin formation in placenta, amnion, chorion laeve, and decidua is increased by treatment with CRH ([Jones and Challis, 1989](#)).

As described in [Chapter 50 \(p. 1351\)](#), a few cases have been reported of Cushing syndrome that developed during pregnancy with spontaneous resolution after delivery ([Aron and co-workers, 1990](#)). It would be interesting to know if the abnormality in some of these women resided in a deficiency in the formation of CRH²²-binding protein such that placental CRH stimulated pituitary ACTH²³ formation.

Glucocorticosteroids act in the hypothalamus to inhibit CRH²⁴ release, but in the trophoblast, glucocorticosteroids stimulate the expression of the CRH gene, with two- to fivefold increases in CRH mRNA and protein after treatment of human trophoblasts in culture ([Robinson and associates, 1988](#)). Therefore, the possibility of a positive feedback loop has been considered in placenta that involves placental CRH stimulation of placental ACTH²⁵ formation, placental ACTH stimulation of glucocorticosteroid formation, and glucocorticosteroid stimulation of placental CRH expression ([Riley and colleagues, 1991](#)).

THYROTROPIN-RELEASING HORMONE (cTRH)

The synthesis of chorionic thyroid-releasing hormone (cTRH) in placenta has been demonstrated, but relatively little is known of its regulation synthesis or biological role.

GROWTH HORMONE-RELEASING HORMONE (GHRH²⁶)

This is also known as **somatocrinin**. It is expressed in selected human tumors and is implicated in the development of acromegaly in persons with such tumors. The mRNA for GHRH²⁷ has been identified in human placenta, ([Berry and co-workers, 1992](#)). The function of placental GHRH is not known.

OTHER PLACENTAL PEPTIDE HORMONES

NEUROPEPTIDE-Y (NPY)

This small 36-amino-acid peptide is widely distributed in brain. It also is found in sympathetic neurons innervating the cardiovascular, respiratory, gastrointestinal, and genitourinary systems. Neuropeptide-Y (NPY²⁸) has been isolated from placenta and localized in cytotrophoblasts ([Petraglia and colleagues, 1989](#)). Receptors for NPY have been demonstrated in placenta, and treatment of placental cells with NPY causes the release of CRH²⁹.

INHIBIN AND ACTIVIN

Inhibin is a glycoprotein hormone that acts preferentially to inhibit FSH³⁰ release by the pituitary. It is produced by human testis and by the granulosa cells of the ovary, including the corpus luteum. Inhibin is a heterodimer with dissimilar α - and β -subunits. The inhibin β -subunit is composed of one of two distinct peptides, β A or β B. Activin is closely related to inhibin and is formed by the combination of two β -subunits. The placenta produces inhibin α -, β A-, and β B-subunits with the greatest levels present at term ([Petraglia and colleagues, 1991](#)). Inhibin, produced in placenta, in conjunction with the large amounts of sex steroid hormones produced in human pregnancy, may serve to inhibit FSH secretion and thereby preclude ovulation during pregnancy. [Petraglia and colleagues \(1994\)](#) found that serum activin A levels decline rapidly after delivery. It is not detectable in fetal blood before labor but is present in umbilical cord blood after labor began. The receptor for activin is expressed in placenta and amnion. Inhibin may act via GnRH³¹ to regulate hCG synthesis/secretion in placenta ([Petraglia and associates, 1987](#)). Chorionic activin and inhibin may serve functions in placental metabolic processes other than GnRH synthesis, but these functions have not been established.

ATRIAL NATRIURETIC PEPTIDE (ANP)

This 28-amino-acid peptide acts to effect natriuresis, diuresis, and vasorelaxation. It normally is produced in atrial myocytes, and also is synthesized in placental cytotrophoblast-like cells ([Lim and Gude, 1995](#)). Atrial natriuretic peptide (ANP³²) receptors are found in placenta myometrial tissues ([Chap. 11, p. 273](#)).

ESTROGENS

The placenta produces huge amounts of estrogens as well as progesterone. Steroid biosynthesis in human syncytium, however, is dependent upon blood-borne steroidal precursors. Near term, normal human pregnancy is a hyperestrogenic state of major proportions. The amount of estrogen produced each day by syncytiotrophoblast during the last few weeks of pregnancy is equivalent to that produced in one day by the ovaries of no fewer than 1000 ovulatory women. By way of another analogy, more estrogen is produced by the placenta during the course of one normal pregnancy than is secreted by the ovaries of 200 ovulatory women during the same 40 weeks. The hyperestrogenic state of human pregnancy is one of continually increasing magnitude as pregnancy progresses, terminating abruptly after delivery.

During the first 2 to 4 weeks of pregnancy, relatively small amounts of estrogen are produced by the maternal ovaries. The levels of urinary estrogens were not reduced, however, after bilateral oophorectomy conducted as early as the 78th day of pregnancy ([Diczfalusy and Borell, 1961](#)). Similar results were obtained in several studies of urinary estrogen levels in pregnant women after surgical removal of the corpus luteum. As early as the seventh week of human pregnancy, more than 50 percent of estrogen entering the maternal circulation is produced in placenta ([MacDonald, 1965](#); [Siiteri and MacDonald, 1963, 1966b](#)).

PLACENTAL ESTROGEN BIOSYNTHESIS. The pathways of estrogen synthesis in human placenta differ from those in the ovarian follicle (granulosa cells) of nonpregnant women. Estrogen is produced in the ovary de novo, from acetate or cholesterol. Specifically, androstenedione, synthesized in ovarian theca cells, is transferred into the follicular fluid, from which it is taken up by the granulosa cells for estradiol-17 β synthesis. Conversely, progesterone synthesis in the human corpus luteum (luteinized granulosa cells) is accomplished by use of preformed cholesterol taken up in LDL³³ particles from plasma.

In human placenta (trophoblast), neither acetate nor cholesterol, nor even progesterone, can serve as precursor for estrogen biosynthesis. A crucial enzyme necessary for sex steroid synthesis—steroid 17 α -hydroxylase/17,20-desmolase, encoded by the CYP17 gene—is not expressed in the human placenta. Consequently, the conversion of C₂₁-steroids to C₁₉-steroids, the latter being the immediate and obligatory precursors of estrogens, is not possible. [Ryan \(1959a\)](#) found that there was an exceptionally high capacity of placenta to convert appropriate C₁₉-steroids to estrone and estradiol-17 β . These C₁₉-steroids are dehydroepiandrosterone, androstenedione, and testosterone, which are converted to estrone, estradiol-17 β , or both. These findings were crucial to the design of investigations conducted later in which the role of plasma-borne, preformed C₁₉-steroids in estrogen biosynthesis in trophoblast was defined.

PLASMA C₁₉-STERIODS AS ESTROGEN PRECURSORS. [Amoroso \(1960\)](#) first suggested that the placenta might, through its abundant enzymatic activity, bring about the formation of active agents by converting inactive materials derived from the fetus. [Frandsen and Stakemann \(1961\)](#) found that the levels of urinary estrogens in women pregnant with an anencephalic fetus were only about a tenth of those in urine of women pregnant with a normal fetus. Because of the characteristic absence of the fetal zone of the adrenal cortex in anencephalic fetuses, they reasoned that the glands might provide a substance(s) that serves to promote placental estrogen formation. The adrenal glands of anencephalic fetuses are atrophic because of the absence of hypothalamic-pituitary function, which precludes ACTH³⁴ stimulation of the fetal adrenal glands.

In subsequent studies, radiolabeled dehydroepiandrosterone sulfate infused into pregnant women was converted to radioactive urinary estrogens in high yield ([Baulieu and Dray, 1963](#); [Siiteri and MacDonald, 1963](#)). Other radiolabeled unconjugated C₁₉-steroids—dehydroepiandrosterone, androstenedione, and testosterone—also were converted to estrogens. The large amounts of dehydroepiandrosterone sulfate in plasma and its much longer half-life uniquely qualified it as the principal circulating precursor for placental estradiol-17 β synthesis. The presentation as a sulfate ester does not preclude its use because the placenta normally is

a rich source of sulfatase activity ([Pulkkinen, 1961](#); [Warren and Timberlake, 1962](#)). By the 30th week, 30 to 40 percent of dehydroepiandrosterone sulfate secreted by the maternal adrenal glands is converted to estradiol-17 β . Conversely, little (less than 0.1 percent) is normally converted to estrogen in men or nonpregnant women ([Siiteri and MacDonald, 1963, 1966b](#)).

PLACENTAL AROMATASE ENZYME. Estrogen formation from androstenedione is catalyzed by an enzyme complex referred to as aromatase, which is composed of a specific cytochrome P-450 monooxygenase, aromatase cytochrome P-450 (P-450_{AROM}; P-450_{XIX}, the product of the CYP19 gene), and a flavoprotein, NADPH-cytochrome P-450 reductase. The principal cellular location of P-450_{AROM} in the placenta is in the syncytiotrophoblast ([Bonenfant and colleagues, 2000](#)). It is found in the ovary in granulosa cells. CYP19 is also expressed in much lower levels in adipose tissue stromal cells, Sertoli and Leydig cells of the testis, hypothalamus, fetal (but not adult) liver, but not normal endometrium.

SECRETED ESTROGENS. The product estrogen in tissues in which aromatase activity is present is dependent on the nature of the substrate available and on the particular 17 β -hydroxysteroid dehydrogenase (17 β HSD) isozyme in that tissue. Estradiol-17 β is the product hormone secreted by the ovary and testis. In the ovary, for example, the aromatization of andro-stenedione gives estrone, which is converted (by 17 β -hydroxysteroid dehydrogenase type 1) to estradiol-17 β before secretion by the granulosa cells. In adipose tissue, however, androstenedione is converted to estrone, and the estrone formed (without conversion in situ to estradiol-17 β) is the product that enters the blood. Testosterone is converted to estradiol-17 β directly in all tissue sites of aromatization.

In human placenta, estradiol-17 β is one estrogen secretory product; but in addition, 16 α -hydroxyandrostenedione is converted to 16 α -hydroxyestrone, which in turn is converted to estriol before secretion by trophoblast. Therefore, the syncytiotrophoblast secretes two estrogens, estradiol-17 β and estriol.

METABOLISM OF DEHYDROEPIANDROSTERONE SULFATE. [Gant and co-workers \(1971\)](#) found that there is a 10- to 20-fold increase in the metabolic clearance rate (MCR) of plasma dehydroepiandrosterone sulfate in normally pregnant women at term compared with that in men and nonpregnant women. As a consequence, there is a progressive decrease in its plasma concentration ([Milewich and colleagues, 1978](#); [Siiteri and MacDonald, 1966a](#)).

The increase in the [MCR](#)³⁵ of plasma dehydroepiandrosterone sulfate in pregnant women appears to be attributable primarily to:

1. Removal through conversion to estradiol-17 β in the syncytium.
2. Accelerated 16 α -hydroxylation (probably in maternal liver) with 30 to 40 percent converted near term to 16 α -hydroxydehydroepiandrosterone sulfate ([Madden and associates, 1976, 1978](#)).

The maternal adrenal glands do not produce sufficient amounts of dehydroepiandrosterone sulfate during pregnancy to account for more than a small fraction of placenta estrogen biosynthesis. **The fetal adrenal glands are the quantitatively important source of placental estrogen precursors in human pregnancy.**

FETAL ADRENAL GLANDS

Morphologically, functionally, and physiologically, the human fetal adrenal glands are remarkable organs. Compared with adult organs, the adrenal cortex is the largest organ of the fetus. At term, they weigh the same as adrenal glands of the adult ([Fig. 6-2](#)). More than 85 percent of the fetal gland is normally composed of a peculiar fetal zone, which is not found in adults.

The daily production of steroids by the fetal adrenal glands near term is estimated to be 100 to 200 mg per day. Steroid secretion in resting adults rarely exceeds 30 to 40 mg/day; thus, the human fetal adrenal gland is a truly prodigious steroidogenic tissue.

The adrenal cortex begins a process of involution commencing immediately after birth. The weight of the adrenal glands decreases strikingly during the first few weeks of life, and the size attained by the fetal glands just before birth is not achieved again until late in adolescence or early adult life.

CONTRIBUTION TO PLACENTAL ESTROGEN FORMATION. As discussed earlier, women pregnant with an anencephalic fetus excrete little urinary estrogen. This together with the finding of high levels of dehydroepiandrosterone sulfate in cord blood of normal newborns, were suggestive that fetal adrenal cortices are the principal source of placental estrogen precursors. The finding that dehydroepiandrosterone sulfate in maternal plasma is converted to estrogen in placenta established this concept. Confirmation was provided by [Bolte and co-workers \(1964a, 1964b\)](#), who demonstrated that radiolabeled dehydroepiandrosterone sulfate perfused through the placenta was converted to estradiol-17 β .

Near term, about half of estradiol-17 β produced in placenta arises from maternal and half from fetal plasma dehydroepiandrosterone sulfate ([Siiteri and MacDonald, 1966b](#)). These findings alone, however, did not provide an explanation for the inordinately large amount of estriol in blood and urine of pregnant women.

PLACENTAL ESTRIOL SYNTHESIS. In nonpregnant women, the estrogen secreted by the granulosa cells of the "chosen" follicle is estradiol-17 β ; the estrogen formed from plasma androstenedione in extraglandular tissues is estrone. These two primary estrogens give rise to all metabolites of estrogen, including estriol. In nonpregnant women, the ratio of the concentration of urinary estriol to that of estrone plus estradiol-17 β is approximately one. This ratio increases to 10 or more near term; thus there is a striking and disproportionate increase in estriol formation during pregnancy. This could not be accounted for by a pregnancy-associated change in metabolism of estrone or estradiol-17 β to favor estriol ([Brown, 1956](#)). Moreover, neither estrone nor estradiol-17 β is converted to estriol in the placenta.

[Ryan \(1959b\)](#) and [MacDonald and Siiteri \(1965b\)](#) found that the 16 α -hydroxylated C₁₉-steroids—16 α -hydroxydehydroepiandrosterone, 16 α -hydroxy-androstenedione, and 16 α -hydroxytestosterone—also were converted to estriol by placental tissue. In addition, large amounts of 16 α -hydroxydehydroepiandrosterone sulfate were found in umbilical cord blood ([Colas and co-workers, 1964](#)). Thus, the disproportionate increase in estriol formation during pregnancy is accounted for by placental synthesis of estriol principally from plasma-borne 16 α -hydroxydehydroepiandrosterone sulfate. This compound is synthesized by the fetal adrenal and by 16 α -hydroxylation of plasma dehydroepiandrosterone sulfate in the fetal liver ([Fig. 6-3](#)). Near term, the fetus is the source of 90 percent of the placental estriol precursor in normal human pregnancy. Maternal plasma dehydroepiandrosterone sulfate is converted in maternal liver to 16 α -hydroxydehydroepiandrosterone sulfate, which is then converted to estriol by the placenta ([Madden and colleagues, 1976, 1978](#)).

FETAL ADRENAL DEVELOPMENT. Early in embryonic life, the adrenal cortex is composed of cells that resemble those that, later in fetal development, comprise the fetal zone. These cells proliferate rapidly prior to the time that vascularization of the pituitary gland by the hypothalamus is complete. This is suggestive that early development of the fetal adrenal glands is under trophic influences that do not conform to those of the adult ([Mulchahey and colleagues, 1987](#)). ACTH³⁶ does not cross the placenta; therefore, it is likely that during the first weeks of pregnancy, ACTH is secreted by the fetal pituitary gland in the absence of hypothalamic corticotropin-releasing hormone ([CRH](#)³⁷) stimulation, or else ACTH (or CRH) arises from a source other than the fetal pituitary gland, such as chorionic ACTH (or CRH), which is synthesized in syncytiotrophoblasts from early in gestation (p. 115).

FETAL ADRENAL GROWTH. The cortex continues to grow throughout gestation; and during the last 5 to 6 weeks of pregnancy, there is a very rapid increase in adrenal size. Relative to body weight, the fetal adrenal glands at term are 25 times larger than those of adults. Because of the enormous size and their very great capacity for steroid synthesis, many investigators have surmised that in addition to ACTH³⁸, there must be other growth stimuli for these glands. Indeed, there is a continual decrease in the concentration of immunoreactive ACTH in human fetal plasma as pregnancy progresses, and the fetal adrenal glands are growing at a rapid rate ([Winters and associates, 1974](#)). Generally, ACTH acts to promote hypertrophy, but not hyperplasia, of adrenal cells.

It now seems most likely that the rate of growth of the fetal adrenal glands is determined by growth factors that may not affect the rate of steroidogenesis directly. There is sufficient ACTH³⁹ in the fetal circulation at all stages of gestation to ensure adequate activity of the cholesterol side-chain cleavage enzyme, the rate-limiting step in adrenal steroidogenesis. The stimulation of fetal adrenal growth (cell replication) leading to an increased mass of functional cells would result in an increase in the capacity of the gland for steroid formation even if the putative growth factor did not act directly to increase steroidogenesis. This would account for the continued growth of the fetal adrenal glands throughout gestation, but rapid involution immediately after birth.

ENZYMATIC CONSIDERATIONS. There is a severe deficiency in the expression of the microsomal enzyme 3 β -hydroxysteroid dehydrogenase, ?⁵⁻⁴-isomerase (3 β HSD) in the fetal zone cells ([Doody and associates, 1990](#)). This limits the conversion of pregnenolone to progesterone and of 17 α -hydroxypregnenolone to 17 α -hydroxyprogesterone, an obligatory step in cortisol biosynthesis. There is, however, very active steroid sulfotransferase activity in the fetal adrenal glands. As a consequence, the principal secretory products of the fetal adrenal glands are pregnenolone sulfate and dehydroepiandrosterone sulfate. Comparatively, cortisol, which likely arises primarily in the neocortex of the fetal adrenal glands and not in the fetal zone, is a minor secretory product of the fetal adrenal.

FETAL ADRENAL STEROID PRECURSOR. The precursor for fetal adrenal steroidogenesis is cholesterol. The rate of steroid biosynthesis in the fetal adrenal is so great that its steroidogenesis alone is equivalent to a fourth of the total daily [LDL](#)⁴⁰ cholesterol turnover in adults.

The fetal adrenal glands can synthesize cholesterol from two-carbon fragments, that is, acetate. The rate of de novo cholesterol synthesis by fetal adrenal tissue, however, is insufficient to account for more than a small part of the steroids produced by these glands. Therefore, cholesterol must be assimilated from the fetal circulation. Plasma cholesterol and its esters are present in the form of lipoproteins designated according to density as determined by ultracentrifugation: very-low-density lipoprotein (VLDL), low-density lipoprotein ([LDL](#)⁴¹), and high-density lipoprotein (HDL).

[Simpson, Carr, and their co-workers \(1979\)](#) ascertained that human fetal adrenal glands take up lipoproteins as a source of cholesterol for steroidogenesis. [HDL](#)⁴² was much less effective than [LDL](#)⁴³, and [VLDL](#)⁴⁴ was devoid of stimulatory activity. They also evaluated the relative contribution of cholesterol synthesized de novo and that of cholesterol derived from LDL uptake. They confirmed that the fetal adrenal glands are highly dependent upon circulating LDL as a source of cholesterol for optimum steroidogenesis ([Carr and colleagues, 1980, 1982; Carr and Simpson, 1981b](#)). A model of cholesterol metabolism in the fetal adrenal glands as described by Carr and Simpson is shown in [Figure 6-4](#).

REGULATION OF FETAL CHOLESTEROL LEVELS. The majority of fetal plasma cholesterol arises by de novo synthesis in the fetal liver ([Carr and Simpson, 1984](#)). The low level of [LDL](#)⁴⁵ cholesterol in fetal plasma is not the consequence of impaired fetal LDL synthesis, but instead, it is the result of the rapid use of LDL by the fetal adrenal glands for steroidogenesis. Early in human pregnancy, fetal plasma levels of LDL cholesterol are similar to those of the adult. As pregnancy progresses, however, levels of LDL cholesterol in fetal plasma decline as the fetal adrenal glands grow. In the normal term newborn, the concentration of LDL cholesterol is only about 30 mg/dL ([Parker and associates, 1980, 1983](#)). In the anencephalic newborn in whom the adrenal glands are atrophic, the levels of LDL cholesterol in umbilical cord plasma are high.

ESTROGEN PRODUCTION IN PREGNANCY: CLINICAL CONSIDERATIONS. A schematic representation of the pathways of estrogen formation in the placenta is presented in [Figure 6-3](#).

FETAL CONDITIONS THAT AFFECT ESTROGEN PRODUCTION. A number of conditions affecting the fetus may alter the rate of steroid synthesis in placenta.

FETAL DEATH. It has been known for many decades that death of the human fetus is followed by a striking reduction in the levels of urinary estrogens. Moreover, it was demonstrated that after ligation of the umbilical cord with the fetus and placenta left in situ, there was an abrupt and striking decrease in the production of placental estrogens ([Cassmer, 1959](#)). The findings of this classical study were subject to at least two interpretations. The first was that maintenance of the fetal placental circulation is essential to the functional integrity of the placenta. This explanation was unlikely to be correct, however, because in Cassmer's study, the placental production of progesterone was maintained after occlusion of the umbilical cord. A second explanation for the marked decrease in urinary estrogens was that after umbilical cord ligation, an important source of precursors of placental estrogen (but not progesterone) biosynthesis was eliminated—that is, the fetus.

FETAL ANENCEPHALY. In the absence of the fetal zone of the adrenal cortex, as in anencephaly, the rate of formation of placental estrogens (especially estriol) is severely limited because of limited availability of C₁₉-steroid precursors. Verification of the diminished levels of precursors in anencephalic fetuses was provided by the finding of low levels of dehydroepiandrosterone sulfate in cord blood of such newborns ([Nichols and co-workers, 1958](#)). Therefore, almost all of the estrogens produced in women pregnant with an anencephalic fetus arise by the placental use of maternal plasma dehydroepiandrosterone sulfate. Furthermore, in such pregnancies the production of estrogens can be increased by the administration (to the mother) of [ACTH](#)⁴⁶, which stimulates the rate of dehydroepiandrosterone sulfate secretion by the maternal adrenal (ACTH does not cross the placenta). Finally, placental production of estrogens is decreased in women pregnant with an anencephalic fetus during the administration of a potent glucocorticosteroid, which suppresses ACTH secretion and thus decreases the rate of secretion of dehydroepiandrosterone sulfate from the maternal adrenal cortex ([MacDonald and Siiteri, 1965a, 1965b](#)). Estriol formation is disproportionately decreased in pregnancies with an anencephalic fetus because the fetal adrenal at term normally provides 90 percent of placental estriol precursor.

FETAL ADRENAL HYPOPLASIA. A rare disorder of human pregnancy involves adrenal hypoplasia in an otherwise normal fetus. Estrogen formation in pregnancies with such a fetus also is very limited because of the absence of fetal adrenal C₁₉-precursors for placental estrogen formation.

PLACENTAL SULFATASE DEFICIENCY. Estrogen formation in placenta is generally regulated by the availability of C₁₉-steroid prohormones in fetal and maternal plasma. Specifically, there is no rate-limiting enzymatic reaction in the placental pathway from C₁₉-steroids to estrogen biosynthesis. Moreover, aside from minor alterations in placental aromatase induced by xenobiotics, the excess of placental enzymatic machinery for estrogen formation is large. An exception to this generalization was found by [France and Liggins \(1969\)](#), who were the first to establish that placental sulfatase deficiency is a cause of very low estrogen levels in otherwise normal (except possibly for dysfunctional labor) pregnancies. Sulfatase deficiency precludes the hydrolysis of C₁₉-steroid sulfates, the first enzymatic step in the placental use of these circulating prohormones for estrogen biosynthesis. This is an X-linked disorder (all affected fetuses are male) associated with the development of ichthyosis in the affected males later in life ([Bradshaw and Carr, 1986](#)).

PLACENTAL AROMATASE DEFICIENCY. There are a few well-documented examples of (placental) aromatase deficiency ([Shozu and colleagues, 1991](#)). Fetal adrenal dehydroepiandrosterone sulfate, which is produced in large quantities, is converted in placenta to androstenedione, but because of the aromatase deficiency, androstenedione could not be converted to estradiol-17 β . Rather, metabolites of dehydroepiandrosterone produced in placenta, including androstenedione and testosterone, are secreted into the maternal and fetal circulations, causing virilization of the mother and the female fetus ([Harada and colleagues, 1992](#)).

Pregnancies with aromatase deficiency and a male fetus are uneventful. In these estrogen-deficient males, however, epiphyseal closure does not occur properly during puberty, and in consequence, the affected men continue to grow during adulthood, becoming very tall and with deficient mineralization of bone ([Morishima and associates, 1995](#)).

DOWN SYNDROME. In the conduct of second-trimester pregnancy screening of maternal blood for levels of hCG and alpha-fetoprotein, it was discovered that serum unconjugated estriol levels were low in pregnancies with a Down syndrome fetus ([Chap. 37, p. 984](#)). The reason for diminished levels of estrogen are not established, but the best possibility would be inadequate formation of C₁₉-steroids in the adrenal glands of these trisomic fetuses. ([Newby and colleagues, 2000](#)).

DEFICIENCY IN FETAL [LDL](#)⁴⁷ CHOLESTEROL BIOSYNTHESIS. A successful pregnancy in a woman with beta-lipoprotein deficiency has been described ([Parker and colleagues, 1986](#)). The absence of [LDL](#)⁴⁸ in the maternal plasma led to little or no progesterone formation in the corpus luteum and restricted the amount of placental progesterone formation. In addition, the levels of estriol were also lower than normal. Presumably, the diminished estrogen production was the result of decreased LDL formation in the fetus, who was heterozygous for the LDL deficiency. Decreased fetal LDL formation will limit fetal adrenal production of dehydroepiandrosterone sulfate and thereby reduce the availability of precursor for placental estrogen synthesis. The fetal adrenal glands are dependent upon plasma LDL as well as the de novo synthesis of cholesterol as precursor for steroidogenesis ([Carr and Simpson, 1981a; Mason and Rainey, 1987](#)).

FETAL ERYTHROBLASTOSIS. In some cases of severe fetal D-antigen isoimmunization, the levels of estrogens in maternal plasma are elevated above normal for gestational age. This is likely due to an increased placental weight (hypertrophy) which occurs in such pregnancies.

DECREASED FETAL ADRENAL USE OF [LDL](#)⁴⁹. The most common cause of decreased placental estrogen formation (aside from fetal death) is an acquired reduction in fetal adrenal use of plasma [LDL](#)⁵⁰. This leads to a reduction in the rate of formation of dehydroepiandrosterone sulfate and thereby a reduction in placental estrogen precursor availability. This sequence of events is observed most commonly in pregnancies complicated by hypertension or more severe forms of diabetes ([Parker and associates, 1984, 1987](#)). As noted before, the final consequence may be as follows: Placental estrogen formation is decreased and estrogen levels in maternal blood and urine are decreased. The levels of dehydro-epiandrosterone sulfate in umbilical venous blood are decreased, but the levels of LDL are increased. At the same time, because of a redistribution of placental estrogens, the levels of estriol in umbilical venous blood may be increased.

MATERNAL CONDITIONS THAT AFFECT PLACENTAL ESTROGEN FORMATION

GLUCOCORTICOSTEROID TREATMENT. The administration of glucocorticosteroids, in moderate to high doses, to pregnant women causes a striking reduction in placental estrogen formation. Glucocorticosteroids act to inhibit [ACTH](#)⁵¹ secretion by the maternal and fetal pituitary glands, resulting in decreased maternal and fetal adrenal secretion of placental estrogen precursor, dehydroepiandrosterone sulfate.

MATERNAL ADRENAL DYSFUNCTION. In pregnant women with Addison disease, maternal urinary estrogen levels are reduced ([Baulieu and co-workers, 1956](#)). The decrease principally affects estrone and estradiol-17 β , because the fetal adrenal contribution to the synthesis of estriol, particularly in the latter part of pregnancy, is quantitatively much more important.

MATERNAL OVARIAN ANDROGEN-PRODUCING TUMORS. The extraordinary efficiency of the placenta in the aromatization of C₁₉-steroids may be exemplified by two considerations. First, [Edman and associates \(1981\)](#) found that the placental clearance of maternal plasma androstenedione to estradiol was very similar to estimated placental blood flow. Thus, virtually all of the androstenedione entering the intervillous space is taken up by syncytium and converted to estradiol-17 β and none of this C₁₉-steroid escapes into the fetus. Second, it is relatively rare that a female fetus is virilized in a pregnant woman who is known to have an androgen-secreting ovarian tumor. This finding also indicates that the placenta efficiently converts aromatizable C₁₉-steroids—including bioactive testosterone—to estrogens, thereby precluding transplacental passage. Indeed, it may be that virilized female fetuses of women with an androgen-producing tumor are cases in which a non-aromatizable C₁₉-steroid androgen is produced by the tumor (e.g., 5 α -dihydrotestosterone), or else testosterone is produced very early in pregnancy in amounts that exceed the capacity of placental aromatase.

MATERNAL RENAL DISEASE. Lower levels of estriol in urine of pregnant women with pyelonephritis may be observed. Presumably this is the consequence of diminished renal clearance, as the levels of estrogen in serum are normal in such pregnancies.

MATERNAL HYPERTENSIVE DISORDERS AND DIABETES. With disorders of the mother associated with decreased uteroplacental blood flow, fetal adrenal formation of dehydroepiandrosterone is impaired (p. 118). Therefore, the primary reason for diminished estrogen formation with these maternal disorders is not a decrease in placental function.

GESTATIONAL TROPHOBLASTIC DISEASE. In the case of complete hydatidiform mole or choriocarcinoma, there is no fetal adrenal source of C₁₉-steroid precursor for trophoblast estrogen biosynthesis. Consequently, estrogen formation in placenta is limited to the use of C₁₉-steroids in the maternal plasma, and therefore the estrogen produced is principally estradiol-17 β ([MacDonald and Siiteri, 1964, 1966](#)). Great variation is observed in the rates of both estradiol-17 β and progesterone formation in molar pregnancies; however, that is not necessarily related to the volume of neoplastic trophoblastic tissue. There is variable disruption of large masses of molar tissue from the uterine wall by blood clots. Consequently, variable amounts of trophoblastic tissue are separated from the maternal blood supply of precursors for estradiol-17 β and progesterone formation ([MacDonald and Siiteri, 1964, 1966](#)).

PROGESTERONE

After the first few (6 to 7) weeks of human gestation, very little progesterone is produced in the ovary ([Diczfalusy and Troen, 1961](#)). Surgical removal of the corpus luteum or even bilateral oophorectomy conducted during the 7th to 10th weeks of pregnancy does not cause a decrease in the rate of excretion of urinary pregnanediol, the principal urinary metabolite of progesterone. There is a gradual increase in the levels of plasma progesterone as well as those of estradiol and estriol in normal human pregnancy, as shown in [Figure 6-5](#).

PROGESTERONE PRODUCTION RATES. Isotope dilution techniques for the measurement of the rates of endogenous hormone production in humans were first applied to the study of progesterone in pregnancy. The results of these studies, conducted by [Pearlman in 1957](#), gave daily production of progesterone in late normal, singleton pregnancies of about 250 mg. The findings of studies in which other methods have been employed since then are in agreement with this value. In some pregnancies with multiple fetuses, however, the daily progesterone production rate may exceed 600 mg per day.

SOURCE OF CHOLESTEROL FOR PLACENTAL PROGESTERONE BIOSYNTHESIS. Progesterone is synthesized from cholesterol in a two-step enzymatic reaction. First, cholesterol is converted, in mitochondria, to the steroid intermediate, pregnenolone, in a reaction catalyzed by cytochrome P₄₅₀ cholesterol side-chain cleavage enzyme. Pregnenolone is converted to progesterone, in microsomes, by 3 β -hydroxysteroid dehydrogenase, ?⁵⁻⁴-isomerase.

The human placenta produces a prodigious amount of progesterone; nonetheless, there is a limited capacity for the biosynthesis of cholesterol in trophoblast. The rate of incorporation of radiolabeled acetate into cholesterol by placental tissue proceeds very slowly, and the activity of the rate-limiting enzyme in cholesterol biosynthesis, 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase, in placental tissue microsomes is small.

Thus, the placenta must rely on exogenous cholesterol for progesterone formation. [Bloch \(1945\)](#) and [Werbin and co-workers \(1957\)](#) found that after the intravenous administration of radiolabeled cholesterol to pregnant women, the specific activity of urinary pregnanediol was similar to that of plasma cholesterol. [Hellig and associates \(1970\)](#) also found that maternal plasma cholesterol was the principal precursor (up to 90 percent) of progesterone biosynthesis in human pregnancy. These findings are consistent with the conclusion that the de novo synthesis of cholesterol in trophoblast is minimal. Placental HMG CoA reductase in trophoblast is inhibited by the high levels of LDL⁵² in blood, causing inhibition of its synthesis. With LDL deficiency, de novo cholesterol synthesis in trophoblast is appreciable, albeit much less than sufficient to meet the needs of placenta for both membrane synthesis and normal progesterone synthesis.

PLACENTAL USE OF MATERNAL PLASMA LDL CHOLESTEROL. In studies similar to those described by use of fetal adrenal tissue, [Simpson and associates \(1979, 1980\)](#) demonstrated that the trophoblast preferentially uses LDL⁵³ cholesterol for progesterone biosynthesis. Thus, the formation of placental progesterone occurs through the uptake and use of a circulating precursor. But unlike estrogens, which are formed principally from fetal adrenal precursors, placental progesterone biosynthesis proceeds by using a maternal precursor, LDL cholesterol. This subject was reviewed by [Casey and colleagues \(1992\)](#).

These findings provide insights into not only the biochemical mechanism for placental progesterone formation but perhaps also into other aspects of maternal-placental-fetal physiology. The rate of progesterone biosynthesis is largely dependent on the number of LDL⁵⁴ receptors on the plasma membrane of the trophoblasts, and thereby primarily independent of uteroplacental blood flow.

[Simpson and Burkhart \(1980\)](#) also found that progesterone, in concentrations similar to those found in human placental tissue, inhibits the activity of the enzyme that catalyzes cholesterol esterification. This physiological event may serve to ensure a supply of cholesterol for progesterone biosynthesis by preventing the sequestration of cholesterol into a nonusable storage form, cholesterol esters, and may protect the liberated essential fatty acids from reesterification with cholesterol.

TROPHOBLAST LDL⁵⁵ RECEPTORS. The LDL⁵⁶ receptors are localized in coated pits on the microvillous membranes of syncytium and are demonstrable as early as 4 weeks after conception. The affinity of these receptors for LDL remains constant throughout human pregnancy and similar to that in other tissues. The trophoblast is unique in that two mRNA species for the LDL receptor are found in human trophoblast, the usual 5.3-kb mRNA and an additional 3.7-kb mRNA. [Furuhashi and colleagues \(1989\)](#) proposed that the differential use of splicing sites may give rise to the smaller LDL receptor mRNA. The expression of LDL receptor gene in trophoblast is highest in the first trimester; this high level of expression may be important in trophoblast growth but this time of pregnancy as well as in provision of progesterone precursor. There is a decrease in the 5.3-kb mRNA for the LDL receptor as pregnancy progresses.

PROGESTERONE SYNTHESIS AND FETAL WELL-BEING. The relationships that exist between fetal well-being and the placental production of estrogen cannot be demonstrated in the case of progesterone. Fetal death, ligation of the umbilical cord with the fetus and placenta remaining in situ, and anencephaly are all conditions associated with very low maternal plasma levels and urinary excretion of estrogens. In these circumstances, however, there is no concomitant decrease in the plasma levels of progesterone to anywhere near the same extent as those of estrogen until some indeterminate time after fetal death. Thus, placental endocrine function, including the formation of protein hormones such as hCG, and progesterone biosynthesis, may persist for long periods (weeks) after fetal death.

PROGESTERONE METABOLISM DURING PREGNANCY. The metabolic clearance rate of progesterone in pregnant women is similar to that found in men and nonpregnant women. This is an important consideration in evaluating the role of progesterone in the initiation of parturition ([Chap. 11, p. 263](#)).

During pregnancy, there is a disproportionate increase in the plasma concentration of 5 α -dihydroprogesterone. Thus the ratio of the concentration of this progesterone metabolite to the concentration of progesterone is increased in pregnant women ([Milewich and co-workers, 1975](#)). The mechanisms for this are not defined completely, but may be relevant to the resistance to pressor agents that normally develop in pregnant women ([Everett and associates, 1978](#); see also [Chap. 8, p. 184](#)). Progesterone also is converted to the potent mineralocorticosteroid deoxycorticosterone in pregnant women and in the fetus. The concentration of deoxycorticosterone is increased strikingly in both the maternal and fetal compartments. The extra-adrenal formation of deoxycorticosterone from circulating progesterone accounts for the vast majority of its production in human pregnancy ([Casey and MacDonald, 1982a, 1982b](#)).

DIRECTIONAL SECRETION OF STEROIDS FROM SYNCYTIOTROPHOBLAST. Estrogens synthesized in syncytium preferentially enter the maternal circulation. [Gurpide and co-workers \(1966\)](#) reported that more than 90 percent of estradiol-17 β and estriol formed in syncytiotrophoblast enters maternal plasma. The same is true of progesterone formed in the syncytium. [Gurpide and co-workers \(1972\)](#) also found that 85 percent or more of placental progesterone enters maternal plasma, and very little maternal plasma progesterone crosses the placenta to the fetus.

The placental estrogens that enter the maternal compartment are estradiol-17 β and estriol. Somewhat surprisingly, estrone as well as estradiol-17 β enter the fetus, and there is preferential entry of estrone rather than estradiol-17 β into the fetal plasma ([Gurpide and co-workers, 1982](#); [Walsh and McCarthy, 1981](#)). They emphasized that this might be attributed to extratrophoblastic conversion of estradiol-17 β to estrone in fetal tissues or erythrocytes.

Estriol synthesized in trophoblasts enters both fetal and maternal plasma, but most (90 percent) enters the mother.

TRANSFER OF STEROIDS FROM SYNCYTIOTROPHOBLASTS INTO MATERNAL AND FETAL BLOOD. The placental arm of the fetal-maternal communication system of human pregnancy is established by way of hemo-chorioendothelial placentation. Therefore, steroids secreted from the syncytiotrophoblast enter maternal blood directly. There is no evidence of specific estrogen binding within the trophoblast; therefore, net transfer between trophoblast and intervillous space favors entry into maternal blood, which rapidly enters the general maternal circulation.

Steroids that leave the syncytium toward the fetal compartment, however, do not enter fetal blood directly. First, steroids traveling toward the fetus must traverse the cytotrophoblasts and then enter the intervillous space. Steroids in this space can reenter the syncytium. Second, steroids that escape the intervillous space toward the fetus must then traverse the wall of the fetal capillaries to reach fetal blood. Steroids in the fetal capillaries of the intervillous space then can reenter the intervillous space and then the syncytium.

The net result of this hemochorioendothelial arrangement is that there is substantially greater entry of steroids formed in syncytium into the maternal circulation compared with the amount that enters the fetal blood.

An interesting phenomenon exists in the distribution of steroids formed in syncytium to the maternal and fetal compartments in pregnancies in which there is decreased uteroplacental blood flow. In newborns of women with pregnancy-induced hypertension, chronic hypertension, and severe diabetes, the umbilical cord plasma levels of estrogens and progesterone are significantly greater than in newborns of normal women. Initially, this was a surprise, because with decreased uteroplacental blood flow, estrogen production in placenta is decreased, as are the levels of estrogen in the maternal compartment. These seemingly discordant findings can be interpreted as follows: As uteroplacental blood flow is reduced, there is relative stasis of maternal blood in the intervillous space. This results in a redistribution of steroids formed in syncytium in favor of the fetal compartment. In particular, there is a decrease in the net exit of steroids into the maternal circulation, probably because of stasis of intervillous blood and thereby greater reentry of steroids from the intervillous space back into the syncytium. This favors a relative increase in the transfer of steroids from the syncytiotrophoblast into the fetal compartment. There is therefore an increase in the concentration of steroids formed in trophoblast in the umbilical vein. This occurs even in the face of a decrease in total placental estrogen formation and, in consequence, a decrease in estrogen levels in the maternal compartment. This is an important concept that may be pertinent in evaluations of the role(s) of steroids produced in the placenta in fetal development, as with lung maturation, which may be accelerated in fetuses of pregnancies in which uteroplacental blood flow is believed to be reduced ([Parker and associates, 1987](#); see also [Chap. 7](#)).

TABLE 6-1. Steroid Production Rates in Nonpregnant and Near-Term Pregnant Women

Steroid ^a	Production Rates (mg/24 hr)	
	Nonpregnant	Pregnant
Estradiol-17 β	0.1-0.6	15-20
Estriol	0.02-0.1	50-150
Progesterone	0.1-40	250-600
Aldosterone	0.05-0.1	0.250-0.600
Deoxycorticosterone	0.05-0.5	1-12
Cortisol	10-30	10-20

^a Estrogens and progesterone are produced by placenta. Aldosterone is produced by the maternal adrenal glands in response to the stimulus of angiotensin II. Deoxycorticosterone is produced in extraglandular tissue sites by way of the 21-hydroxylation of plasma progesterone. Cortisol production during pregnancy is not increased, even though the blood levels are elevated because of decreased clearance caused by increased cortisol-binding globulin.

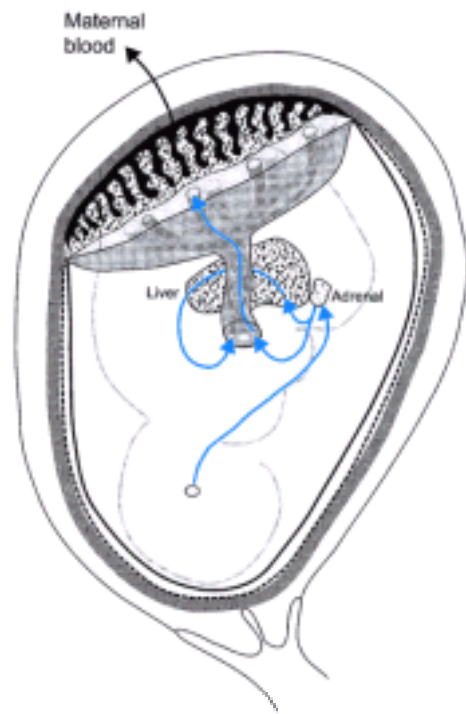

FIGURE 6-1. Anatomical parts of the endocrine component of the placental arm of the fetal-maternal communication system. Adrenocorticotropin hormone (ACTH) from the fetal pituitary gland stimulates fetal adrenal steroidogenesis. Fetal adrenal dehydroepiandrosterone sulfate and 16 α -OH-dehydroepiandrosterone sulfate are transported to the placenta and converted to estradiol-17 β and estriol, respectively ([Fig. 6-3](#)). Fetal liver is the major site of production of low-density lipoprotein (LDL) cholesterol, the principal precursor for fetal adrenal steroidogenesis. Cholesterol, derived from LDL in maternal plasma, serves as the precursor for progesterone biosynthesis in placenta.

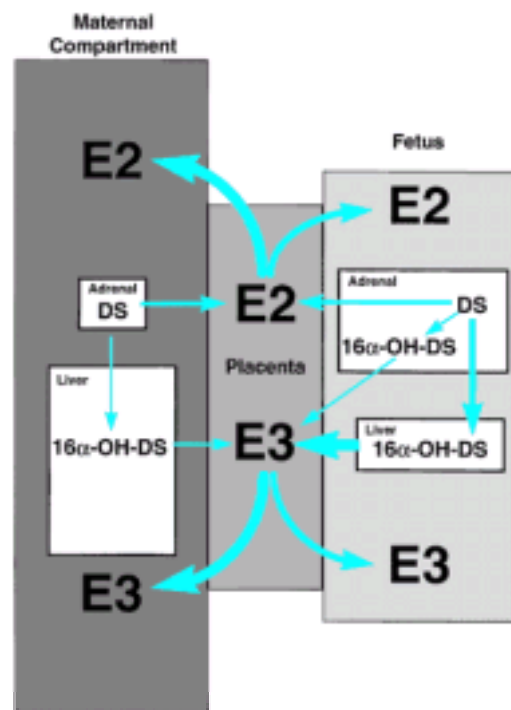

FIGURE 6-3. Schematic presentation of the biosynthesis of estrogen in the human placenta. Dehydroepiandrosterone sulfate (DS), secreted in prodigious amounts by the fetal adrenal glands, is converted to 16 α -hydroxydehydroepiandrosterone sulfate (16 α -OH-DS) in fetal adrenal glands and liver. These steroids, DS and 16 α -OH-DS, are converted in the placenta to estrogens, namely, estradiol-17 β (E2) and estriol (E3). Near term, half of E2 is derived from fetal adrenal DS and half from maternal DS. On the other hand, 90 percent of E3 in the placenta arises from fetal 16 α -OH-DS and only 10 percent from all other sources. Most (80 to 90 percent) of steroids produced in the placenta are secreted into the maternal blood.

7. Fetal Growth and Development

The high purposes of obstetrics are to maintain the health of the pregnant woman and to ensure the optimal well-being of the newborn. To this end, contemporary obstetrical research focuses on the physiology and pathophysiology of the fetus, its development, and its environment.

An important direct result of this research is that the status of the fetus has been elevated to that of a patient who, in large measure, can be given the same meticulous care that obstetricians provide for pregnant women. In the course of these studies it has become apparent that the conceptus is the dynamic force in the pregnancy unit. In general, the maternal organism responds passively to signals emanating from embryonic-fetal and extraembryonic tissues. The contributions of the conceptus to implantation, maternal recognition of pregnancy, immunological acceptance, endocrine function, nutrition, and parturition are enormous, and absolutely essential for successful pregnancy (see [Fig. 2-3](#)).

Normal fetal development is considered in this chapter. In [Chapters 36, 37, 40, and 41](#), techniques used to evaluate fetal well-being, or fetal health, are presented in some detail. Anomalies, injuries, and diseases that affect the fetus and newborn are addressed in detail in [Chapter 39](#).

DETERMINATION OF GESTATIONAL AGE

Several different terms are used to define the duration of pregnancy, and thus fetal age, but these are somewhat confusing. Gestational age or menstrual age is the time elapsed since the first day of the last menstrual period, a time that actually precedes conception. This starting time, which is usually about 2 weeks before ovulation and fertilization and nearly 3 weeks before implantation of the blastocyst, has traditionally been used because most women know when their last period was but not when they last ovulated, although the increasing use of infertility therapy has changed this somewhat. Embryologists, however, describe embryo-fetal development in days or weeks from the time of ovulation (ovulation age) or conception (postconceptional age), the latter two being nearly identical.

Obstetricians customarily calculate gestational age as menstrual age of a given pregnancy. About 280 days, or 40 weeks, elapse on average between the first day of the last menstrual period and the birth of the fetus; 280 days correspond to 9 1/3 calendar months, or 10 units of 28 days each. The unit of 28 days has been referred to, commonly but imprecisely, as a lunar month of pregnancy; actually, the time from one new moon to the next is 29 1/2 days. A quick estimate of the due date of a pregnancy based on menstrual cycle can be made as follows: add 7 days to the first day of the last menstrual period and subtract 3 months. For example, if the first day of the last menses was June 8, the due date of this pregnancy is 06 08 + 7 (days) minus 3 (months) = 03 15, or March 15 of the following year. As noted in [Chapter 41 \(p. 116\)](#), however, many women now undergo first or early second trimester ultrasound examination to confirm gestational age, and the sonographic estimate is usually a few days later than that determined by the last period. To rectify this inconsistency—and to reduce the number of pregnancies diagnosed as postterm—some authorities suggest assuming that the average pregnancy is actually 283 days long instead of 280, and thus adding 10 days to the last menses instead of 7 ([Olsen and Clausen, 1998](#)).

The period of gestation can also be divided into three units of three calendar months each, or three trimesters, because important obstetrical milestones can be designated conveniently by trimesters. The possibility of spontaneous abortion, for example, is limited principally to the first trimester, whereas the likelihood of survival of the infant born preterm is increased greatly in pregnancies that reach the third trimester.

MORPHOLOGICAL GROWTH

OVUM, ZYGOTE, AND BLASTOCYST

During the first 2 weeks after ovulation, several successive phases of development can be identified:

1. Ovulation.
2. Fertilization of the ovum.
3. Formation of free blastocyst.
4. Implantation of the blastocyst ([Fig. 7-1](#)).

Primitive chorionic villi are formed soon after implantation. With the development of chorionic villi, it is conventional to refer to the products of conception not as a fertilized ovum, or zygote, but as an embryo. The early stages of preplacental development, and formation of the placenta, are described in [Chapter 5](#).

EMBRYO

The embryonic period commences at the beginning of the third week after ovulation/fertilization, which coincides in time with the expected day that the next menstruation would have started. Most pregnancy tests that measure human chorionic gonadotropin (hCG) use are positive by this time ([Chap. 2](#), p. 26), and the embryonic disc is well defined. The body stalk is differentiated; the chorionic sac is approximately 1 cm in diameter ([Figs. 7-2 and 7-3](#)). There is a true intervillous space that contains maternal blood and villous cores in which angioblastic chorionic mesoderm can be distinguished.

By the end of the fourth week after ovulation, the chorionic sac is 2 to 3 cm in diameter, and the embryo is about 4 to 5 mm in length ([Fig. 7-4](#)). Partitioning of the primitive heart begins in the middle of the fourth week. Arm and leg buds are present, and the amnion is beginning to unsheathe the body stalk, which thereafter becomes the umbilical cord.

At the end of the sixth week after fertilization, the embryo is 22 to 24 mm in length, and the head is quite large compared with the trunk. The heart is completely formed. Fingers and toes are present, and the arms bend at the elbows. The upper lip is complete and the external ears form definitive elevations on either side of the head.

FETUS

The end of the embryonic period and the beginning of the fetal period is arbitrarily designated by most embryologists to occur 8 weeks after fertilization, or 10 weeks after the onset of the last menstrual period. At this time, the embryo-fetus is nearly 4 cm long. The major portion of lung development is yet to occur, but few other new major body structures are formed after this time. Development during the fetal period of gestation consists of growth and maturation of structures that were formed during the embryonic period.

12 GESTATIONAL WEEKS. By the end of the 12th week of pregnancy, when the uterus usually is just palpable above the symphysis pubis, the crown-rump length of the fetus is 6 to 7 cm ([Fig. 7-5](#)). Centers of ossification have appeared in most of the fetal bones, and the fingers and toes have become differentiated. Skin and nails have developed and scattered rudiments of hair appear; the external genitalia are beginning to show definitive signs of male or female gender. The fetus begins to make spontaneous movements.

16 GESTATIONAL WEEKS. By the end of the 16th week, the crown-rump length of the fetus is 12 cm, and the weight is 110 g. Gender can be correctly determined by experienced observers by inspection of the external genitalia by 14 (menstrual) weeks.

20 GESTATIONAL WEEKS. The end of the 20th week is the midpoint of pregnancy as estimated from the beginning of the last normal menstrual period. The fetus now weighs somewhat more than 300 g, and the weight begins to increase in a linear manner. The fetal skin has become less transparent, a downy lanugo covers its entire body, and some scalp hair has developed.

24 GESTATIONAL WEEKS. By the end of the 24th week, the fetus weighs about 630 g. The skin is characteristically wrinkled, and fat deposition begins. The head is still comparatively quite large; eyebrows and eyelashes are usually recognizable. The canalicular period of lung development, during which the bronchi and bronchioles enlarge and alveolar ducts develop, is nearly completed. A fetus born at this period will attempt to breathe, but most will die because the terminal sacs, required for gas exchange, have not yet formed.

28 GESTATIONAL WEEKS. By the end of the 28th week, a crown-rump length of about 25 cm is attained and the fetus weighs about 1100 g. The thin skin is red and covered with vernix caseosa. The pupillary membrane has just disappeared from the eyes. An infant born at this time moves the limbs quite energetically and cries weakly. The otherwise normal infant of this age has a 90 percent chance of intact survival.

32 GESTATIONAL WEEKS. At the end of 32 gestational weeks, the fetus has attained a crown-rump length of about 28 cm and a weight of about 1800 g. The surface of the skin is still red and wrinkled. Barring other complications, infants born at this period usually survive intact.

36 GESTATIONAL WEEKS. At the end of 36 weeks gestation, the average crown-rump length of the fetus is about 32 cm and the weight is about 2500 g. Because of the deposition of subcutaneous fat, the body has become more rotund, and the previous wrinkled appearance of the face has been lost. Infants born at this time have an excellent chance of survival with proper care.

40 GESTATIONAL WEEKS. Term is reached at 40 weeks from the onset of the last menstrual period. At this time, the fetus is fully developed, with the characteristic features of the newborn infant to be described here. The average crown-rump length of the fetus at term is about 36 cm, and the weight is approximately 3400 g, with variations to be discussed subsequently.

LENGTH OF FETUS. Because of the variability in the length of the legs and the difficulty of maintaining them in extension, measurements corresponding to the sitting height (crown-to-rump) are more accurate than those corresponding to the standing height. The average sitting height and weight of the fetus at the end of each lunar month were determined by [Streeter \(1920\)](#) from 704 specimens. These values are similar to those found more recently and shown in [Table 7-1](#). Such values are approximate, but generally, length is a more accurate criterion of gestational age than weight.

WEIGHT OF THE NEWBORN. The average term infant in the United States at birth weighs about 3000 to 3600 g, depending upon race, parental economic status, size of the parents, parity of the mother, and altitude, with boys about 100 g (3 oz) heavier than girls. During the second half of pregnancy, the fetal weight increases in a linear manner with time until about the 37th week of gestation, and then the rate slows variably. The principal determinants of fetal growth late in pregnancy are related, in large part, to factors influenced by the socioeconomic status of the mother, such as diet, smoking, or substance abuse. In general, the greater the socioeconomic deprivation, the slower the rate of fetal growth late in pregnancy.

Birthweights over 5000 g occur occasionally ([Chap. 29](#), p. 757), but many tales of huge babies vastly exceeding this figure are based on hearsay or inaccurate measurements at best. Presumably, the largest baby recorded in the medical literature is that described by [Belcher \(1916\)](#), a stillborn female weighing 11,340 g (25 lb). Term infants, however, frequently weigh less than 3200 g, and sometimes as little as 2250 g (5 lb) or even less. It was customary in the past, when the birthweight was 2500 g or less, to classify the infant as preterm even though in some cases the low birthweight was not the consequence of preterm birth but rather the result of restricted growth.

FETAL HEAD. From an obstetrical viewpoint, the size of the fetal head is important because an essential feature of labor is the adaptation between the fetal head and the maternal bony pelvis. Only a comparatively small part of the head at term is represented by the face; the rest is composed of the firm skull, which is made up of two frontal, two parietal, and two temporal bones, along with the upper portion of the occipital bone and the wings of the sphenoid.

These bones are not united rigidly, but rather are separated by membranous spaces, called sutures ([Fig. 7-6](#)). The most important sutures are the frontal, between the two frontal bones; the sagittal, between the two parietal bones; the two coronal, between the frontal and parietal bones; and the two lambdoid, between the posterior margins of the parietal bones and upper margin of the occipital bone. With a vertex presentation, all of the sutures are palpable during labor except the temporal sutures, which are situated on either side between the inferior margin of the parietal and upper margin of the temporal bones, covered by soft parts, and cannot be felt in the living fetus.

Where several sutures meet, an irregular space forms, which is enclosed by a membrane and designated as a fontanel ([Fig. 7-6](#)). The three most clinically important fontanels are the greater, the lesser, and the temporal fontanels. The greater or anterior fontanel is a lozenge-shaped space that is situated at the junction of the sagittal and the coronal sutures. The lesser or posterior fontanel is represented by a small triangular area at the intersection of the sagittal and lambdoid sutures. Both can be palpated readily during labor. The localization of these fontanels gives important information concerning the presentation and position of the fetus. The temporal, or cassarian fontanels, situated at the junction of the lambdoid and temporal sutures, have no diagnostic significance.

It is customary to measure certain critical diameters and circumferences of newborn head ([Fig. 7-7](#)). The diameters most frequently used, and the average lengths thereof, are as follows:

1. The *occipitofrontal* (11.5 cm), which follows a line extending from a point just above the root of the nose to the most prominent portion of the occipital bone.
2. The *biparietal* (9.5 cm), the greatest transverse diameter of the head, which extends from one parietal boss to the other.
3. The *bitemporal* (8.0 cm), the greatest distance between the two temporal sutures.
4. The *occipitomenta* (12.5 cm), from the chin to the most prominent portion of the occiput.
5. The *suboccipitobregmatic* (9.5 cm), which follows a line drawn from the middle of the large fontanel to the undersurface of the occipital bone just where it joins the neck ([Figs. 7-6](#) and [7-7](#)).

The greatest circumference of the head, which corresponds to the plane of the occipitofrontal diameter, averages 34.5 cm, a size too large to fit through the pelvis without flexion. The smallest circumference, corresponding to the plane of the suboccipitobregmatic diameter, is 32 cm. As a rule, white infants have larger heads than nonwhite infants; boys, somewhat larger than girls; and the infants of multiparas, larger heads than those of nulliparas. The bones of the cranium are normally connected only by a thin layer of fibrous tissue which allows considerable shifting or sliding of each bone to accommodate the size and shape of the maternal pelvis. This intrapartum process is termed *molding*. Because of the varying mobility of the bones of the skull and varying presentations of the fetal head relative to the pelvis, a variety of newborn head shapes are possible. The head position and degree of skull ossification result in a spectrum of cranial plasticity from minimal to great and, in some cases, undoubtedly contributes to fetopelvic disproportion, a leading indication for cesarean delivery ([Chap. 18](#), p. 440).

FETAL BRAIN. There is a steady gestational age-related change in the appearance and function of the fetal brain ([Fig. 7-8](#)). It is therefore possible to identify fetal age rather precisely from its external appearance ([Dolman, 1977](#)). Myelination of the ventral roots of the cerebrospinal nerves and brainstem begins at approximately 6 months, but the major portion of myelination occurs after birth. The lack of myelin and the incomplete ossification of the fetal skull permit the structure of the brain to be seen with ultrasound throughout gestation.

THE FETAL-MATERNAL COMMUNICATION SYSTEM: PLACENTAL ARM

The transfer of oxygen and a great variety of nutrients from the mother to the fetus, and conversely the transfer of carbon dioxide and other metabolic wastes from fetus to mother, is accomplished by way of the nutritive component of the placental arm of the fetal-maternal communication system (see [Fig. 2-3](#)). The placenta is the organ of transfer between mother and fetus. The placenta, and to a limited extent the attached membranes, supply all materials required for fetal growth and energy production while removing products of fetal catabolism.

There are no direct communications between the fetal blood, which is contained in the fetal capillaries in the intervillous space of the chorionic villi, and the maternal blood, which remains in the intervillous space. The one exception to this dictum is the occasional development of breaks in the chorionic villi, permitting the escape of fetal erythrocytes and leukocytes, in various numbers, into the maternal circulation. This leakage is the mechanism by which some D-negative women become sensitized by the erythrocytes of their D-positive fetus ([Chap. 39](#), p. 1057). Aside from these occasional leaks, however, there is no gross intermingling of the macromolecular constituents of the two circulations. The transfer of substances from mother to fetus and from fetus to mother, therefore, depends primarily on the processes that permit or facilitate the transport of such substances through the syncytiotrophoblast of the intact chorionic villi.

THE INTERVILLOUS SPACE: MATERNAL BLOOD. The intervillous space is the primary biological compartment of maternal-fetal transfer. Maternal blood in this extravascular compartment directly bathes the trophoblasts. Substances transferred from mother to fetus first enter the intervillous space and are then transported to the syncytiotrophoblast. Substances transported from the fetus to the mother are transferred from the syncytium into the same space. This process of transfer supplies

the fetus with oxygen as well as nutrients and provides for elimination of metabolic waste products. Thus the chorionic villi and the intervillous space, together, function for the fetus as lung, gastrointestinal tract, and kidney.

Although renal function develops gradually, fetal urination begins early in pregnancy, and fetal urine comprises the major portion of the amniotic fluid after 16 weeks. At 22 weeks, an average of 2.2 mL/h is produced, increasing to 10 mL/h at 30 weeks and 50 mL/h at term ([Kurjak and associates, 1981](#)).

The circulation of maternal blood within the intervillous space is described in [Chapter 5 \(p. 100\)](#). The residual volume of the intervillous space of the term placenta measures about 140 mL; the normal volume of the intervillous space before delivery, however, may be twice this value ([Aherne and Dunnill, 1966](#)). Uteroplacental blood flow near term has been estimated to be about 700 to 900 mL/min, with most of the blood apparently going to the intervillous space.

The forceful uterine contractions of active labor cause a reduction in blood flow into the intervillous space, the degree of reduction depending in large measure upon the intensity of the contraction. Blood pressure within the intervillous space is significantly less than the uterine arterial pressure, but somewhat greater than uterine venous pressure. Uterine venous pressure, in turn, varies depending upon several factors, including maternal position. When supine, for example, pressure in the lower part of the inferior vena cava is elevated; consequently, in this position, pressure in the uterine and ovarian veins, and in turn in the intervillous space, is increased. An even greater increase in intervillous pressure is likely when the pregnant woman is standing.

FETAL CAPILLARIES OF THE INTRAVILLOUS SPACE: FETAL BLOOD. The hydrostatic pressure in the fetal capillaries that traverse the chorionic villi is probably not appreciably different from that in the intervillous space. During normal labor, the rise in fetal blood pressure must be parallel to the pressure in the amniotic fluid and the intervillous space. Otherwise, the capillaries in the chorionic villi would collapse and fetal blood flow through the placenta would cease.

PLACENTAL TRANSFER

CHORIONIC VILLUS. Substances that pass from maternal blood to fetal blood must traverse (1) syncytiotrophoblast, (2) stroma of the intervillous space, and (3) fetal capillary wall. Although this histological barrier separates the blood in the maternal and fetal circulations, it does not behave in a uniform manner like a simple physical barrier. Throughout pregnancy, syncytiotrophoblast actively or passively permits, facilitates, and adjusts the amount and rate of transfer of a wide range of substances to the fetus. After midpregnancy, the number of Langhans cells, or cytotrophoblasts, lining the innermost layer of villi decreases, and the villous epithelium then consists predominantly of syncytiotrophoblast. The walls of the villous capillaries likewise become thinner, and the relative number of fetal vessels increases in relation to the villous connective tissue. It is important to recall that the walls of the fetal placental surface vessels, after branching from the truncal arteries of the chorionic vessels, do not contain smooth muscle cells ([Chap. 5](#), p. 99). Several attempts have been made to estimate the total surface area of chorionic villi in the human placenta at term. From the planimetric measurements made by [Aherne and Dunnill \(1966\)](#) of the villous surface area of the placenta, it is evident that there is a close correlation with fetal weight. The total surface area at term has been estimated to be approximately 10 m².

REGULATION OF PLACENTAL TRANSFER. The syncytiotrophoblast is the fetal tissue interface of the placental arm of the fetal-maternal (communication) transport system. The maternal-facing surface of this tissue is characterized by a complex microvillus structure. The fetal-facing (basal) cell membrane of the trophoblast is the site of transfer to the intervillous space through which the fetal capillaries traverse. The fetal capillaries are an additional site for transport from the intervillous space into fetal blood, or vice versa.

In determining the effectiveness of the human placenta as an organ of transfer, at least 10 variables are important:

1. The concentration of the substance under consideration in the maternal plasma, and in some instances the extent to which it is bound to another compound, such as a carrier protein.
2. The rate of maternal blood flow through the intervillous space.
3. The area available for exchange across the villous trophoblast epithelium.
4. If the substance is transferred by diffusion, the physical properties of the tissue barrier interposed between blood in the intervillous space and in the fetal capillaries.
5. For any substance actively transported, the capacity of the biochemical machinery of the placenta for effecting active transfer, for example, specific receptors on the plasma membrane of the trophoblast.
6. The amount of the substance metabolized by the placenta during transfer.
7. The area for exchange across the fetal capillaries in the placenta.
8. The concentration of the substance in the fetal blood, exclusive of any that is bound.
9. Specific binding or carrier proteins in the fetal or maternal circulation.
10. The rate of fetal blood flow through the villus capillaries.

MECHANISMS OF TRANSFER. Most substances with a molecular mass less than 500 d diffuse readily through the placental tissue interposed between the maternal and fetal circulations. Molecular weight is clearly important in determining the rate of transfer by diffusion; all other things being equal, the smaller the molecule, the more rapid the transfer rate.

Simple diffusion, however, is by no means the only mechanism of transfer of low molecular weight compounds. The syncytiotrophoblast actively facilitates the transfer of a variety of small compounds, especially those that are in low concentration in maternal plasma but are essential for the normal growth and development of the fetus. Simple diffusion appears to be the mechanism involved in the transfer of oxygen, carbon dioxide, water, and most (but not all) electrolytes. Anesthetic gases also pass through the placenta rapidly by simple diffusion.

Insulin, steroid hormones, and thyroid hormones cross the placenta, but at very slow rates. The hormones synthesized in situ in the trophoblasts enter both the maternal and fetal circulations, but not equally ([Chap. 6](#)). For example, concentrations of chorionic gonadotropin and placental lactogen in fetal plasma are very much lower than in maternal plasma. Substances of very high molecular weight usually do not traverse the placenta, but there are important exceptions, such as immune gamma globulin G—with an M_r of about 160,000—which is transferred by way of a specific trophoblast receptor-mediated mechanism.

TRANSFER OF OXYGEN AND CARBON DIOXIDE. In their excellent account of placental transport, [Morriss and associates \(1994\)](#) recall that Mayow, in 1674, suggested that the placenta served as the fetal lung. Erasmus Darwin, in 1796, only 22 years after the discovery of oxygen, observed that the color of blood passing through lungs and gills became bright red. He deduced that from the structure as well as the position of the placenta, that it appeared to be a respiratory organ by which the fetus becomes oxygenated.

The transfer of carbon dioxide across the placenta is diffusion limited. The transfer of oxygen, however, is blood-flow limited, and there are other limitations. The placenta supplies about 8 mL O₂/min/kg of fetal weight, and because fetal blood oxygen stores are sufficient for only 1 to 2 minutes, this supply must be continuous ([Longo, 1991](#)). Normal values for oxygen, carbon dioxide, and pH in maternal and fetal blood, are presented in [Table 7-2](#). Because of the continuous passage of oxygen from the maternal blood in the intervillous space to the fetus, the oxygen saturation of this blood resembles that in the maternal capillaries. The average oxygen saturation of intervillous space blood is estimated to be 65 to 75 percent, with a partial pressure (PO₂) of about 30 to 35 mm Hg. The oxygen saturation of umbilical vein blood is similar, but with an oxygen partial pressure somewhat lower.

Despite the relatively low PO₂, the fetus normally does not suffer from lack of oxygen. The human fetus probably behaves like the lamb fetus, and therefore has a cardiac output considerably greater per unit of body weight than does the adult. The high cardiac output, the increased oxygen-carrying capacity of fetal hemoglobin, and, late in pregnancy, a higher hemoglobin concentration than in adults, compensate effectively for the low oxygen tension (see p. 146). Additional evidence that the fetus normally does not experience lack of oxygen is provided by measurements of the lactic acid content of fetal blood, which is only slightly higher than that of the mother ([Morriss and associates, 1994](#)).

In general, transfer of fetal carbon dioxide is accomplished by diffusion. The placenta is highly permeable to carbon dioxide, which traverses the chorionic villus more rapidly than oxygen. Near term, the partial pressure of carbon dioxide (PCO_2) in the umbilical arteries is estimated to average about 48 mm Hg, or about 5 mm Hg more than in the maternal intervillous blood. Fetal blood has less affinity for carbon dioxide than does maternal blood, thereby favoring the transfer of carbon dioxide from the fetus to the mother. Also, mild hyperventilation by the pregnant woman results in a fall in PCO_2 favoring a transfer of carbon dioxide from the fetal compartment into maternal blood.

SELECTIVE TRANSFER AND FACILITATED DIFFUSION. While simple diffusion is an important method of placental transfer, the trophoblast and chorionic villus unit demonstrate enormous selectivity in transfer. This results in different concentrations of a variety of metabolites on the two sides of the villus.

The concentrations of a number of substances which are not synthesized by the fetus are several times higher in fetal than in maternal blood. Ascorbic acid is a good example of this phenomenon. This relatively low molecular weight substance resembles the pentose and hexose sugars and might be expected to traverse the placenta by simple diffusion. The concentration of ascorbic acid, however, is two to four times higher in fetal plasma than in maternal plasma ([Morris and associates, 1994](#)). The unidirectional transfer of iron across the placenta provides another example of transport and sequestration of selected agents. Typically, iron is present in the plasma of the pregnant woman at a lower concentration than in her fetus; and at the same time, the iron-binding capacity of maternal plasma is much greater. Nonetheless, iron is transported actively from maternal to fetal plasma; and in the human fetus, the amount transferred appears to be independent of maternal iron status.

Infections of the fetus caused by viruses, bacteria, and protozoa are occasionally encountered ([Chap. 39](#)). Many viruses, including rubella, varicella, cytomegalovirus, and human immunodeficiency virus may cross the placenta and infect the fetus. A number of bacteria, notably treponemes and tuberculosis; as well as protozoans like toxoplasma and plasmodium also may cause fetal infection. With protozoal and bacterial—but not necessarily viral—infections, there is almost always histological evidence of placental involvement.

Rarely, malignant cells arising in neoplasias in the pregnant woman are transferred to the placenta, the fetus, or both ([Gilstrap and Cunningham, 1996](#)). As discussed in [Chapter 32 \(p. 848\)](#), most such cases are limited to the placenta, but occasionally malignant melanomas or hematopoietic cell malignancies can metastasize to the fetus origin.

NUTRITION OF THE FETUS

During the first 2 months of pregnancy, the embryo consists almost entirely of water; later in fetal development, relatively more solids are added. The amounts of water, fat, nitrogen, and certain minerals in the fetus at successive weeks of gestation are given in [Table 7-3](#). Because of the small amount of yolk in the human ovum, growth of the embryo-fetus from the very early stage of development is dependent on nutrients obtained from the mother. During the first few days after implantation, the nutrition of the blastocyst comes from the interstitial fluid of the endometrium and the surrounding maternal tissue. Within the next week, the forerunners of the intervillous space are formed. In the beginning, these are simply lacunae that are filled with maternal blood, but during the third week after fertilization the fetal blood vessels in the chorionic villi appear. During the fourth week, a cardiovascular system has formed, and thereby a true circulation is established both within the embryo and between the embryo and the chorionic villi.

Ultimately, the maternal diet provides all nutrients supplied to the fetus. Ingested foodstuff is translated into storage forms that are made available continuously, in an orderly fashion, to meet the demands for energy, tissue repair, and new growth, including maternal needs for pregnancy. Three major maternal storage depots, the liver, muscle, and adipose tissue and the storage hormone insulin, are intimately involved in the metabolism of the nutrients absorbed from the maternal gut. Maternal insulin is released in response to various compounds liberated during digestion and absorption. Insulin secretion is sustained by increased serum levels of glucose and amino acids. The net effect is storage of glucose as glycogen primarily in liver and muscle, retention of some amino acids as protein, and storage of the excess as fat. Storage of maternal fat peaks in the second trimester, and then declines as fetal demands increase in late pregnancy ([Pipe and colleagues, 1979](#)).

During times of fasting, glucose is released from glycogen, but maternal glycogen stores are not large and cannot provide an adequate amount of glucose to meet requirements for maternal energy and fetal growth. Cleavage of triacylglycerols, stored in adipose tissue, however, provides the mother with energy in the form of free fatty acids. Lipolysis is activated, directly or indirectly, by a number of hormones, including glucagon, norepinephrine, placental lactogen (hPL), glucocorticosteroids, and thyroxine.

GLUCOSE AND FETAL GROWTH. The fetus is not exposed to a constant supply of glucose, and maternal plasma levels may vary by up to 75 percent. Although the fetus is quite dependent on the mother for nutrition, the fetus is not a passive parasite and actively participates in providing for its own nutrition. At midpregnancy, fetal glucose concentration is independent of and may exceed maternal levels ([Bozzetti and colleagues, 1988](#)).

Glucose is a major nutrient for fetal growth and energy. It is thus logical that mechanisms exist during pregnancy to minimize maternal glucose use so that the limited maternal supply is available to the fetus. It is believed that placental lactogen (hPL), a hormone normally present in abundance in the mother but not the fetus, blocks the peripheral uptake and use of glucose while promoting the mobilization and use of free fatty acids by maternal tissues ([Chap. 6](#), p. 114). It does not appear however, that hPL, nor placental growth hormone, are absolutely required for a normal pregnancy outcome.

GLUCOSE TRANSPORT. The transfer of D-glucose across cell membranes is accomplished by a carrier-mediated, stereospecific, nonconcentrating process of facilitated diffusion. Six separate glucose transport proteins (GLUT) have been discovered. They belong to the 12-transmembrane segment transporter superfamily and are characterized further by tissue-specific distribution ([Chap. 29](#), p. 745). Transporter proteins for D-glucose, GLUT-1, and GLUT-3, have been identified in the plasma membrane (the microvilli) of human syncytiotrophoblast. GLUT-1 expression is prominent in human placenta, increases as pregnancy advances, and is induced by almost all growth factors ([Sakata and colleagues, 1995](#)). GLUT-3 is also expressed prominently in placenta, being localized in human syncytiotrophoblast ([Hahn and associates, 1995](#)).

A great deal of investigative effort continues to be focused on maternal nutrition and its effect on fetal growth and development. Fetal size is a function not only of fetal age, but of the efficiency of nutrient transport, nutrient availability, and a number of cofactors. For example, in women with maternal diabetes with no significant maternal vascular disease, the fetus may be larger than normal because of high maternal glucose levels and efficient transfer. Conversely, if severe maternal vascular disease is a complication of the diabetes, the fetus may be appreciably smaller than normal because transport is impaired ([Chap. 29](#), p. 751).

GLUCOSE, INSULIN, AND FETAL MACROSOMIA. The precise biomolecular events in the pathophysiology of fetal macrosomia are not defined. Nonetheless, it seems clear that fetal hyperinsulinemia is one driving force ([Schwartz and colleagues, 1994](#)). As discussed in [Chapter 29 \(p. 744\)](#), insulin-like growth factor (IGF-I), as well as fibroblast-growth factor (FGF-2), also are involved ([Guidice and associates, 1995](#); [Hill and colleagues, 1995](#)). Therefore, a hyperinsulinemic state with increased levels of selected growth factors, together with increased expression of GLUT proteins in syncytiotrophoblast, may promote excessive fetal growth.

LACTATE. This substance also is transported across the placenta by facilitated diffusion. By way of co-transport with hydrogen ions, lactate is probably transported as lactic acid.

FREE FATTY ACIDS AND TRIGLYCERIDES. Among mammalian neonates, the human newborn has a large proportion of fat, specifically 15 percent of body weight on average ([Kimura, 1991](#)). This is indicative that late in pregnancy, a substantial part of substrate transferred to the human fetus is stored as fat. Neutral fat (triacylglycerols) does not cross the placenta, but glycerol does. It is likely that most fatty acids cross the placenta by simple diffusion. Moreover, fatty acids are also synthesized in the placenta. Lipoprotein lipase is present on the maternal but not on the fetal side of the placenta. This arrangement should favor hydrolysis of triacylglycerols in the maternal intervillous space while preserving these neutral lipids in fetal blood. Fatty acids transferred to the fetus can be converted to triacylglycerols in the fetal liver.

The placental uptake and use of low-density lipoprotein (LDL) was cited in [Chapter 6 \(p. 123\)](#) as an alternate mechanism for fetal assimilation of essential fatty acids and amino acids. The LDL^1 particles from maternal plasma bind to specific LDL receptors in the coated-pit regions of the microvilli on the maternal-facing side of the syncytiotrophoblast. The large (about 250,000 d) LDL particle is taken up by a process of receptor-mediated endocytosis. The apoprotein and cholesterol esters of LDL are hydrolyzed by lysosomal enzymes in the syncytium to give:

1. Cholesterol for progesterone synthesis.
2. Free amino acids—including essential amino acids.

3. Essential fatty acids, primarily linoleic acid.

Indeed, the concentration of arachidonic acid, which is synthesized from linoleic acid in fetal plasma, is greater than that in maternal plasma. Linoleic acid (and/or arachidonic acid) must be assimilated from maternal dietary intake.

AMINO ACIDS. In addition to the hydrolysis of [LDL](#)¹, the placenta is known to concentrate a large number of amino acids intracellularly ([Lemons, 1979](#)). Neutral amino acids from maternal plasma are taken up by trophoblasts by at least three specific processes. Presumably, amino acids are concentrated in the syncytiotrophoblasts, and thence transferred to the fetal side by diffusion. Based upon data from cordocentesis blood samples, the concentration of amino acids in cord umbilical plasma is greater than in maternal venous or arterial plasma ([Morris and associates, 1994](#)).

PROTEINS. Generally, there is very limited transfer of larger proteins across the placenta. There are important exceptions; for example, immunoglobulin G (IgG) crosses the placenta in large amounts. Another exception is retinol-binding protein.

Near term, [IgG](#)² is present in approximately the same concentrations in cord and maternal sera, but [IgA](#)³ and [IgM](#)⁴ in cord serum are considerably lower. Although IgA and IgM of maternal origin are effectively excluded from the fetus, IgG crosses the placenta with considerable efficiency ([Gitlin and colleagues, 1972](#)). Fc receptors are present on trophoblasts; the transport of IgG is accomplished by way of these receptors through a classical process of endocytosis. Increased amounts of IgM are found in the fetus only after the fetal immune system has been provoked into antibody response by infection in the fetus.

IONS AND TRACE METALS. Iodide transport across the placenta is clearly attributable to a carrier-mediated, energy-requiring active process; indeed, the placenta concentrates iodide. The concentrations of zinc in the fetal plasma also are greater than those in maternal plasma. Conversely, copper levels in fetal plasma are less than those in maternal plasma. This is of particular interest because important copper-requiring enzymes are required for fetal development.

PLACENTAL SEQUESTRATION OF HEAVY METALS. The heavy metal-binding protein, metallothionein-1, is expressed in human syncytiotrophoblast. This protein binds (sequesters) a host of heavy metals including zinc, copper, lead, and cadmium.

The most common source of cadmium in the environment is cigarette smoke. Cadmium levels in maternal blood and placenta are increased with maternal smoking, but there is no increase in cadmium transfer into the fetus. The cadmium concentration in cord blood is less than that in maternal blood, and there is little or no cadmium in fetal liver or kidney. Presumably, the low levels of cadmium in the fetus are attributable to the sequestration (binding) of cadmium by metallothionein(s) in trophoblast. This comes about because cadmium acts to increase the transcription of the metallothionein gene(s); and cadmium-induced increases in trophoblast metallothionein levels result in placenta cadmium accumulation (sequestration). Metallothionein also binds (sequesters) copper (Cu^{2+}) in placenta, thus accounting for the low levels of Cu^{2+} in cord blood. A number of mammalian enzymes require Cu^{2+} , and its deficiency results in inadequate collagen cross-linking and, in turn, diminished tensile strength of tissues.

The concentration of cadmium in amniotic fluid is similar to that in maternal blood. The incidence of preterm premature rupture of the fetal membranes (amnion) is increased in women who smoke. It is possible that cadmium provokes metallothionein synthesis in amnion, causing sequestration of Cu^{2+} and a pseudocopper deficiency.

CALCIUM AND PHOSPHORUS. These also are actively transported from mother to fetus. A calcium-binding protein is present in placenta. Parathyroid hormone-related protein (PTH-rP), as the name implies, acts as a surrogate PTH in many systems, including the activation of adenylate cyclase and the movement of Ca^{2+} . The history and selected special actions proposed for [PTH-rP](#)⁵ in endometrium/decidua are described in [Chapter 4 \(p. 73\)](#). The production of PTH-rP in placenta is addressed in [Chapter 6 \(p. 115\)](#), and the potential role of this agent in myometrium is cited in [Chapter 11 \(p. 272\)](#). PTH-rP is not produced in normal adult parathyroid glands, but is produced in the fetal parathyroid and in the placenta and other fetal tissues, especially the fetal kidney. Moreover, PTH is not demonstrable in human fetal plasma, but PTH-rP is present. For those reasons, some refer to PTH-rP as the fetal parathormone ([Abbas and associates, 1990](#)). There is a Ca^{2+} -sensing receptor in trophoblast as there is in the parathyroid glands ([Juhlin and colleagues, 1990](#)). The expression of PTH-rP in cytotrophoblasts is modulated by the extracellular concentration of Ca^{2+} ([Hellman and co-workers, 1992](#)). It seems possible, therefore, that PTH-rP synthesized in decidua, placenta, and other fetal tissues is important in fetal calcium transfer and homeostasis.

VITAMINS. The concentration of *vitamin A (retinol)* is greater in fetal than in maternal plasma. Vitamin A in fetal plasma is bound to retinol-binding protein and to prealbumin. Retinol-binding protein is transferred from the maternal compartment across the syncytium. The transport of *vitamin C (ascorbic acid)* across the placenta from mother to fetus is accomplished by an energy-dependent, carrier-mediated process. The levels of the principal *vitamin D (cholecalciferol)* metabolites, including 1,25-dihydroxycholecalciferol, are greater in maternal plasma than are those in fetal plasma. The 1 α -hydroxylation of 25-hydroxyvitamin D₃ is known to take place in placenta and in decidua.

PHYSIOLOGY OF THE FETUS

AMNIONIC FLUID

In early pregnancy, amniotic fluid is an ultrafiltrate of maternal plasma. By the beginning of the second trimester, it consists largely of extracellular fluid which diffuses through the fetal skin, and thus reflects the composition of fetal plasma ([Gilbert and Brace, 1993](#)). After 20 weeks, however, the cornification of fetal skin prevents this diffusion and amniotic fluid is composed largely of fetal urine. The fetal kidneys start producing urine at 12 weeks' gestation, and by 18 weeks are producing 7 to 14 mL per day. Fetal urine contains more urea, creatinine, and uric acid than plasma, as well as desquamated fetal cells, vernix, lanugo, and various secretions. Because these are hypotonic, the net effect is decreasing amniotic fluid osmolality with advancing gestation. Pulmonary fluid contributes a small proportion of the amniotic volume, and fluid filtering through the placenta accounts for the rest.

The volume of amniotic fluid at each week of gestation is quite variable. In general, the volume increases by 10 mL per week at 8 weeks and increases up to 60 mL per week at 21 weeks, then declines gradually back to a steady state by 33 weeks ([Brace and Wolf, 1989](#)). The usual amniotic fluid volume thus increases from 50 mL at 12 weeks to 400 mL at midpregnancy and 1000 mL at term ([Gillibrand, 1969](#)).

Amniotic fluid serves to cushion the fetus, allowing musculoskeletal development and protecting it from trauma. It also maintains temperature and has a minimal nutritive function. Epidermal growth factor (EGF) and [EGF](#)⁶-like growth factors, such as transforming growth factor- α , are present in amniotic fluid. Ingestion of amniotic fluid into the lung and gastrointestinal tract may promote growth and differentiation of these tissues by inspiration and swallowing amniotic fluid. [PTH-rP](#)⁷ and endothelin-1 also are present in amniotic fluid, and it has been proposed that these peptides may be involved in fetal development. Both act as growth factors in selected cells, and PTH-rP promotes surfactant synthesis cells in type II pneumocytes in vitro ([Rubin and co-workers, 1994](#)).

A more important function, however, is to promote the normal growth and development of the lungs and gastrointestinal tract. Animal studies have shown that pulmonary hypoplasia can be produced by draining off amniotic fluid, by banding the trachea to prevent "inhalation" of fluid into the lungs, by chronically draining pulmonary fluid through the trachea, and by physically preventing the prenatal chest excursions that mimic breathing ([Adzick and associates, 1984](#); [Alcorn and colleagues, 1977](#)). Thus the formation of intrapulmonary fluid and, at least as important, the alternating egress and retention of fluid in the lungs by breathing movements, are essential to normal pulmonary development. Clinical implications of oligohydramnios and pulmonary hypoplasia are discussed in [Chapter 31 \(p. 822\)](#).

FETAL CIRCULATION

This differs fundamentally from that of the adult. For example, because fetal blood does not need to enter the pulmonary vasculature to be oxygenated, the major portion of the right ventricular output bypasses the lungs. Oxygen and nutrient materials required for fetal growth and maturation are delivered to the fetus from the placenta by the single umbilical vein, and thus do not need to be absorbed through the gastrointestinal tract ([Fig. 7-9](#)). Additionally, the chambers of the fetal heart work in parallel, not in series, which effectively supplies the brain and heart with more highly oxygenated blood than the rest of the body. The fetal circulation is unique, and functions smoothly until the moment of birth, when it is required to change dramatically.

Oxygenated blood is brought to the fetus by the umbilical vein, which enters the abdomen through the umbilical ring and ascends along the anterior abdominal wall toward the liver. The vein then divides into the ductus venosus and the portal sinus. The ductus venosus is the major branch of the umbilical vein, and traverses the

liver to enter the inferior vena cava directly. Because it does not supply oxygen to the intervening tissues, it carries well-oxygenated blood directly to the heart. In contrast, the portal sinus carries blood to the hepatic veins primarily on the left side of the liver, where oxygen is extracted. The relatively deoxygenated blood from the liver then flows back into the inferior vena cava, which also receives less oxygenated blood returning from the lower body. Blood flowing to the fetal heart from the inferior vena cava, therefore, consists of an admixture of arterial-like blood that passes directly through the ductus venosus and less well-oxygenated blood that returns from most of the veins below the level of the diaphragm. The oxygen content of blood delivered to the heart from the inferior vena cava is thus lower than that which leaves the placenta.

In contrast to postnatal life, the ventricles of the fetal heart work in parallel, not in series. Well-oxygenated blood enters the left ventricle, which supplies the heart and brain, and less oxygenated blood enters the right ventricle, which supplies the rest of the body. The two separate circulations are maintained by the structure of the right atrium, which effectively directs entering blood to either the left atrium or the right ventricle, depending on its oxygen content. This separation of blood according to its oxygen content is facilitated by the pattern of blood flow in the inferior vena cava. The well-oxygenated blood tends to course along the medial aspect of the inferior vena cava and the less oxygenated blood stays along the lateral vessel wall, facilitating their shunting into opposite sides of the heart. Once this blood enters the atrium, the configuration of the upper interatrial septum, called the crista dividens, is such that it preferentially shunts the well-oxygenated blood from the medial side of the inferior vena cava and the ductus venosus through the foramen ovale into the left heart and then to the heart and brain ([Dawes, 1962](#)). After these tissues have extracted needed oxygen, the resulting less oxygenated blood returns to the right heart through the superior vena cava.

The less oxygenated blood coursing along the lateral wall of the inferior vena cava enters the right atrium and is deflected through the tricuspid valve to the right ventricle. The superior vena cava courses inferiorly and anteriorly as it enters the right atrium, ensuring that less well-oxygenated blood returning from the brain and upper body will also be shunted directly to the right ventricle. Similarly, the ostium of the coronary sinus lies just superior to the tricuspid valve so that less oxygenated blood from the heart also returns to the right ventricle. As a result of this blood flow pattern, blood in the right ventricle is 15 to 20 percent less saturated than blood in the left ventricle.

The major portion (87 percent) of blood exiting the right ventricle is then shunted through the ductus arteriosus to the descending aorta. The high pulmonary vascular resistance and the comparatively lower resistance in the ductus arteriosus and the umbilical-placental vasculature ensure that only approximately 13 percent of right ventricular output (8 percent of the combined ventricular output) goes to the lungs ([Teitel, 1992](#)). One third of the blood passing through the ductus arteriosus is delivered to the body, and the remaining right ventricular output returns to the placenta through the two hypogastric arteries, which distally become the umbilical arteries. In the placenta, this blood picks up oxygen and other nutrients, and is then recirculated back through the umbilical vein.

After birth, the umbilical vessels, ductus arteriosus, foramen ovale, and ductus venosus normally constrict or collapse. With the functional closure of the ductus arteriosus and the expansion of the lungs, blood leaving the right ventricle preferentially enters the pulmonary vasculature to become oxygenated before it returns to the left heart. Virtually instantaneously, the ventricles which had worked in parallel in fetal life now effectively work in series. The more distal portions of the hypogastric arteries, which course from the level of the bladder along the abdominal wall to the umbilical ring and into the cord as the umbilical arteries, undergo atrophy and obliteration within 3 to 4 days after birth. These become the umbilical ligaments while the intra-abdominal remnants of the umbilical vein form the ligamentum teres. The ductus venosus constricts by 10 to 96 hours after birth and is anatomically closed by 2 to 3 weeks, resulting in the formation of the ligamentum venosum ([Clymann and Heymann, 1981](#)).

ANIMAL STUDIES. The lamb fetus has been studied intensively by several groups of investigators who have concluded that the circulatory function of the mature lamb fetus is similar (in many respects) to that of the mature human fetus. Attempts to measure cardiac output in the lamb fetus have yielded somewhat variable results. [Assali and associates \(1968\)](#) found a mean output of about 225 mL/kg/min, but with considerable individual variation. [Paton and co-workers \(1973\)](#) found very similar values in baboon fetuses. Such a high fetal cardiac output, which per unit of body weight is about three times that of an adult at rest, would serve to compensate for the low oxygen content of fetal blood. The high cardiac output is accomplished, in part, by the fast heart rate of the fetus and a low systemic (peripheral) resistance.

It is estimated that in the fetal lamb, about half the combined output of the two ventricles goes to the placenta. By injecting isotopically labeled plastic microspheres into the fetal lamb circulation at various sites, the distribution of cardiac output during the last third of gestation was determined to be approximately as follows: placenta, 40 percent; carcass, 35 percent; brain, 5 percent; heart, 5 percent; gastrointestinal tract, 5 percent; lungs, 4 percent; kidneys, 2 percent; spleen, 2 percent; and liver (hepatic artery only), 2 percent ([Rudolph and Heymann, 1968](#)).

Clamping of the umbilical cord and expansion of the fetal lungs, either through spontaneous breathing or artificial respiration, promptly induce a variety of hemodynamic changes in sheep ([Assali and associates, 1968](#)). The systemic arterial pressure initially falls slightly, apparently the result of the reversal in the direction of blood flow in the ductus arteriosus, but it soon recovers and then rises above the control value. These investigators concluded that several factors served to regulate the flow of blood through the ductus arteriosus. One is the difference in pressure between the pulmonary artery and aorta, and another is the oxygen tension of the blood passing through the ductus arteriosus. They were able to influence flow through the ductus arteriosus by altering the PO_2 of the blood. When the lungs were ventilated with oxygen and the PO_2 rose above 55 mm Hg, ductus flow dropped, but ventilation with nitrogen, initially at least, returned the ductus flow to the original pattern.

The effects of variations in the oxygen tension of blood flowing through the ductus arteriosus are believed to be mediated through the actions of prostaglandins on the ductus. Prostaglandin E_2 dilates the constricted ductus arteriosus and is intimately involved in maintaining normal patency in utero. Inhibitors of prostaglandin synthase, when given to the mother, may lead to premature closure of the ductus arteriosus ([Chap. 27](#), p. 716; [Chap. 38](#), p. 1027). These drugs also can be used pharmacologically to close a symptomatic patent ductus arteriosus postnatally ([Brash and associates, 1981](#)).

FETAL BLOOD

HEMOPOIESIS. In the very early embryo, hemopoiesis is demonstrable first in the yolk sac. The next major site of erythropoiesis is the liver, and finally the bone marrow. The contributions made by each site throughout the growth and development of the embryo and fetus are demonstrated graphically in [Figure 7-10](#). Erythropoiesis is regulated primarily by erythropoietin, which increases along with gestational age ([Thomas and colleagues, 1983](#)).

The first erythrocytes released into the fetal circulation are nucleated and macrocytic. The mean cell volume is at least 180 fL in the embryo and normally decreases to 105 to 115 fL at term. The erythrocytes of aneuploid fetuses generally do not undergo this maturation and maintain high mean cell volumes, 130 fL on average ([Sipes and associates, 1991](#)). As fetal development progresses, more and more of the circulating erythrocytes are smaller and nonnucleated. As the fetus grows, not only does the volume of blood in the common fetoplacental circulation increase, but hemoglobin concentration rises as well (see [Fig. 39-13](#), p. 1065). Hemoglobin content of fetal blood rises to the level of about 12 g/dL at midpregnancy. By term, it is about 18 g/dL, a hemoglobin concentration that is high by maternal standards ([Walker and Turnbull, 1953](#)).

Fetal erythrocytes have a short life span. The life span of nucleated red blood cells is shorter in immature fetuses and progressively lengthens to approximately 90 days at term ([Pearson, 1966](#)). As a consequence, red cell production is increased. Reticulocytes are initially present at high levels, but decrease to about 4 to 5 percent of the total at term. The erythrocytes of the fetus differ structurally and metabolically from those of the adult. Fetal erythrocytes are more deformable, which serves to offset their higher viscosity, and contain several enzymes with appreciably different activities ([Smith and co-workers, 1981](#)).

ERYTHROPOIESIS. This process is controlled primarily by erythropoietin made by the fetus. Maternal erythropoietin does not cross the placenta. Fetal erythropoietin production is apparently under fetal control and is not influenced by maternal factors ([Stockman and deAlarcon, 1992](#)). It is produced in response to hypoxic stress such as that associated with bleeding, labor, or isoimmunization ([Stangenberg and associates, 1993](#); [Widness and colleagues, 1984](#)). The concentration of erythropoietin correlates inversely with the hemoglobin concentration in fetuses of D-antigen-sensitized pregnancies. Erythropoietin production is influenced by testosterone, estrogen, prostaglandins, thyroid hormone, and lipoproteins ([Stockman and deAlarcon, 1992](#)). Erythropoietin levels increase with fetal maturity as do the numbers of erythrocytes responsive to it. The exact site of erythropoietin production is disputed, but the fetal liver appears to be an important source until renal production begins. There is a close correlation between the concentration of erythropoietin in amniotic fluid and that in umbilical venous blood obtained by cordocentesis. After birth, erythropoietin normally may not be detectable for up to 3 months.

FETAL BLOOD VOLUME. Precise measurements of human fetoplacental volume are lacking. [Usher and associates \(1963\)](#), however, have measured blood volume of term normal infants very soon after birth and found an average of 78 mL/kg when immediate cord-clamping was conducted. [Gruenwald \(1967\)](#) found the volume of blood of fetal origin contained in the placenta after prompt cord-clamping to average 45 mL/kg of fetus. Thus, fetoplacental blood volume at term is approximately 125 mL/kg of fetus.

FETAL HEMOGLOBIN. Hemoglobin is a tetramer composed of two copies each of two different peptide chains. The identity of the two peptide chains determines the type of hemoglobin produced; α and β chains make up normal adult hemoglobin A. During embryonic and fetal life, a variety of α and β chain precursors are produced, resulting in the serial production of several different embryonic hemoglobins. The genes that direct production of the various embryonic versions of these chains are arranged in the order in which they are activated on chromosome 11 (β -type chains) and 16 (α -type chains). This sequence is shown in [Figure 7-11](#) and each of these genes is turned on and then off during fetal life, until the α and β genes, which direct the production of hemoglobin A, are permanently activated.

Interestingly, the timing of the production of each of these early hemoglobin versions corresponds to changes in the site of hemoglobin production. As [Figure 7-10](#) illustrates, fetal blood is first produced in the yolk sac, where hemoglobins Gower 1, Gower 2, and Portland are made. Erythropoiesis then moves to the liver, where hemoglobin F (fetal hemoglobin) is produced. When hemopoiesis finally moves to the bone marrow at around 11 weeks, normal hemoglobin A appears in fetal red cells and is present in progressively greater amounts as the fetus matures ([Pataryas and Stamatoyannopoulos, 1972](#)).

The final adult version of the α chain is produced exclusively by 6 weeks—after this there are no functional alternative versions. If an α gene mutation or deletion occurs, there is thus no alternate α type chain which could substitute to form functional hemoglobin. In contrast, at least two versions of the β chain, delta and gamma, remain in production throughout fetal life and beyond. In the case of a β gene mutation or deletion, these two other versions of the β chain often continue to be produced resulting in hemoglobin A₂ or hemoglobin F, which substitute for the abnormal or missing hemoglobin.

The mechanism by which genes are turned off is methylation of the control region ([Chap. 36](#), p. 963). Thus the switch from the various embryonic hemoglobins to hemoglobin A likely is associated with methylation of the early globin genes. In some situations, methylation does not occur, and in newborns of diabetic women there may be persistence of hemoglobin F from hypomethylation of the γ -gene ([Perrine and associates, 1988](#)). With sickle cell anemia, the γ -gene remains unmethylated, and large quantities of fetal hemoglobin continue to be produced ([Chap. 49](#), p. 1319).

There is a functional difference between hemoglobin A and F. At any given oxygen tension and at identical pH, fetal erythrocytes that contain mostly hemoglobin F bind more oxygen than do erythrocytes that contain nearly all hemoglobin A (see [Fig. 43-4](#), p. 1166). The major reason for this is that hemoglobin A binds 2,3-diphosphoglycerate (2,3-DPG) more avidly than does hemoglobin F and this lowers the affinity of hemoglobin A for oxygen ([De Verdier and Garby, 1969](#)). The increased oxygen affinity of the fetal erythrocyte results from a lower concentration of 2,3-DPG compared with that of the maternal erythrocyte in which the 2,3-DPG level is increased during pregnancy.

The amount of hemoglobin F in fetal erythrocytes falls somewhat during the latter weeks of pregnancy. At term, about three fourths of the total hemoglobin normally is hemoglobin F. During the first 6 to 12 months of life, the proportion of hemoglobin F continues to decrease, eventually to reach the low level found in erythrocytes of normal adults. One factor that appears to mediate the switch from fetal to adult hemoglobin is the action of glucocorticosteroids, the effect of which is irreversible ([Zitnik and associates, 1995](#)).

COAGULATION FACTORS IN THE FETUS. There are no embryonic forms of the various hemostatic proteins. With the exception of fibrinogen, the fetus starts producing normal, adult-type, procoagulant, fibrinolytic, and anticoagulant proteins by about 12 weeks, but at appreciably reduced levels. The fetus does not benefit from the higher levels of these proteins found in maternal blood, as they do not cross the placenta. The concentrations of several coagulation factors at birth are thus markedly below the levels that develop within a few weeks of life ([Corrigan, 1992](#)). Factors that are low in cord blood are II, VII, IX, X, XI, XII, XIII, and fibrinogen. Without prophylactic vitamin K treatment, K-dependent coagulation factors usually decrease even further during the first few days after birth, especially in breast-fed infants, and may lead to hemorrhage in the newborn (see [Chap. 39](#), p. 1071).

Fetal fibrinogen, which appears as early as 5 weeks, has the same amino acid composition as adult fibrinogen, but has different properties ([Klagsburn and colleagues, 1988](#)). It forms a less compressible clot and the fibrin monomer has a lower degree of aggregation ([Heimark and Schwartz, 1988](#)). For reasons unknown, the time for conversion of fibrinogen in plasma to fibrin clot when thrombin is added (thrombin time) is somewhat prolonged compared with that of older children and adults. Fibrinogen levels at birth are somewhat less than in nonpregnant adults.

Functional factor XIII (fibrin-stabilizing factor) levels in plasma are significantly reduced compared with those in normal adults ([Henriksson and co-workers, 1974](#)). Severe deficiencies of factor VIII, IX, XI, or XIII are usually suspected after observing a continuous "ooze" from the umbilical stump. [Nielsen \(1969\)](#) described low levels of plasminogen and somewhat increased fibrinolytic activity in cord plasma compared with maternal plasma. Platelet counts in cord blood are in the normal range for nonpregnant adults.

Despite this relative reduction in protein factors necessary for coagulation, the fetus seems to be protected from hemorrhage, and fetal bleeding is a rare event. Excessive bleeding does not usually occur even after invasive fetal procedures like cordocentesis. [Ney and colleagues \(1989\)](#) have shown that amniotic fluid thromboplastins and some factor in Wharton jelly combine to facilitate coagulation at the umbilical cord puncture site.

A variety of thrombophilias such as protein C, S, or antithrombin III deficiency, or the Leiden (factor V) mutation may cause thromboses and pregnancy complications in adults ([Chap. 49](#), p. 1332). If the fetus inherits one of these mutations, thrombosis and infarction can develop. [Thorarensen and colleagues \(1997\)](#) described three neonates with ischemic infarction or hemorrhagic stroke who were heterozygous for factor V Leiden mutation. One had multiple thromboses in the placental vasculature. Similarly, [Tharakan and co-workers \(1993\)](#) described a stillbirth followed by maternal pulmonary embolism associated with protein S deficiency.

FETAL PLASMA PROTEINS. Liver enzymes and other plasma proteins are produced by the fetus, and these levels do not correlate with maternal levels ([Weiner and colleagues, 1992](#)). Concentrations of plasma protein, albumin, lactic dehydrogenase, aspartate aminotransferase, γ -glutamyl transpeptidase, and alanine transferase all increase with gestational age. At birth, the mean total plasma protein and albumin concentrations in fetal blood are similar to maternal levels ([Foley and associates, 1978](#)).

ONTOGENY OF THE FETAL IMMUNE RESPONSE. Infections in utero have provided an opportunity to examine some of the mechanisms for immune response by the human fetus. Evidence of immunological competence has been reported as early as 13 weeks. [Altshuler \(1974\)](#) described infection of the placenta and fetus by cytomegalovirus with characteristic severe inflammatory cell proliferation as well as viral inclusions. Fetal synthesis of complement late in the first trimester has been demonstrated by [Kohler \(1973\)](#) and confirmed by [Stabile and co-workers \(1988\)](#). All components of complement are produced at an early stage of fetal development. In cord blood at or near term, the average level for most components is about half of the adult value ([Adinolfi, 1977](#)).

IMMUNOCOMPETENCE OF THE FETUS. In the absence of a direct antigenic stimulus, such as infection, the immunoglobulins in the fetus consist almost totally of immune globulin G (IgG⁸) synthesized in the maternal compartment and subsequently transferred across the placenta by receptor-mediated processes in syncytiotrophoblast, as described later. Therefore, antibodies in the fetus and the newborn infant are most often reflective of maternal immunological experiences.

IMMUNOGLOBULIN G. IgG⁹ transport from mother to fetus begins at about 16 weeks and increases thereafter. The bulk of IgG is acquired by the fetus from the mother during the last 4 weeks of pregnancy ([Gitlin, 1971](#)). Accordingly, preterm infants are endowed relatively poorly with maternal antibodies. Newborns begin to produce IgG, but slowly and, adult values are not attained until 3 years of age. In certain situations, the transfer of IgG antibodies from mother to fetus can be harmful rather than protective to the fetus. The classical example is hemolytic disease of the fetus and newborn resulting from D-antigen isoimmunization ([Chap. 39](#), p. 1057).

IMMUNOGLOBULIN M. In the adult, production of immune globulin M (IgM) in response to antigen is superseded in a week or so predominantly by production of IgG¹⁰. In contrast, the IgM¹¹ response is dominant in the fetus and remains so for weeks to months in the newborn. IgM is not transported from mother to fetus; therefore, any IgM in the fetus or newborn is that which it produced. Very little IgM is produced by normal, healthy fetuses and that which is produced may include antibody to maternal T lymphocytes ([Hayward, 1983](#)). Increased levels of IgM are also found in newborns with congenital infection such as rubella, cytomegalovirus, or toxoplasmosis. Serum IgM levels in umbilical cord blood and identification of specific antibodies may be useful in the diagnosis of intrauterine infection. Adult levels of IgM are normally attained by 9 months of age.

IMMUNOGLOBULIN A. Differing from many animals, the human newborn infant does not acquire much in the way of passive immunity from the absorption of humoral antibodies ingested in colostrum. Nevertheless, immunoglobulin A (IgA¹²) ingested in colostrum provides mucosal protection against enteric infections. This is likely also true for IgA ingested with amniotic fluid before delivery.

LYMPHOCYTES. The immune system begins to mature early in fetal life. B lymphocytes appear in liver by 9 weeks and are present in blood and spleen by 12 weeks. T lymphocytes begin to leave the thymus at about 14 weeks ([Hayward, 1983](#)). Despite this, the newborn responds poorly to immunization, and especially poorly to bacterial capsular polysaccharides. This immaturity of response may be due to either deficient response of newborn B cells to polyclonal activators, or lack of T cells

that proliferate in response to specific stimuli ([Hayward, 1983](#)).

MONOCYTES. In the newborn, monocytes are able to process and present antigen when tested with maternal antigen-specific T cells.

NERVOUS SYSTEM AND SENSORY ORGANS

The spinal cord extends along the entire length of the vertebral column in the embryo, but after that it grows more slowly. By 24 weeks, the spinal cord extends only to S₁, at birth to L₃, and in the adult to L₁. Myelination of the spinal cord begins in the middle of gestation and continues through the first year of life. Synaptic function is sufficiently developed by the eighth week to demonstrate flexion of neck and trunk ([Temiras and co-workers, 1968](#)). At 10 weeks, local stimuli may evoke squinting, opening the mouth, incomplete finger closure, and plantar flexion of the toes. Complete finger closure is achieved during the fourth lunar month. Swallowing begins at about 10 weeks and respiration is evident at 14 to 16 weeks ([Miller, 1982](#)). Rudimentary taste buds are present at 7 weeks, and mature receptors are present by 12 weeks ([Mistretta, 1975](#)). The ability to suck is not present until at least 24 weeks ([Lebenthal and Lee, 1983](#)). During the third trimester, integration of nervous and muscular function proceeds rapidly.

The internal, middle, and external components of the ear are well developed by midpregnancy. The fetus apparently hears some sounds in utero as early as 24 to 26 weeks. By 28 weeks, the eye is sensitive to light, but perception of form and color is not complete until long after birth.

GASTROINTESTINAL TRACT

Swallowing begins at 10 to 12 weeks, coincident with the ability of the small intestine to undergo peristalsis and transport glucose actively ([Koldovsky and colleagues, 1965](#); [Miller, 1982](#)). Much of the water in swallowed fluid is absorbed, and unabsorbed matter is propelled as far as the lower colon ([Fig. 7-12](#)). It is not clear what stimulates swallowing, but the fetal neural analog of thirst, gastric emptying, and change in the amniotic fluid composition are potential factors ([Boyle, 1992](#)). The fetal taste buds may play a role because saccharin injected into amniotic fluid increases swallowing, while injection of a noxious chemical inhibits it ([Liley, 1972](#)). Fetal swallowing appears to have little effect on amniotic fluid volume early in pregnancy, because the volume swallowed is small compared with the total volume. Late in pregnancy, however, the volume of amniotic fluid appears to be regulated substantially by fetal swallowing, for when swallowing is inhibited, hydramnios is common ([Chap. 31](#), p. 817). Term fetuses reportedly swallow between 200 and 760 mL per day—an amount comparable with the neonate ([Pritchard, 1966](#)).

In late pregnancy, swallowing serves to remove some of the insoluble debris that is normally shed into the amniotic sac and sometimes abnormally excreted into it. Hydrochloric acid and some adult digestive enzymes are present in the stomach and small intestine in very small amounts in the early fetus. Intrinsic factor is detectable by 11 weeks, and pepsinogen by 16 weeks. In the preterm infant, however, transient deficiencies of these enzymes are often present depending upon the gestational age when born ([Lebenthal and Lee, 1983](#)).

Stomach emptying appears to be stimulated primarily by volume. Movement of amniotic fluid through the gastrointestinal system may enhance growth and development of the alimentary canal and condition the fetus for alimentation after birth. Other regulatory factors may be involved, however, as anencephalic fetuses, in whom swallowing is limited, often have normal amniotic fluid volumes and normal appearing gastrointestinal tracts. The undigested portions of the swallowed debris can be identified in meconium. The amniotic fluid swallowed probably contributes little to the caloric requirements of the fetus but may contribute essential nutrients. [Gitlin \(1974\)](#) demonstrated that late in pregnancy about 0.8 g of soluble protein, approximately half albumin, appears to be ingested by the fetus each day.

Several anomalies can affect normal fetal gastrointestinal function. *Hirschsprung disease*, or *congenital aganglionic megacolon*, prevents the bowel from undergoing parasympathetic-mediated relaxation and thus emptying normally ([Watkins, 1992](#)). It may be recognized prenatally by grossly enlarged bowel on sonography. Obstructions such as duodenal atresia, megacystis/microcolon syndrome, or imperforate anus can also prevent the bowel from emptying normally. Meconium ileus, commonly found with fetal cystic fibrosis, is bowel obstruction caused by thick, viscid meconium which blocks the distal ileum.

MECONIUM. This consists not only of undigested debris from swallowed amniotic fluid, but to a larger degree, of various products of secretion such as glycerophospholipids from the lung, desquamated fetal cells, lanugo, scalp hair, and vernix. The dark greenish-black appearance is caused by pigments, especially biliverdin. Meconium passage can occur as the result of normal bowel peristalsis in the mature fetus or as the result of vagal stimulation due to cord compression. It can also occur when hypoxia stimulates arginine vasopressin (AVP) release from the fetal pituitary gland. [AVP¹³](#) stimulates the smooth muscle of the colon to contract, resulting in intra-amniotic defecation ([DeVane and co-workers, 1982](#); [Rosenfeld and Porter, 1985](#)).

Small bowel obstruction may lead to vomiting in utero ([Shrand, 1972](#)). Fetuses who suffer from congenital chloride diarrhea may have diarrhea in utero, which leads to hydramnios and preterm delivery ([Holmberg and associates, 1977](#)).

LIVER. Hepatic function in the fetus differs, in several ways, from that of the adult. As discussed earlier, fetal liver enzyme levels increase with gestational age, but are present in reduced amounts compared with those in later life. The liver has a very limited capacity for converting free bilirubin to bilirubin diglucuronoside ([Chap. 39](#), p. 1067). The more immature the fetus, the more deficient the system for conjugating bilirubin.

Because the life span of fetal erythrocytes is shorter than that of adult erythrocytes, relatively more bilirubin is produced. Most of the bilirubin is transferred to the maternal circulation through the placenta ([Bashore and colleagues, 1969](#)). The fetal liver conjugates only a small fraction, which is excreted through the biliary tract into the intestine and ultimately oxidized to biliverdin. Unconjugated bilirubin, however, is excreted into the amniotic fluid after 12 weeks and is then transferred across the placenta. Placental transfer, however, is bidirectional. To illustrate, a pregnant woman with sickle cell anemia who was isoimmunized as the result of red cell transfusions could not be evaluated with amniotic fluid OD_{450} measurements because maternal bilirubin readily passed into the amniotic fluid ([Goepfert and colleagues, personal communication](#)). Conjugated bilirubin is not exchanged to any significant degree between mother and fetus.

Most of the cholesterol in the fetus is produced in fetal liver. Indeed, the large demand for [LDL¹](#) cholesterol by the fetal adrenal glands is met primarily by fetal hepatic synthesis.

Glycogen is present in low concentration in fetal liver during the second trimester, but near term there is a rapid and marked increase to levels two to three times those in adult liver. After birth, glycogen content falls precipitously.

PANCREAS. The discovery of insulin by [Banting and Best \(1922\)](#) came from its extraction from the fetal calf pancreas. Insulin-containing granules can be identified in the human fetal pancreas by 9 to 10 weeks, and insulin in fetal plasma is detectable at 12 weeks ([Adam and associates, 1969](#)). The fetal pancreas responds to hyperglycemia by increasing plasma insulin ([Obenshain and colleagues, 1970](#)). Although the precise role of insulin of fetal origin is not clear, fetal growth must be determined to a considerable extent by the amounts of basic nutrients from the mother with anabolism through the action of fetal insulin. Serum insulin levels are high in newborns of diabetic mothers and in other large-for-gestational-age infants, but insulin levels are low in infants who are small-for-gestational age ([Brinsmead and Liggins, 1979](#)). This relationship is discussed further in [Chapter 29](#).

Glucagon has been identified in the fetal pancreas at 8 weeks. Induced hypoglycemia and infused alanine cause an increase in maternal glucagon levels in the rhesus monkey, yet similar stimuli to the fetus do not. Within 12 hours of birth, however, the infant is capable of responding ([Chez and co-workers, 1975](#)). Fetal pancreatic α -cells are capable of responding to L-dopa ([Epstein and associates, 1977](#)). Therefore, α -cell nonresponsiveness to hypoglycemia is likely the consequence of failure of glucagon release rather than inadequate production. This is consistent with findings of the developmental expression of pancreatic genes in the fetus ([Mally and associates, 1994](#)).

Most pancreatic enzymes are present by 16 weeks. Trypsin, chymotrypsin, phospholipase A, and lipase are present in the 14-week fetus at low levels, and they increase with gestational age ([Werlin, 1992](#)). Amylase has been identified in amniotic fluid at 14 weeks ([Davis, 1986](#)).

The exocrine function of the fetal pancreas is limited. Physiologically important secretion occurs only after stimulation by a secretagogue such as acetylcholine, which is released locally after vagal stimulation ([Werlin, 1992](#)). Cholecystikinin is normally released only after ingestion of protein, and thus would not ordinarily be found in the fetus. Its release, however, can be stimulated experimentally. [Pritchard \(1965\)](#) injected radioiodine-labeled albumin into the amniotic sac where it was swallowed by the fetus, digested, and absorbed from the fetal intestine. Evidence of digestion and absorption was provided by the prompt excretion of the iodine in the maternal urine.

URINARY SYSTEM

Two primitive urinary systems, the pronephros and the mesonephros, precede the development of the metanephros. The pronephros has involuted by 2 weeks and the mesonephros is producing urine at 5 weeks and degenerates by 11 to 12 weeks. Failure of these two structures either to form or to regress may result in anomalous development of the definitive urinary system. Between 9 and 12 weeks, the ureteric bud and the nephrogenic blastema interact to produce the metanephros. By week 14 the loop of Henle is functional and reabsorption occurs ([Smith and associates, 1992](#)). New nephrons continue to be formed until 36 weeks, however, and their formation continues after birth in preterm infants.

Although the fetal kidneys produce urine, their ability to concentrate and modify the pH of urine is quite limited even in the mature fetus. Fetal urine is hypotonic with respect to fetal plasma and has low concentrations of electrolytes. In the human fetus, the kidneys receive between 2 and 4 percent of the cardiac output, compared with 15 and 18 percent in the newborn ([Gilbert, 1980](#)). Renal vascular resistance is high and the filtration fraction is low compared with later life ([Smith, 1992](#)). Fetal renal blood flow and thus urine production are controlled or influenced by the renin-angiotensin system, the sympathetic nervous system, prostaglandins, kallikrein, and atrial natriuretic factor. The glomerular filtration rate is low in the fetus, but increases with gestational age from less than 0.1 mL/min at 12 weeks to 0.3 mL/min at 20 weeks. In later gestation, the glomerular filtration rate remains constant when corrected for fetal weight ([Smith and colleagues, 1992](#)). Hemorrhage or hypoxia generally results in a decrease in renal blood flow, glomerular filtration rate, and urine output.

Urine is usually found in the bladder even in small fetuses. The fetal kidneys start producing urine at 12 weeks' gestation. By 18 weeks they are producing 7 to 14 mL/day, and at term this increases to 27 mL/hr or 650 mL/day ([Wladimiroff and Campbell, 1974](#)). Maternally administered diuretics (furosemide) increase fetal urine formation, and uteroplacental insufficiency and other types of fetal stress decrease it. [Kurjak and associates \(1981\)](#) found that fetal glomerular filtration rates and fetal tubular water reabsorption were decreased in 33 percent of growth-restricted infants and in 17 percent of infants of diabetic mothers. All values were normal in anencephalic infants and in cases of polyhydramnios.

Obstruction of the urethra, bladder, ureters, or renal pelvis can damage renal parenchyma and distort fetal anatomy; the bladder may become sufficiently distended that it ruptures or dystocia results. Kidneys are not essential for survival in utero, but are important in the control of the composition and volume of amniotic fluid. Furthermore, abnormalities that cause chronic anuria are usually accompanied by oligohydramnios and hypoplasia of the lungs. Pathological correlates and prenatal therapy of urinary tract obstruction are discussed in [Chapter 37 \(p. 995\)](#).

PULMONARY SYSTEM

As discussed in [Chapter 39 \(p. 1042\)](#), the timetable of lung maturation and the identification of biochemical indices of functional fetal lung maturity are of considerable importance (and concern) to the obstetrician. Morphological or functional immaturity of the lung at birth leads to the development of the respiratory distress syndrome, and complicates the course and treatment of other neonatal disorders.

The presence of a sufficient amount of surface-active materials in the amniotic fluid is usually taken as evidence of fetal lung maturity. As [Liggins \(1994\)](#) emphasized, however, the structural and morphological maturation of fetal lung also is extraordinarily important to proper lung function in newborns. It is also important to the choice of therapeutic agents used to hasten fetal lung maturation when preterm delivery seems likely or mandated. Therefore, two separate but complementary aspects of fetal lung maturation must be considered. These are anatomical and morphological development and the capacity of fetal lung for surfactant formation.

ANATOMICAL MATURATION OF THE FETAL LUNG. Like the branching of a tree, lung development proceeds along an established timetable that apparently cannot be hastened by antenatal or neonatal therapy. The limits of viability, therefore, appear to be determined by the usual process of pulmonary growth. There are three essential stages of lung development as described by [Moore \(1983\)](#). During the *pseudoglandular stage*, which entails the growth of the intrasegmental bronchial tree between the fifth and 17th weeks, the lung looks microscopically like a gland. This period is followed by the *canalicular stage*, from 16 to 25 weeks, during which the bronchial cartilage plates extend peripherally. Each terminal bronchiole gives rise to several respiratory bronchioles, and each of these in turn divides into multiple saccular ducts. The final stage is the *terminal sac stage*, during which the alveoli give rise to the primitive pulmonary alveoli, called the terminal sacs. Simultaneously, an extracellular matrix develops from proximal to distal lung segments until term, an extensive capillary network develops, the lymph system forms, and the type II cells start to produce surfactant. At birth, only about 15 percent of the adult number of alveoli are present, and thus the lung continues to grow, adding more alveoli, from late fetal life up to about 8 years.

Various insults can upset this process, and the timing of the insult determines the outcome. With renal agenesis, for example, no amniotic fluid is present from the beginning of lung growth, and major defects occur in all three stages. The fetus with membrane rupture before 20 weeks usually exhibits nearly normal bronchial branching and cartilage development but has immature alveoli. Membrane rupture occurring after 24 weeks may have little long-term effect on pulmonary structure.

SURFACTANT. After birth, the terminal sacs must remain expanded despite the pressure imparted by the tissue-air interface within them; surfactant keeps them from collapsing. There are more than 40 cell types in the lung, but surfactant is formed specifically in the type II pneumocytes that line the alveoli ([Fig. 7-13](#)). The type II cells are characterized by multivesicular bodies which produce the lamellar bodies in which surfactant is assembled. During late fetal life, at a time when the alveolus is characterized by a water-to-tissue interface, the intact lamellar bodies are secreted from the lung and swept into the amniotic fluid during fetal respiratory-like movements, that is, fetal breathing.

At birth, with the first breath, an air-to-tissue interface is produced in the lung alveolus. This permits surfactant to uncoil from the lamellar bodies; the surface tension-lowering material then spreads to line the alveolus and thereby prevents alveolar collapse during expiration. Therefore, it is the capacity for fetal lungs to produce surfactant, and not the actual laying down of this material in the lungs in utero, that establishes lung maturity before birth.

SURFACTANT COMPOSITION. The principal surface-active component of surfactant is a specific lecithin, or dipalmitoylphosphatidylcholine. From the work of [Gluck and associates \(1967, 1970, 1972\)](#) and [Hallman and co-workers \(1976\)](#), it is now known that about 90 percent of surfactant (dry weight) is lipid. Proteins account for the other 10 percent of surfactant mass.

Approximately 80 percent of the glycerophospholipids are phosphatidylcholines (lecithins), of which disaturated lecithin, accounts for nearly 50 percent ([Fig. 7-14](#)). Phosphatidylglycerol, the second most surface-active glycerophospholipid component of surfactant, accounts for 8 to 15 percent ([Keidel and Gluck, 1975](#)). Phosphatidylglycerol is capable of reducing surface tension in the alveolus, but its precise role is unclear. Infants born with a "mature" L/S ratio, but without phosphatidylglycerol, usually do well.

SURFACTANT SYNTHESIS. Surfactant biosynthesis takes place in the type II cells of the lung. The apoproteins are produced in the endoplasmic reticulum and the glycerophospholipids are synthesized by cooperative interactions of several cellular organelles. Phospholipid is the primary surface tension-lowering component of surfactant, while the surfactant apoproteins serve to facilitate the forming and re-forming of a surface film in the alveoli during respiration.

The surface properties of the surfactant phospholipids are determined by the composition and degree of saturation of the long chain fatty acids, the presence and identity of minor lipids and proteins, and the temperature. The regulation of phosphatidylglycerol synthesis is especially important. [Hallman and co-workers \(1976\)](#) have shown that increased surfactant concentrations of phosphatidylglycerol, together with decreased concentrations of phosphatidylinositol, also herald lung maturation ([Fig. 7-15](#)).

Three surfactant-associated proteins are known: surfactant proteins A, B, and C ([Whitsett, 1992](#)). The major apoprotein is surfactant A (SP-A), a glycoprotein (M_r about 28,000 to 35,000). It is synthesized in the type II cells, and increased synthesis is related temporally to increased surfactant formation in maturing fetal lungs. The amniotic fluid content of SP-A also increases, as does the L/S ratio, as a function of gestational age and fetal lung maturity. Synthesis of SP-A is known to be increased by treatment of fetal lung tissue with cyclic AMP (analogues) and by epidermal growth factor and triiodothyronine. SP-A seems to be important in the structural transformation of the secreted lamellar body into tubular myelin within the lumen of the alveolus. SP-A also may be involved in the endocytosis and recycling of secreted surfactant by the type II cells.

There are also a number of smaller molecular weight apoproteins (M_r about 5000 to 18,000). SP-B and SP-C are believed to be important in optimizing the surface-active properties of surfactant. Deletions in the surfactant SP-B gene have been discovered. Newborns with this abnormality do not survive despite the production of large amounts of surfactant lipids. In addition, SP-A, after being taken back into the type II cells by receptor-mediated endocytosis, acts to inhibit surfactant glycerophospholipid synthesis and secretion.

Increases in surfactant apoprotein synthesis precede the increase in surfactant glycerophospholipid synthesis ([Mendelson and associates, 1986](#)). SP-A gene expression is not detectable at 16 to 20 weeks, but is demonstrable at 29 weeks (Snyder and colleagues, 1988). More recently it has been demonstrated that there are two separate SP-A genes (SP-A1 and SP-A2), and that the regulation of synthesis of these two genes (chromosome 10) is distinctive and different. [McCormick](#)

and Mendelson (1994) found that the two SP-A genes are differentially regulated. Cyclic AMP is more important in SP-A2 expression (11-fold), whereas dexamethasone caused a decrease in SP-A2 expression.

CORTICOSTEROIDS AND FETAL LUNG MATURATION. Liggins (1969) observed that there appeared to be accelerated lung maturation in lambs delivered preterm that had been treated with glucocorticosteroids prior to birth. Since that time, many investigators have suggested that cortisol, produced in the fetal adrenal glands, is the natural stimulus for lung maturation and augmented surfactant synthesis. Corticosteroids may not be the only stimulus for augmented surfactant formation in the maturing human fetal lung. Respiratory distress syndrome is not necessarily observed in human neonates in whom the capacity to secrete cortisol is limited, such as those with anencephaly, adrenal hypoplasia, or congenital adrenal hyperplasia. There is now appreciable evidence that glucocorticosteroids administered in large amounts to the woman at certain critical times during gestation effect an increase in the rate of fetal lung maturation. In addition, the advent of neonatal surfactant therapy, given alone or after prenatal corticosteroid treatment, has significantly reduced the incidence of respiratory disease. The use of betamethasone to accelerate fetal lung maturity followed by surfactant therapy as needed is widely accepted, as discussed in [Chapters 27 \(p. 708\)](#) and [39 \(p. 1040\)](#).

OTHER THERAPIES USED FOR FETAL LUNG MATURATION. Buoyed by the success of betamethasone, or perhaps dismayed by its side effects, investigators have searched for other pharmacological means to hasten fetal pulmonary maturity. Animal studies suggested that administration of *thyroxine* to fetuses at various stages of gestation was associated with accelerated lung maturation and an early appearance of osmophilic lamellar inclusions within the type II pneumocytes (Rooney and colleagues, 1974; Wu and associates, 1971, 1973). Others found that thyroxine had no effect on the activities of the enzymes involved in surfactant synthesis or surfactant concentration (Mason, 1973; Rooney and associates, 1974). Others have tested maternally administered *aminophylline*, *prolactin*, *cAMP*, and *thyroid-releasing hormone* (Ballard and colleagues, 1992; DiRenzo and associates, 1989; O'Brien, 1991). One multicenter randomized trial compared betamethasone alone to betamethasone plus thyrotropin-releasing hormone in 190 women in preterm labor, and found no difference in outcome between the two groups (Collaborative Santiago Surfactant Group, 1998). None of the studies to date have documented significant additional benefit from therapies other than betamethasone given to the mother 24 to 48 hours before delivery followed by neonatal surfactant therapy.

RESPIRATION. Within a very few minutes after birth, the respiratory system must be able to provide oxygen as well as eliminate carbon dioxide. Respiratory muscles develop early and movements of the fetal chest wall have been detected by ultrasonic techniques as early as 11 weeks (Boddy and Dawes, 1975). From the beginning of the fourth month, the fetus is capable of respiratory movement sufficiently intense to move amniotic fluid in and out of the respiratory tract. In the radiograph in [Figure 7-12](#), obtained 26 hours after injection of radiopaque dye into the amniotic sac, the contrast medium is present in fetal lung.

VAGITUS UTERI. Crying in utero is a rare phenomenon. After rupture of the membranes, air may gain access to the amniotic cavity and be inspired by the fetus. Thiery and associates (1973) described three cases in which fetal crying was heard during vaginal examination, amnioscopy, or application of a clip electrode to the fetus. Fetal hiccupping is a more common phenomenon, and frequently the movement produced by the fetus is appreciated by the mother.

ENDOCRINE GLANDS

PITUITARY GLAND. The fetal endocrine system is functional for some time before the central nervous system reaches a state of maturity competent to perform many functions associated with homeostasis (Mulchahey and co-workers, 1987). The endocrine system of the fetus does not necessarily mimic that of the adult, but nonetheless may be one of the first homeostatic systems to develop. The fetal pituitary develops from two different sources. The adenohypophysis develops from the oral ectoderm—Rathke pouch; and the neurohypophysis develops from the neuroectoderm.

ANTERIOR PITUITARY. The adenohypophysis, or anterior pituitary, differentiates into five cell types which secrete six protein hormones: (1) lactotropes, producing prolactin (PRL); (2) somatotropes, producing growth hormone (GH); (3) corticotropes, producing corticotropin (ACTH); (4) thyrotropes, producing thyroid-stimulating hormone (TSH); and (5) gonadotropes, producing luteinizing hormone (LH) and follicle-stimulating hormone (FSH). ACTH is first detected in the fetal pituitary gland at 7 weeks, and before the end of the 17th week the fetal pituitary gland is able to synthesize and store all pituitary hormones. GH¹⁴, ACTH, and LH have been identified by 13 weeks. Moreover, the fetal pituitary is responsive to hypophysiotropic hormones and is capable of secreting these hormones from early in gestation (Grumbach and Kaplan, 1974).

The levels of immunoreactive growth hormone are rather high in cord blood, although its role in fetal growth and development is not clear. Anencephalic fetuses, with little pituitary tissue, are not remarkably different in weight from normal fetuses. The fetal pituitary produces and releases β -endorphin in a manner separate from maternal plasma levels (Browning and colleagues, 1983). Furthermore, cord blood levels of β -endorphin and β -lipotropin were found to decrease with declining fetal pH but correlate in a positive manner with fetal Pco₂.

NEUROHYPOPHYSIS. This is well developed by 10 to 12 weeks, and oxytocin and arginine vasopressin (AVP¹⁵) are demonstrable. In addition, the neurohypophyseal hormone of submammalian vertebrates, arginine vasotocin (AVT), is present in fetal pituitary and pineal glands. AVT¹⁶ is present only in fetal life in humans (Fisher, 1986). It is probable that oxytocin as well as AVP function in the fetus to conserve water by actions largely at the level of lung and placenta rather than kidney. Levels of AVP in umbilical cord plasma are increased strikingly compared with the maternal levels (Chard and associates, 1971; Polin and co-workers, 1977). AVP in cord and fetal blood appears to be elevated with fetal stress (DeVane and Porter, 1980; DeVane and co-workers, 1982).

INTERMEDIATE PITUITARY GLAND. There is a well-developed intermediate lobe in the pituitary gland of the human fetus. The cells of this structure begin to disappear before term and are absent from the pituitary of adults. The principal secretory products of the intermediate lobe cells are α -melanocyte-stimulating hormone (α -MSH) and β -endorphin. The levels of fetal α -MSH decrease progressively with gestation.

THYROID. The pituitary-thyroid system is functional by the end of the first trimester (Table 7-4). The thyroid gland is able to synthesize hormones by 10 to 12 weeks, and TSH¹⁷, thyroxine, and thyroid-binding globulin have been detected in fetal serum as early as 11 weeks (Ballabio and colleagues, 1989). The placenta actively concentrates iodide on the fetal side and, by 12 weeks and throughout pregnancy, the fetal thyroid concentrates iodide more avidly than does the maternal thyroid. Thus, administering either radioiodide or appreciable amounts of ordinary iodide to the mother is hazardous after this time. Normal fetal levels of free T₄, free T₃, and thyroxin-binding globulin increase steadily throughout gestation (Ballabio and associates, 1989). Fetal serum concentrations of TSH are higher than the adult level and total and free T₃ concentrations are lower than the adult level, while the T₄ concentration is similar to that in adults by 36 weeks. This suggests that the fetal pituitary may not become sensitive to feedback until late in fetal life (Thorpe-Beeston and co-workers, 1991; Wenstrom and colleagues, 1990).

Fetal thyroid hormone plays a role in the normal development of virtually all fetal tissues, but especially the brain. Its influence is illustrated by congenital hyperthyroidism, which occurs when maternal thyroid-stimulating antibody crosses the placenta to stimulate the fetal thyroid. These fetuses develop tachycardia, hepatosplenomegaly, hematological abnormalities, craniosynostosis, and growth restriction. As children they have perceptual motor difficulties, hyperactivity, and reduced growth (Wenstrom and colleagues, 1990).

Placental tissue and membranes appear to prevent substantial passage of maternal thyroid hormones to the fetus by rapidly deiodinating maternal T₄ and T₃ to reverse -T₃, a relatively inactive form (Vulsma and colleagues, 1989). However, the long-acting thyroid stimulators, LATS and LATS-protector, and thyroid-stimulating immunoglobulin cross the placenta readily when present in high concentrations in the mother (Chap. 50, p. 1341).

Maternal thyroid hormones cross the placenta to a very limited degree, as illustrated by congenital hypothyroidism. The latter results in a variety of neonatal problems, including neurological abnormalities, respiratory difficulties, dysmorphic facies, lethargy and hypotonia, and myxedema of the larynx and epiglottis. These problems typically develop only after birth, and can be avoided with prompt thyroid replacement. Although it was previously thought that normal fetal growth and development provided evidence that the thyroid was not essential for fetal growth, it is now known that this proceeds normally without fetal thyroid hormone because small quantities of maternal T₄ reach the fetus and prevent antenatal cretinism. Vulsma and colleagues (1989) studied fetuses who were markedly hypothyroid because of thyroid agenesis or because they had congenital absence of thyroid peroxidase, an enzyme necessary for iodination of thyroglobulin. They found that fetal levels of T₄ were very low and represented maternal hormone that crossed the placenta.

Immediately after birth, there are major changes in thyroid function and metabolism. Atmospheric cooling evokes sudden and marked increase in thyrotropin secretion, which in turn causes a progressive increase in serum T₄ levels maximal 24 to 36 hours after birth. There are nearly simultaneous elevations of serum T₃ levels. Failure of these changes to occur, such as when the fetus is congenitally hypothyroid, causes multiple problems including cretinism, a form of mental retardation resulting from postnatal brain injury.

ADRENAL GLANDS. These are much larger in relation to total body size than in adults. The bulk of the enlargement is made up of the inner or so-called *fetal zone* of

the adrenal cortex. The normally hypertrophied fetal zone involutes rapidly after birth. It is scant to absent in rare instances where the fetal pituitary gland is congenitally absent. The function of the fetal adrenal glands and the control of fetal adrenal steroidogenesis (dehydroepiandrosterone sulfate and cortisol) are discussed in detail in [Chapter 6 \(p. 118\)](#).

The fetal adrenal glands also synthesize aldosterone. In one study, aldosterone levels in cord plasma near term exceeded those in maternal plasma, as did renin and renin substrate ([Katz and colleagues, 1974](#)). The renal tubules of the newborn, and presumably the fetus, appear relatively insensitive to aldosterone ([Kaplan, 1972](#)).

FETAL GENDER

The establishment of the primary sex ratio in humans is impractical, for it would require the recovery and assignment of sex to zygotes that fail to cleave, blastocysts that fail to implant, and early pregnancy losses. [Carr \(1963\)](#) suggested that the primary sex ratio in humans may be unity. The secondary sex ratio, however, that is, the sex ratio of fetuses that reach viability is usually quoted as approximately 106 males to 100 females. Studies from industrialized nations more recently suggest that the proportion of male births is dropping. [Davis and colleagues \(1998\)](#) report a significant decline in male births since 1950 in Denmark, Sweden, the Netherlands, the United States, Germany, Norway, and Finland. [Allan and co-workers \(1997\)](#) reviewed the male:female ratio for all live births in Canada and found that since 1970, the proportion of males has dropped by 2.2 male births per 1000 live births. In the Atlantic region, the decline was 5.6 male births per 1000!

Although theoretically there should be as many Y-bearing as X-bearing sperm, and thus a primary sex ratio of one at the time of fertilization, recent data dispute this. Many factors, such as differential susceptibility to toxins and other environmental exposures and concomitant medical disorders, have been shown to contribute to the sex at conception. Parental age appears to influence the primary sex ratio and [Manning \(1997\)](#) reported that couples with a large age discrepancy have an excess of male offspring. [James \(1986\)](#) theorizes that this may be due to high stress in urbanized society which may increase corticotropin secretion that stimulates maternal adrenal androgen secretion that favors male conceptions. If this is not the case, the unbalanced secondary sex ratio can only be explained by the loss of more female than male embryo-fetuses during the early months of pregnancy.

GENDER ASSIGNMENT AT BIRTH

The first thing that parents in the delivery room want to know is the sex of their infant. If the external genitalia of the newborn are ambiguous, the obstetrician faces a profound dilemma. [Griffin and Wilson \(1986\)](#) state that it is no exaggeration to say that the detection of sexual ambiguity in the newborn constitutes a true medical emergency. An incorrect assignment of gender portends grave psychological and social problems for the baby and family. Furthermore, several endocrinological causes of sexual ambiguity are associated with profound blood pressure instability and serious metabolic abnormalities.

It is no longer believed that the proper functional sex assignment for newborns with genital ambiguity can be made in the delivery room. Assignment to one sex or the other requires knowledge of the karyotypic sex, gonadal sex, hormonal milieu to which the fetus was exposed, anatomy, and all possibilities for surgical correction. In the past, many physicians simply assigned all infants with a small or likely insufficient phallus to the female gender. Based on what is now known of the role of fetal exposure to hormones in establishing sexual preference and behavior, it can be seen why such a policy caused gender identity disorder ([Slijper and colleagues, 1998](#)). Thus, the best approach is to tell the parents that the baby appears healthy, but to honestly admit that the sex will need to be determined by a series of tests. In order to develop a plan by which to determine the cause of ambiguous genitalia, the mechanisms of normal and abnormal sexual differentiation must be considered.

SEXUAL DIFFERENTIATION OF THE EMBRYO-FETUS

Ultimate gender differentiation is determined by chromosomal make-up, acting in conjunction with gonad development; together they result in phenotypic gender.

CHROMOSOMAL SEX. Genetic sex, XX or XY, is established at the time of fertilization of the ovum. For the first 6 weeks thereafter, however, the development of male and female embryos is morphologically indistinguishable. The differentiation of the primordial gonad into testis or ovary heralds the establishment of gonadal sex ([Fig. 7-16](#)).

GONADAL SEX. Primordial germ cells originate in the endoderm of the yolk sac and migrate to the genital ridge to form the indifferent gonad ([Simpson, 1997](#)). If a Y chromosome is present, at about 6 weeks after conception the gonad begins developing into a testis. Testes development is directed by a gene located on the short arm of Y, namely *testis-determining factor (TDF)*, also called *sex-determining region (SRY)*. This gene encodes a transcription factor that acts to modulate the rate of transcription of a number of genes involved in gonadal differentiation. The SRY gene is specific to the Y chromosome and is expressed in the human single-cell zygote immediately after ovum fertilization. It is not expressed in the spermatozoa ([Fiddler and co-workers, 1995](#); [Gustafson and Donahoe, 1994](#)).

In addition, testis development requires a *dose-dependent sex reversal (DDS)* region on the X chromosome, as well as yet unidentified autosomal genes. It is not clear how these genes, or the Y chromosome, direct the biomolecular events involved in gonadal differentiation into testis.

The contribution of chromosomal sex to gonadal sex is illustrated by several paradoxical conditions. The incidence of 46,XX phenotypic human males is estimated to be about 1 in 20,000 male births. These apparently result from translocation of the Y chromosome fragment containing TDF to the X chromosome during meiosis of male germ cells ([George and Wilson, 1988](#)). Similarly, individuals with XY chromosomes can appear phenotypically female if they carry a mutation in the TDF (SRY) gene. There is evidence that genes on Xp are capable of suppressing testicular development, despite the presence of the SRY gene. Indeed, this accounts for a form of X-linked recessive gonadal dysgenesis.

The existence of autosomal sex-determining genes is supported by several genetic syndromes in which disruption of an autosomal gene causes, among other things, gonadal dysgenesis. For example, campomelic dysplasia, localized to chromosome 17, is associated with XY sex reversal. Similarly, male pseudohermaphroditism has been associated with a mutation in the Wilms tumor suppressor gene on chromosome 11.

PHENOTYPIC SEX. After establishment of gonadal sex, phenotypic sex develops very rapidly. It is clear that male phenotypic sexual differentiation is directed by the function of the fetal testis. In the absence of the testis, female differentiation ensues irrespective of the genetic sex.

The development of urogenital tracts in both sexes of human embryos is indistinguishable before 8 weeks. Thereafter, development (differentiation) of the internal and external genitalia to the male phenotype is dependent upon testicular function. The fundamental experiments to determine the role of the testis in male sexual differentiation were conducted by the French anatomist, Alfred Jost. Ultimately, he established that the induced-phenotype is male and that secretions from the gonads are not necessary for female differentiation. Specifically, the fetal ovary is not required for female sexual differentiation.

[Jost and associates \(1973\)](#) found that if castration of rabbit fetuses was conducted before differentiation of the genital anlagen, all newborns were phenotypic females with female external and internal genitalia. Thus, the mullerian ducts developed into uterus, fallopian tubes, and upper vagina.

If castration of fetuses was conducted before differentiation of the genital anlagen, and thereafter a testis was implanted on one side in place of the removed gonad, the phenotype of all fetuses was male. Thus, the external genitalia of such fetuses was masculinized. On the side of the testicular implant, the wolffian duct developed into the epididymis, vas deferens, and seminal vesicle. On the side of the testicular implant, mullerian structures, including the uterine horn and fallopian tube, were not present. On the side without the implant, the mullerian duct did develop (with castration) but the wolffian duct did not.

In another experiment, these investigators found that if after castration of the fetus at the sexually indifferent stage, an androgen pellet was implanted on one side—in the site of a removed gonad—that the external genitalia masculinized. So did the wolffian duct on the side of the androgen pellet. The mullerian duct, however, did not regress; that is, the uterine horn and fallopian tube developed in spite of the androgen implant.

[Wilson and Gloyna \(1970\)](#) and [Wilson and Lasnitzki \(1971\)](#) demonstrated that testosterone action was amplified by conversion to 5 α -dihydrotestosterone. All of these observations form the basic framework of our understanding of the mechanisms of sexual differentiation of the human embryo-fetus. These investigators demonstrated convincingly that in most androgen-responsive tissues, testosterone is converted to 5 α -dihydrotestosterone in a reaction catalyzed by the enzyme(s) 5 α -reductase. This hormone acts primarily (almost exclusively) in the genital tubercle and labioscrotal folds.

PHYSIOLOGICAL AND BIOMOLECULAR BASIS OF SEXUAL DIFFERENTIATION. Based on these observations, the physiological basis of sexual differentiation can be summarized as follows: Genetic sex is established at fertilization. Gonadal sex is determined primarily by factors encoded by genes on the Y chromosome, such as the SRY gene. In a manner not yet understood, differentiation of the primitive gonad into a testis is accomplished.

FETAL TESTICULAR CONTRIBUTIONS TO MALE SEXUAL DIFFERENTIATION. The fetal testis secretes a proteinaceous substance called *mullerian-inhibiting substance*, a dimeric glycoprotein (M_r about 140,000). It acts locally as a paracrine factor to cause regression of the mullerian duct. Thus, it prevents the development of uterus, fallopian tube, and upper vagina. Fetal testes secrete testosterone, which acts to cause virilization of the external and internal genital anlagen.

Mullerian-inhibiting substance is produced by the Sertoli cells of the seminiferous tubules. Importantly, these tubules appear in fetal gonads before differentiation of Leydig cells, which are the cellular site of testosterone synthesis. Thus, mullerian-inhibiting substance is produced by Sertoli cells even before differentiation of the seminiferous tubules, and is secreted as early as 7 weeks. Mullerian duct regression is completed by 9 to 10 weeks, which is before testosterone secretion has commenced. Because it acts locally near its site of formation, if a testis were absent on one side, the mullerian duct on that side would persist and the uterus and fallopian tube would develop on that side.

Secretion of mullerian-inhibiting substance continues throughout fetal life and after birth, but the expression of its receptor is very brief in embryonic life. The levels of mullerian-inhibiting substance in serum of young boys remains high (10 to 50 ng/mL) before declining to baseline values of 1 to 5 ng/mL at puberty. Mullerian-inhibiting substance also is produced in granulosa cells of the ovary, but not during fetal or postnatal life until near the expected time of puberty. Serum levels of mullerian-inhibiting substance, however, may be distinctly elevated in women with granulosa cell tumors of the ovary ([Gustafson and Donahoe, 1994](#)).

FETAL TESTOSTERONE SECRETION. Apparently through stimulation initially by chorionic gonadotropin (hCG), and later by fetal pituitary LH, the fetal testes secrete testosterone. Some investigators are of the view that early embryo-fetal testosterone synthesis is gonadotropin independent. Testosterone acts directly on the wolffian duct to effect the development of the vas deferens, epididymidis, and seminal vesicles. Testosterone also enters fetal blood and acts on the anlagen of the external genitalia. In these tissues, however, testosterone is converted to 5 α -dihydrotestosterone, which amplifies the androgen action of testosterone to cause virilization of the external genitalia.

GENITAL AMBIGUITY OF THE NEWBORN. This ambiguity is the result of either excessive androgen action in an embryo-fetus that was destined to be female, or inadequate androgen representation for one destined to be male. Rarely, genital ambiguity indicates true hermaphroditism. **If the neonate is a phenotypic male with bilateral cryptorchidism, or if the genitalia are completely ambiguous, congenital adrenal hyperplasia is diagnosed and the neonate treated until appropriate tests confirm or rule it out.** This obtains because, of all the causes of genital ambiguity, only congenital adrenal hyperplasia can be life threatening. If not treated immediately, adrenal failure provokes nausea, vomiting, diarrhea, dehydration, and shock ([Speroff and co-workers, 1994](#)).

The human abnormalities of sexual differentiation causing genital ambiguity can be assigned to one of four clinically defined categories:

1. Female pseudohermaphroditism.
2. Male pseudohermaphroditism.
3. Dysgenetic gonads, including true hermaphroditism.
4. (Rarely) true hermaphroditism.

CATEGORY 1. FEMALE PSEUDOHERMAPHRODITISM. In this condition:

1. Mullerian-inhibiting substance is not produced.
2. Androgen exposure of the embryo-fetus is excessive, but variable, for a fetus destined to be female.
3. The karyotype is 46,XX.
4. Ovaries are present.

Therefore, by genetic and gonadal sex, all subjects of this category are destined to be female, and the basic abnormality is androgen excess. Because mullerian-inhibiting substance is not produced, the uterus, fallopian tubes, and upper vagina develop in these subjects. If affected fetuses were exposed to a small androgen excess reasonably late in fetal development, the only genital abnormality will be slight to modest clitoral hypertrophy, with an otherwise normal female phenotype. With somewhat greater androgen exposure, clitoral hypertrophy will be more pronounced and posterior labial fusion will develop. With progressively increasing androgen excess somewhat earlier in embryonic development, progressively more severe virilization can occur. This includes formation of labioscrotal folds, development of a urogenital sinus (in which the vagina empties into the posterior urethra), and even to the development of a penile urethra with scrotal formation (the empty scrotum syndrome).

The androgenic excess in fetuses with female pseudohermaphroditism most commonly arises as the result of congenital adrenal hyperplasia. These defects in steroidogenic enzymes in the synthesis of cortisol from cholesterol cause increased secretion of androgenic prehormones by the fetal adrenal cortex. With impaired cortisol synthesis, pituitary ACTH secretion is not inhibited and excessive ACTH stimulation of the fetal adrenal glands leads to the secretion of large amounts of cortisol precursors, including androgenic prehormones. These prehormones, for example, androstenedione, are converted to testosterone in extra-adrenal fetal tissues. The enzyme deficiency may involve any of several enzymes, but the most common are steroid 21-hydroxylase, 11- β -hydroxylase, or 3- β -hydroxysteroid dehydrogenase. Deficiency of 3- β -hydroxysteroid dehydrogenase prevents synthesis of virtually all steroid hormones. Deficiency of either 17- β -hydroxylase or 11- β -hydroxylase results in the increased production of deoxycorticosterone, which causes hypertension and hypokalemic acidosis. These forms of congenital adrenal hyperplasia thus constitute medical emergencies.

Another cause of androgen excess in the female embryo-fetus is the transfer of androgen from the maternal compartment. Excess maternal androgen secretion may arise from the ovaries with hyperreactio luteinalis or theca lutein cysts or tumors such as luteomas, arrhenoblastomas (Sertoli/Leydig cell tumors), or hilar cell tumors. In most of these, however, the female does not become virilized. This is because during most of pregnancy, the fetus is protected from excess maternal androgen by the extraordinary capacity of the syncytiotrophoblast to convert most C₁₉-steroids (including testosterone) to estradiol-17 β . The only exception to this generalization is that with fetal aromatase deficiency there is both maternal and fetal virilization ([Chap. 6](#), p. 121). Drugs ingested in pregnancy can also cause female fetal androgen excess. Most commonly, the drugs implicated are synthetic progestins or anabolic steroids ([Chap. 38](#), p. 1051).

Importantly, all subjects with female pseudohermaphroditism, except those with aromatase deficiency, can be normal, fertile women if the proper diagnosis is made and appropriate and timely treatment is initiated.

CATEGORY 2. MALE PSEUDOHERMAPHRODITISM. These subjects are characterized by:

1. Production of mullerian-inhibiting substance.
2. Incomplete but variable androgenic representation for a fetus destined to be male.
3. A 46,XY karyotype.
4. The presence of testes or else no gonads.

Incomplete masculinization of the fetus destined to be male is caused by inadequate production of testosterone by the fetal testis. It also may arise from diminished responsiveness of the genital anlagen to normal quantities of androgen, which includes failure of the in situ formation of 5 α -dihydrotestosterone in androgen-responsive tissue. Because testes were present, at least at some time in embryonic life, mullerian-inhibiting substance is produced during embryonic life. Thus, the uterus, fallopian tubes, and upper vagina do not develop.

Deficient fetal testicular testosterone production may occur if there is an enzymatic defect of steroidogenesis that involves any one of four enzymes in the biosynthetic pathway for testosterone synthesis. Impaired fetal testicular steroidogenesis can also be caused by an abnormality in the LH/hCG receptor and by Leydig cell hypoplasia.

With embryonic testicular regression, the testes regress during embryonic or fetal life, and there is no testosterone production thereafter ([Edman and associates, 1977](#)). These subjects have a spectrum of phenotypes that varies from a normal female with absent uterus, fallopian tubes, and upper vagina, to normal male phenotype with anorchia.

Androgen resistance, or deficiencies in androgen responsiveness, are caused by an abnormal (or absent) androgen receptor protein, or else by failure of conversion of testosterone to 5 α -dihydrotestosterone in such tissues because of deficient enzyme activity ([Wilson and MacDonald, 1978](#)).

ANDROGEN INSENSITIVITY SYNDROME. This formerly was called testicular feminization and it is the most extreme form of the androgen resistance syndrome. These individuals have no tissue responsiveness to androgen. Affected subjects have a female phenotype with a short, blind-ending vagina, no uterus or fallopian tubes, and no wolffian duct structures. At the expected time of puberty, testosterone levels in affected women increase to values similar to normal men. Nonetheless, virilization does not occur, and even pubic and axillary hair do not develop because of end-organ resistance. Presumably, because of androgen resistance at the level of the brain and pituitary, LH levels also are elevated. In response to high concentrations of LH, there is also increased testicular secretion of estradiol-17 β compared with that in normal men ([MacDonald and colleagues, 1979](#)). Increased estrogen secretion, and absence of androgen responsiveness, act in concert to cause feminization (breast development).

Individuals with *incomplete androgen insensitivity* are slightly responsive to androgen. They ordinarily have modest clitoral hypertrophy at birth; but at the expected time of puberty, pubic and axillary hair develop although virilization does not occur. These women also develop feminine breasts, presumably through the same endocrine mechanisms as in women with the complete form of the disorder ([Madden and co-workers, 1975](#)).

Another group has been referred to as *familial male pseudohermaphroditism, type I* ([Walsh and colleagues, 1974](#)). It also is commonly referred to as *Reifenstein syndrome*, but constitutes a spectrum of incomplete genital virilization that can vary from a phenotype similar to that of women with incomplete androgen insensitivity to that of a male phenotype with only a bifid scrotum, infertility, and gynecomastia. In these subjects, androgen resistance is demonstrated by demonstrating diminished 5 α -dihydrotestosterone-binding capacity in fibroblasts grown in culture from genital skin biopsies.

The gene encoding the androgen receptor is located on the X chromosome. More than 100 different mutations of this gene have been demonstrated. This accounts for the wide variability in androgen responsiveness among persons in whom the androgen receptor protein is absent or abnormal, and for the many different mutations associated with one disorder ([McPhaul and associates, 1991](#); [Patterson and co-workers, 1994](#)).

An alternate form of androgen resistance is caused by 5 α -reductase deficiency in androgen-responsive tissues. Because androgen action in the external genitalia anlagen is mediated by 5 α -dihydrotestosterone, persons with this enzyme deficiency have external genitalia that are female (modest clitoral hypertrophy). But because androgen action in the wolffian duct is mediated directly by testosterone, there are well-developed epididymides, seminal vesicles, and vas deferens, and the male ejaculatory ducts empty into the vagina ([Walsh and associates, 1974](#)).

[Andersson and co-workers \(1991\)](#) have demonstrated that there are two genes that encode for steroid 5 α -reductase. The type 1 gene is expressed in many tissues and the enzyme encoded by this gene functions primarily as the initial reaction in testosterone metabolism by the liver. The type 2 gene is expressed primarily in androgen-responsive tissues and abnormal expression causes male pseudohermaphroditism. A composite photograph of the external genitalia of subjects with each of four types of androgen resistance is shown in [Figure 7-17](#).

CATEGORY 3: DYSGENETIC GONADS. This category includes abnormalities of sexual differentiation that have in common several features:

1. Mullerian-inhibiting substance is not produced.
2. Fetal androgen exposure is variable.
3. The karyotype varies among subjects and is commonly abnormal.
4. Neither normal ovaries nor testes are present—rarely, both ovarian and testicular tissues are found. The uterus, fallopian tubes, and upper vagina are present in all of the subjects of this category.

In the majority of subjects of category 3, the gonads are dysgenetic. With the most common form of gonadal dysgenesis, *Turner syndrome (46X)*, the phenotype is female, but secondary sex characteristics do not develop at the time of expected puberty, and sexual infantilism persists. In some persons with dysgenetic gonads, the genitalia are ambiguous, a finding indicating that an abnormal gonad produced androgen, albeit in small amounts, during embryo-fetal life. Generally, there is mixed gonadal dysgenesis in these subjects, and an example is a dysgenetic gonad on one side and an abnormal testis or dysontogenetic tumor on the other side.

CATEGORY 4: TRUE HERMAPHRODITISM. In most subjects with true hermaphroditism, the guidelines for category 3 are met. In addition, true hermaphrodites have both ovarian and testicular tissues, and in particular, germ cells (ova and sperm) of both sexes are found in the abnormal gonads.

PRELIMINARY DIAGNOSIS OF THE CAUSE OF GENITAL AMBIGUITY. A *preliminary* diagnosis of the etiology and pathogenesis of genital ambiguity can be made at the time of birth of an affected child. By physical and ultrasonic examination of the newborn, the experienced examiner can ascertain important findings. These include whether gonads are palpable, and if so, where they are; phallus length and diameter; position of the urethral meatus; degree of labioscrotal fold fusion; and whether there is a vagina, vaginal pouch, or urogenital sinus ([Speroff and associates, 1994](#)). If the uterus is present, the diagnosis must be female pseudohermaphroditism, testicular or gonadal dysgenesis, or true hermaphroditism. A family history of congenital adrenal hyperplasia is helpful. If the uterus is not present, the diagnosis is male pseudohermaphroditism. Androgen resistance and enzymatic defects in testicular testosterone biosynthesis are often familial.

TABLE 7-1. Criteria for Estimating Age During the Fetal Period

Age (wk)		Crown-Rump Length (mm) ^a	Foot Length (mm) ^a	Fetal Weight (g) ^b	Main External Characteristics
Menstrual	Fertilization				
11	9	50	7	8	Eyes closing or closed. Head more rounded. External genitalia still not distinguishable as male or female. Intestines are in the umbilical cord.
12	10	61	9	14	Intestines in abdomen. Early fingernail development.
14	12	87	14	45	Sex distinguishable externally. Well-defined neck.
16	14	120	20	110	Head erect. Lower limbs well developed.
18	16	140	27	200	Ears stand out from head.
20	18	160	33	320	Vernix caseosa present. Early toenail development.
22	20	190	39	460	Head and body (lanugo) hair visible.
24	22	210	45	630	Skin wrinkled and red.
26	24	230	50	820	Fingernails present. Lean body.
28	26	250	55	1000	Eyes partially open. Eyelashes present.
30	28	270	59	1300	Eyes open. Good head of hair. Skin slightly wrinkled.
32	30	280	63	1700	Toenails present. Body filling out. Testes descending.
34	32	300	68	2100	Fingernails reach fingertips. Skin pink and smooth.
38	36	340	79	2900	Body usually plump. Lanugo hairs almost absent. Toenails reach toe tips.
40	38	360	83	3400	Prominent chest; breast protrudes. Testes in scrotum or palpable in inguinal canals. Fingernails extend beyond fingertips.

^a These measurements are averages and so may not apply to specific cases; dimensional variations increase with age.

^b These weights refer to fetuses that have been fixed for about 2 weeks in 10 percent formalin. Fresh specimens usually weigh about 5 percent less.

8. Maternal Adaptations to Pregnancy

The anatomical, physiological, and biochemical adaptations to pregnancy are profound. Many of these changes begin soon after fertilization and continue throughout gestation, and most of these remarkable adaptations occur in response to physiological stimuli provided by the fetus. Equally astounding is that the woman who was pregnant is returned almost completely to her pre-pregnancy state after delivery and lactation. The understanding of these adaptations to pregnancy remains a major goal of obstetrics, and without such knowledge, it is almost impossible to understand the disease processes that can threaten women during pregnancy and the puerperium.

Because of these physiological adaptations, in some cases there are marked aberrations that would be perceived as abnormal in the nonpregnant state. For example, cardiovascular changes normally include substantive increases in blood volume and cardiac output, with hemodynamic adaptations that accompany them. This "high-output state" resembles thyrotoxicosis and other abnormal states. At the same time, underlying heart disease may lead to cardiac failure with these burdens.

Thus, physiological adaptations of normal pregnancy can be misinterpreted as disease, but they also may unmask or worsen preexisting disease. A number of laboratory values may appear abnormal, for example, pregnancy hypervolemia is accompanied by plasma volume expansion out of proportion to red cell mass increase. The result is so-called "physiological anemia" that is a major misnomer. The impact of these marked physiological changes on underlying disease, and vice versa, are considered in some detail in Section XII, which deals with medical and surgical complications of pregnancy.

GENITAL TRACT

UTERUS

In the nonpregnant woman, the uterus is an almost-solid structure weighing about 70 g and with a cavity of 10 mL or less. During pregnancy, the uterus is transformed into a relatively thin-walled muscular organ of sufficient capacity to accommodate the fetus, placenta, and amniotic fluid. The total volume of the contents at term averages about 5 L but may be 20 L or more, so that by the end of pregnancy the uterus has achieved a 500 to 1000 times greater capacity than in the nonpregnant state. There is a corresponding increase in uterine weight, and at term, the organ weighs approximately 1100 g.

During pregnancy, uterine enlargement involves stretching and marked hypertrophy of muscle cells, whereas the production of new myocytes is limited. The myometrial smooth muscle cells are surrounded by an irregular array of collagen fibrils. The force of contraction is transmitted from the contractile proteins of the myocytes to the surrounding connective tissue through the collagen reticulum.

Accompanying the increase in size of muscle cells is an accumulation of fibrous tissue, particularly in the external muscle layer, together with a considerable increase in elastic tissue. The network that is formed adds materially to the strength of the uterine wall. Concomitantly, there is a great increase in size and number of blood vessels and lymphatics. The veins that drain the placental site are transformed into large uterine sinuses, and there is hypertrophy of the nerves exemplified by the increase in size of the Frankenhauser cervical ganglion.

During the first few months, uterine hypertrophy is probably stimulated chiefly by the action of estrogen and perhaps that of progesterone. It is apparent that early hypertrophy is not entirely in response to mechanical distention by the products of conception, because similar uterine changes are observed with ectopic pregnancy ([Chap. 34, p. 890](#)). But after about 12 weeks, the increase in uterine size is in large part related in some manner to the effect of pressure exerted by the expanding products of conception.

During the first few months of pregnancy, the uterine walls become considerably thicker, but as gestation advances the walls gradually thin. At term, the walls of the corpus are only about 1.5 cm or less in thickness. Early in pregnancy, the uterus loses the firmness and resistance characteristic of the nonpregnant organ. In the later months, the uterus is changed into a muscular sac with thin, soft, readily indentable walls, demonstrable by the ease with which the fetus usually can be palpated.

Uterine enlargement is not symmetrical, and it is most marked in the fundus. The differential growth is readily apparent by observing the relative positions of the attachments of the fallopian tubes and ovarian and round ligaments. In the early months of pregnancy, these structures attach only slightly below the apex of the fundus, whereas in the later months, they are located slightly above the middle of the uterus (see [Fig. 3-9, p. 41](#)). The position of the placenta also influences the extent of uterine hypertrophy, because the portion of the uterus surrounding the placental site enlarges more rapidly than does the rest.

ARRANGEMENT OF THE MUSCLE CELLS. The uterine musculature during pregnancy is arranged in three strata:

1. An external hoodlike layer, which arches over the fundus and extends into the various ligaments.
2. An internal layer, consisting of sphincter-like fibers around the orifices of the tubes and the internal os.
3. Lying between these two, a dense network of muscle fibers perforated in all directions by blood vessels.

The main portion of the uterine wall is formed by the middle layer, which consists of an interlacing network of muscle fibers between which extend the blood vessels. Each cell in this layer has a double curve, so that the interlacing of any two gives approximately the form of the figure eight. As a result of this arrangement, when the cells contract after delivery they constrict the penetrating blood vessels and thus act as ligatures.

The muscle cells composing the uterine wall in pregnancy, especially in its lower portion, overlap one another like shingles on a roof. One end of each fiber arises beneath the serosa of the uterus and extends obliquely downward and inward toward the decidua, forming a large number of muscular lamellae that are interconnected by short muscular processes.

UTERINE SIZE, SHAPE, AND POSITION. For the first few weeks the uterus maintains its original pear shape, but as pregnancy advances the corpus and fundus assume a more globular form, becoming almost spherical by 12 weeks. Subsequently, the organ increases more rapidly in length than in width and assumes an ovoid shape. **By the end of 12 weeks, the uterus has become too large to remain totally within the pelvis.** As the uterus continues to enlarge, it contacts the anterior abdominal wall, displaces the intestines laterally and superiorly, and continues to rise, ultimately reaching almost to the liver. As the uterus rises, tension is exerted upon the broad ligaments and upon the round ligaments.

With the pregnant woman standing, the longitudinal axis of the uterus corresponds to an extension of the axis of the pelvic inlet. The abdominal wall supports the uterus and, unless it is quite relaxed, maintains this relation between the long axis of the uterus and the axis of the pelvic inlet. When the pregnant woman is supine, the uterus falls back to rest upon the vertebral column and the adjacent great vessels, especially the inferior vena cava and the aorta.

With ascent of the uterus from the pelvis, it usually undergoes rotation to the right, and this *dextrorotation* likely is caused by the rectosigmoid on the left side of the pelvis.

CONTRACTILITY. From the first trimester onward, the uterus undergoes irregular contractions, which are normally painless. In the second trimester, these contractions may be detected by bimanual examination. Because attention was first called to this phenomenon in 1872 by J. Braxton Hicks, the contractions have been known by his name. Such contractions appear unpredictably and sporadically, are usually nonrhythmic, and their intensity varies between approximately 5 and 25 mm Hg ([Alvarez and Caldeyro-Barcia, 1950](#)). Until the last month of gestation, *Braxton Hicks contractions* are infrequent, but increase during the last week or two. At this time, the contractions may develop as often as every 10 to 20 minutes and may also assume some degree of rhythmicity. Late in pregnancy, these contractions may cause some discomfort and account for so-called *false labor* ([Chap. 14, p. 355](#)).

UTEROPLACENTAL BLOOD FLOW. The delivery of most substances essential for growth and metabolism of the fetus and placenta, as well as removal of most metabolic wastes, is dependent upon adequate perfusion of the placental intervillous space ([Chap. 5, p. 98](#)). Placental perfusion is dependent upon uterine blood flow through the uterine and ovarian arteries. There is a progressive increase in uteroplacental blood flow during pregnancy, and the reported values range from 450 to 650 mL/min late in pregnancy. Values must be viewed as approximations because of inherent errors in the methods of measurement as well as the appreciable changes in uterine blood flow that are likely induced by changes in position ([Edman and associates, 1981](#); [Kauppila and colleagues, 1980](#)).

[Assali and co-workers \(1968\)](#), using electromagnetic flow meters, studied the effects of labor on uteroplacental blood flow in sheep and dogs at term. They found that uterine contractions, either spontaneous or induced, caused a decrease in uterine blood flow that was approximately proportional to the intensity of the contraction, and that a tetanic contraction caused a precipitous fall in uterine blood flow. [Harbert and associates \(1969\)](#) made similar observations in gravid monkeys.

[Janbu and Nesheim \(1987\)](#) studied normal women in labor and correlated Doppler waveforms with intrauterine pressure readings. They found an almost linear correlation between pressure and decreased velocity. With contractions generating 50 mm Hg pressure, velocity was decreased by 60 percent. Uterine contractions appear to affect fetal circulation much less, and [Brar and colleagues \(1988\)](#) reported no adverse effects on umbilical artery flow.

CONTROL OF UTEROPLACENTAL BLOOD FLOW. Increases in uterine blood flow occur progressively throughout gestation in both the human and sheep. In sheep, however, there is a definite redistribution of blood flow within the gravid uterus ([Makowski and co-workers, 1968](#)). Before pregnancy, uterine blood flow is divided equally among myometrium, endometrium, and future placental implantation sites. By the end of the first third of ovine pregnancy, endometrial blood flow is 50 percent of the total. By term, blood flow to the placental cotyledons accounts for approximately 90 percent of total uterine blood flow ([Rosenfeld and associates, 1974](#)).

It is not clear what induces the increase in uterine blood flow during the first two thirds of ovine pregnancy. It is in part the consequence of increasing placental size and number of blood vessels ([Teasdale, 1976](#)). The increase in maternal-placental blood flow principally occurs by means of vasodilation, whereas fetal-placental blood flow is increased by a continuing increase in placental vessels. [Palmer and colleagues \(1992\)](#) showed that uterine artery diameter doubled by 20 weeks and concomitant flow velocity was increased eightfold. It appears likely that this late-pregnancy vasodilation is at least in part the consequence of estrogen stimulation. [Naden and Rosenfeld \(1985\)](#) showed that estradiol-17 β administration to nonpregnant sheep induced cardiovascular changes similar to those observed in pregnant animals. Using measurements of uterine resistance index, [Jauniaux and associates \(1994\)](#) found that both estradiol and progesterone contributed to the downstream fall in resistance to blood flow with advancing gestational age in humans.

CATECHOLAMINES. Both epinephrine and norepinephrine cause significant decreases in placental perfusion in sheep even in the absence of any change in blood pressure ([Rosenfeld and co-workers, 1976](#); [Rosenfeld and West, 1977](#)). Such a response is likely the consequence of a greater sensitivity to catecholamines of the uteroplacental vascular beds when compared with the systemic vasculature.

ANGIOTENSIN II. Vascular refractoriness to the pressor effects of angiotensin II appears to be a normal response of both human and ovine pregnancy ([Gant and co-workers, 1973](#); [Rosenfeld and Gant, 1981](#)). The initial increase in uteroplacental blood flow characteristic of normal pregnancy likely results as a consequence of a blunted uterine vascular resistance to angiotensin II, and possibly other pressor agents such as endothelin.

NITRIC OXIDE. This compound may have important implications for uteroplacental perfusion and setting of vascular tone or resistance in a number of tissue beds. Once called *endothelium-derived relaxing factor (EDRF)*, nitric oxide is a potent vasodilator released by endothelial cells and it also inhibits platelet aggregation and adhesion to vascular endothelium ([Hull and associates, 1994](#); [Seligman and co-workers, 1994](#)). *Nitric oxide synthase (NOS)* has been demonstrated in 97 percent of endothelial cells of the umbilical vein, but in only 7 percent of endothelial cells of umbilical arteries ([Dikranian and colleagues, 1994](#)). It is also found in the amnionic epithelium and in cells of Wharton jelly. [Izumi and colleagues \(1994\)](#) suggested that the amount of endothelium-derived nitric oxide, as well as the sensitivity of smooth muscle to nitric oxide, both decrease as gestation advances.

CERVIX. During pregnancy, there is pronounced softening and cyanosis of the cervix, often demonstrable as early as a month after conception. The factors responsible for these changes are increased vascularity and edema of the entire cervix, together with hypertrophy and hyperplasia of the cervical glands. Although the cervix contains a small amount of smooth muscle, its major component is connective tissue. The cervix will undergo a rearrangement of its collagen-rich connective tissue, producing a 12-fold reduction in mechanical strength by term ([Rechberger and colleagues, 1988](#)).

As shown in [Figure 8-1](#), the glands of the cervix undergo such marked proliferation that by the end of pregnancy they occupy approximately half of the entire cervical mass, rather than a small fraction as in the nonpregnant state. Moreover, the septa separating the glandular spaces become progressively thinner, resulting in the formation of a structure resembling a honeycomb, the meshes of which are filled with tenacious mucus. Soon after conception, a clot of very thick mucus obstructs the cervical canal. At the onset of labor, if not before, this so-called *mucus plug* is expelled, resulting in a *bloody show*. The glands near the external os proliferate beneath the stratified squamous epithelium of the portio vaginalis. These are customarily red and velvety in appearance and are covered by columnar epithelium. These normal pregnancy-induced changes represent an extension, or *eversion*, of the proliferating columnar endocervical glands. This tissue tends to be friable and bleeds even with minor trauma, such as with taking Pap smears.

There is a change in the consistency of the cervical mucus during pregnancy. In the great majority of pregnant women, cervical mucus, spread and dried on a glass slide, is characterized by fragmentary crystallization, or *beading*, typical of the effect of progesterone. In some women, arborization of the crystals, or *ferning*, is observed.

During pregnancy, basal cells near the squamocolumnar junction histologically are likely to be prominent in size, shape, and staining qualities. These changes are considered to be estrogen induced. The frequency of less-than-optimal Pap smears is increased in the pregnant woman ([Kost and associates, 1993](#)).

OVARIES

Ovulation ceases during pregnancy and the maturation of new follicles is suspended. Ordinarily, only a single corpus luteum of pregnancy can be found in the ovaries of pregnant women. This most likely functions maximally during the first 6 to 7 weeks of pregnancy (4 to 5 weeks postovulation), and thereafter, contributes relatively little to progesterone production. These observations have been confirmed in vivo by surgical removal of the corpus luteum before 7 weeks (5 weeks postovulation), which results in a rapid fall in maternal serum progesterone and then spontaneous abortion ([Csapo and co-workers, 1973](#)). After this time, however, corpus luteum removal ordinarily does not cause abortion or labor.

RELAXIN. Human relaxin is a protein hormone composed of nonidentical A and B chains of similar length. There are structural features of relaxin that are similar to insulin and insulin-like growth factors I and II. Its major biological action in mammals is remodeling of the connective tissue of the reproductive tract, allowing accommodation of pregnancy and successful parturition ([Weiss and colleagues, 1993](#)). Relaxin is secreted by the corpus luteum of pregnancy, the placenta, and by the decidua parietalis ([Bogic and colleagues, 1995](#)). The pattern of secretion is similar to that of chorionic gonadotropin.

Whereas 17 α -hydroxyprogesterone and progesterone secretion by the corpus luteum declines to negligible rates by 7 to 8 weeks, appreciable relaxin secretion continues throughout pregnancy. Among 15 women between 8 and 13 weeks, the median concentration of relaxin was 1000 ng/L in maternal serum, 122 ng/L in coelomic fluid, and 9 ng/L in amniotic fluid ([Johnson and colleagues, 1994a, 1994b](#)). Between 10 and 12 weeks, relaxin levels correlated with the number of fetuses; however, levels did not fall with reduction of fetal number. They suggested that circulating levels of relaxin throughout pregnancy are determined by gonadotropin stimulation, and within the first 10 weeks by the luteotropic stimulus from the conceptus.

The role of relaxin during human pregnancy is not completely defined; however, it is known to have effects on the biochemical structure of the cervix ([Bell and colleagues, 1993](#)). The hormone also affects contractility of the myometrium that may be implicated in preterm birth ([Weiss and colleagues, 1993](#)). Although peripheral joint laxity increases during human pregnancy, this change does not correlate with serum relaxin levels ([Schauberger and colleagues, 1996](#)).

PREGNANCY LUTEOMA. In 1963, [Sternberg](#) described a solid ovarian tumor that developed during pregnancy that was composed of large acidophilic luteinized cells. Luteoma of pregnancy represents an exaggeration of the luteinization reaction of the ovary of normal pregnancy. Thus, while not true neoplasms, they may present as quite large abdominal masses ([Fig. 8-2](#)). The luteoma regresses after delivery, but may recur in subsequent pregnancies ([Shortle and associates, 1987](#)).

Even though maternal virilization may be prominent, the female fetus is usually not affected, presumably because of the protective role of the placenta through its high capacity to convert androgens and androgen-like steroids to estrogens ([Edman and co-workers, 1979](#)). Despite this, a female fetus can become virilized ([Cohen and associates, 1982](#)).

HYPERREACTIO LUTEINALIS

This is a second benign lesion of the ovary that causes maternal virilization during pregnancy. Although the cellular pattern is similar to that of a luteoma, the two tumors are different grossly. The luteoma is solid, and hyperreactio luteinalis is a cystic tumor. Additionally, hyperreactio luteinalis is commonly associated with

extremely high serum chorionic gonadotropin levels ([Muechler and colleagues, 1987](#)) [Bradshaw and co-workers \(1986\)](#) described a nullipara who developed temporal balding, hirsutism, and clitoromegaly during the third trimester Levels of androstenedione and testosterone were elevated massively in maternal serum but were normal in umbilical cord blood Maternal serum levels of chorionic gonadotropin were twice the mean for normal late pregnancy Bilateral multicystic ovarian masses obstructed fetal descent during labor and necessitated cesarean delivery Increased ovarian responsiveness to gonadotropin was confirmed 8 weeks postpartum

OTHER CHANGES. A *decidual* reaction on and beneath the surface of the ovaries, similar to that found in the endometrial stroma, is common in pregnancy and may be observed at cesarean delivery. These elevated patches of tissue bleed easily and may, on first glance, resemble freshly torn adhesions. Similar decidual reactions are occasionally seen on the posterior uterine serosa and upon or within other pelvic or even extrapelvic abdominal organs.

The enormous caliber of the ovarian veins viewed at cesarean delivery is startling. [Hodgkinson \(1953\)](#) found that the diameter of the ovarian vascular pedicle increased during pregnancy from 0.9 cm to approximately 2.6 cm at term.

FALLOPIAN TUBES. The musculature of the fallopian tubes undergoes little hypertrophy during pregnancy. The epithelium of the tubal mucosa becomes flattened compared with the nonpregnant state. Decidual cells may develop in the stroma of the endosalpinx, but a continuous decidual membrane is not formed.

VAGINA AND PERINEUM

During pregnancy, increased vascularity and hyperemia develop in the skin and muscles of the perineum and vulva, and there is softening of the normally abundant connective tissue of these structures Increased vascularity prominently affects the vagina The copious secretion and the characteristic violet color of the vagina during pregnancy (*Chadwick sign*) result chiefly from hyperemia The vaginal walls undergo striking changes seemingly in preparation for the distention that occurs during labor There is considerable increase in thickness of the mucosa, loosening of the connective tissue, and hypertrophy of the smooth-muscle cells to nearly the same extent as in the uterus These changes effect such an increase in length of the vaginal walls that sometimes, in parous women, the lower portion of the anterior vaginal wall protrudes slightly through the vulvar opening The papillae of the vaginal mucosa also undergo considerable hypertrophy, creating a fine, hobnailed appearance

SECRETIONS. The considerably increased cervical and vaginal secretions during pregnancy consist of a somewhat thick, white discharge. Its pH is acidic, varying from 3.5 to 6, the result of increased production of lactic acid from glycogen in the vaginal epithelium by the action of *Lactobacillus acidophilus*.

HISTOPATHOLOGY. Early in pregnancy the vaginal epithelial cells are similar to those found during the luteal phase. As pregnancy advances, two patterns of response may be seen:

1. Small intermediate cells, called *navicular cells* by Papanicolaou, are found in abundance in small, dense clusters. These ovoid cells contain a vesicular, somewhat elongated nucleus.
2. Vesicular nuclei without cytoplasm, or so-called naked nuclei, are evident along with an abundance of *Lactobacillus*.

SKIN

ABDOMINAL WALL

In the later months of pregnancy, reddish, slightly depressed streaks commonly develop in the skin of the abdomen and sometimes in the skin over the breasts and thighs in about half of pregnant women In multiparous women, in addition to the reddish striae of the present pregnancy, glistening, silvery lines that represent the cicatrices of previous striae frequently are seen

Occasionally the muscles of the abdominal walls do not withstand the tension to which they are subjected, and the rectus muscles separate in the midline, creating a diastasis recti of varying extent. If severe, a considerable portion of the anterior uterine wall is covered by only a layer of skin, attenuated fascia, and peritoneum.

PIGMENTATION

In many women, the midline of the abdominal skin becomes markedly pigmented, assuming a brownish-black color to form the *linea nigra* Occasionally, irregular brownish patches of varying size appear on the face and neck, giving rise to *chloasma* or *melasma gravidarum* (*mask of pregnancy*) There is also accentuation of pigment of the areolae and genital skin Fortunately, this usually disappears, or at least regresses considerably after delivery ([Chap 54, p 1430](#)) Oral contraceptives may cause similar pigmentation in these same women There is very little known of the nature of these pigmentary changes, although melanocyte-stimulating hormone, a polypeptide similar to corticotropin, has been shown to be elevated remarkably from the end of the second month of pregnancy until term (see also [Chap 6](#)) Estrogen and progesterone are reported to have some melanocyte-stimulating effects [Vaughn Jones and Black \(1999\)](#) attribute most changes to estrogen These are considered in greater detail in [Chapter 54](#)

VASCULAR CHANGES

Angiomas, called *vascular spiders*, develop in about two thirds of white women and approximately 10 percent of African-American women during pregnancy These are minute, red elevations on the skin, particularly common on the face, neck, upper chest, and arms, with radicles branching out from a central body The condition is often designated as nevus, angioma, or telangiectasis *Palmar erythema* is encountered in pregnancy in about two thirds of white women and a third of black women The two conditions are of no clinical significance and disappear in most women shortly after pregnancy They are most likely the consequence of the hyperestrogenemia of pregnancy

BREASTS

In the early weeks, the pregnant woman often experiences tenderness and tingling. After the second month, the breasts increase in size and delicate veins become visible just beneath the skin. The nipples become considerably larger, more deeply pigmented, and more erectile. After the first few months, a thick, yellowish fluid, *colostrum*, can often be expressed from the nipples by gentle massage. At that time, the areolae become broader and more deeply pigmented. Scattered through the areolae are a number of small elevations, the so-called glands of Montgomery, which are hypertrophic sebaceous glands. If the increase in size of the breasts is very extensive, striations similar to those observed in the abdomen may develop. Interestingly, prepregnancy breast size and volume of milk production do not correlate ([Hyttén, 1995](#)). Histological and functional changes of the breasts induced by pregnancy and lactation are further discussed in [Chapter 17 \(p. 407\)](#).

METABOLIC CHANGES

In response to the rapidly growing fetus and placenta and their increasing demands, the pregnant woman undergoes metabolic changes that are numerous and intense. Certainly no other physiological event in postnatal life induces such profound metabolic alterations.

WEIGHT GAIN

Most of the increase in weight during pregnancy is attributable to the uterus and its contents, the breasts, and increases in blood volume and extravascular extracellular fluid A smaller fraction of the increased weight is the result of metabolic alterations that result in an increase in cellular water and deposition of new fat and protein, so-called *maternal reserves* [Hyttén \(1991\)](#) reported an average weight gain of 125 kg ([Table 8-1](#)) Maternal aspects of weight gain during pregnancy are considered in [Chapter 10 \(p 231\)](#)

METABOLISM

WATER METABOLISM. Increased water retention is a normal physiological alteration of pregnancy. This is mediated, at least in part, by a fall in plasma osmolality of approximately 10 mOsm/kg induced by a resetting of osmotic thresholds for thirst and vasopressin secretion ([Lindheimer and Davidson, 1995](#)). As shown in [Figure 8-3](#), this phenomenon is functioning by early pregnancy.

At term, the water content of the fetus, placenta, and amniotic fluid amounts to about 3.5 L. Another 3.0 L accumulates as a result of increases in the maternal blood

volume and in the size of the uterus and the breasts. Thus, the minimum amount of extra water that the average women retains during normal pregnancy is about 6.5 L. Clearly demonstrable pitting edema of the ankles and legs is seen in a substantial proportion of pregnant women, especially at the end of the day. This accumulation of fluid, which may amount to a liter or so, is caused by an increase in venous pressure below the level of the uterus as a consequence of partial occlusion of the vena cava. A decrease in interstitial colloid osmotic pressure induced by normal pregnancy also favors edema late in pregnancy ([Oian and co-workers, 1985](#)).

Longitudinal studies of body composition have shown a progressive increase in total body water and fat mass during pregnancy. It has been known for decades that both initial maternal weight and the weight gained during pregnancy are highly associated with birthweight. It is unclear, however, what role maternal fat or water have in fetal growth. Recent studies in well-nourished term women suggest that maternal body water, rather than fat, contributes more significantly to infant birthweight ([Lederman and associates, 1999](#); [Mardones-Santander and associates, 1998](#)).

PROTEIN METABOLISM. The products of conception, as well as uterus and maternal blood, are relatively rich in protein rather than fat or carbohydrate. At term, the fetus and placenta together weigh about 4 kg and contain approximately 500 g of protein, or about half of the total pregnancy increase ([Hyttén and Leitch, 1971](#)). The remaining 500 g is added to the uterus as contractile protein, to the breasts primarily in the glands, and to the maternal blood as hemoglobin and plasma proteins.

From nitrogen balance studies in pregnant women, it appears that actual nitrogen use is only 25 percent ([Calloway, 1974](#)). Therefore, daily requirements for protein intake during pregnancy are increased appreciably to correct for this. Equally important is the ingestion of adequate carbohydrates and fat. If these are not consumed in adequate amounts, energy requirements must be met by catabolism of maternal protein stores. Amino acids used for energy are not available for synthesis of maternal protein. With increasing intake of fat and carbohydrates as energy sources, less dietary protein is required to maintain positive nitrogen balance.

CARBOHYDRATE METABOLISM. Normal pregnancy is characterized by mild fasting hypoglycemia, postprandial hyperglycemia, and hyperinsulinemia ([Fig. 8-4](#)). The fasting plasma glucose concentration falls somewhat, possibly due to increased plasma levels of insulin. This cannot be explained by a change in the metabolism of insulin because its half-life during pregnancy is not changed ([Lind and associates, 1977](#)).

The increased basal level of plasma insulin observed in normal pregnancy is associated with several unique responses to glucose ingestion. For example, after an oral glucose meal, there is both prolonged hyperglycemia and hyperinsulinemia in pregnant women, with a greater suppression of glucagon ([Phelps and associates, 1981](#)). The purpose of such a mechanism is likely to ensure a sustained or maintained postprandial supply of glucose to the fetus. This response is consistent with a pregnancy-induced state of peripheral resistance to insulin, which is suggested by three observations:

1. Increased insulin response to glucose.
2. Reduced peripheral uptake of glucose.
3. Suppressed glucagon response.

The mechanism(s) responsible for insulin resistance is not completely understood. Progesterone and estrogen may act, directly or indirectly, to mediate this resistance. Plasma levels of placental lactogen increase with gestation, and this protein hormone is characterized by growth hormone-like action that may result in increased lipolysis with liberation of free fatty acids ([Freinkel, 1980](#)). The increased concentration of circulating free fatty acids also may facilitate increased tissue resistance to insulin.

The mechanisms cited ensure that a continuous supply of glucose is available for transfer to the fetus. The pregnant woman, however, changes rapidly from a postprandial state characterized by elevated and sustained glucose levels to a fasting state characterized by decreased plasma glucose and amino acids such as alanine. There also are higher plasma concentrations of free fatty acids, triglycerides, and cholesterol in the pregnant woman during fasting ([Fig. 8-5](#)). [Freinkel and colleagues \(1985\)](#) have referred to this pregnancy-induced switch in fuels from glucose to lipids as **accelerated starvation**. Certainly, when fasting is prolonged in the pregnant woman, these alterations are exaggerated and ketonemia rapidly appears.

[Hornnes and Kuhl \(1980\)](#) measured glucagon and insulin responses to a standard glucose stimulus late in normal pregnancy and again in the same women postpartum. The peak insulin response to glucose infusion was increased fourfold in late pregnancy. In contrast, plasma glucagon concentrations were suppressed, and the degree was similar in late pregnancy and the puerperium. These results are consistent with the view that β -cell sensitivity to a glucose challenge is increased significantly in normal pregnant women, but that the α -cell sensitivity to a glucose stimulus is unaltered.

FAT METABOLISM. The concentrations of lipids, lipoproteins, and apolipoproteins in plasma increase appreciably during pregnancy. [Desoye and co-workers \(1987\)](#) found that there were positive correlations between the concentrations of lipids shown in [Figure 8-5](#) and those of estradiol, progesterone, and placental lactogen.

Plasma lipoprotein cholesterol levels also increase significantly. Low-density lipoprotein cholesterol (LDL-C) levels peak at approximately week 36, likely the consequence of the hepatic effects of estradiol and progesterone ([Desoye and associates, 1987](#)). High-density lipoprotein cholesterol (HDL-C) peaks at week 25, decreases until week 32, and remains constant for the remainder of pregnancy. The initial increase is believed to be caused by estrogen. High-density lipoprotein-2 and -3 cholesterol levels peak at approximately 28 weeks and remain unchanged throughout the remainder of pregnancy. [Brizzi and colleagues \(1999\)](#) have suggested that changes in the low-density lipoprotein (LDL) pattern during normal pregnancy might be used to identify those women who later in life may be predisposed to atherosclerosis.

After delivery, the concentrations of these lipids, lipoproteins, and apolipoproteins decrease at different rates ([Desoye and co-workers, 1987](#)). Lactation increases the rate of decrease of many of these compounds ([Darmady and Postle, 1982](#)).

[Hyttén and Thomson \(1968\)](#) and [Pipe and co-workers \(1979\)](#) concluded that storage of fat occurs primarily during midpregnancy. This fat is deposited mostly in central rather than peripheral sites. Later in pregnancy, as fetal nutritional demands increase remarkably, maternal fat storage decreases. [Hyttén and Thomson \(1968\)](#) cited some evidence that progesterone may act to reset a *lipostat* in the hypothalamus, and at the end of pregnancy the lipostat returns to its previous nonpregnant level and the added fat is lost. Such a mechanism for energy storage, theoretically at least, might protect the mother and fetus during times of prolonged starvation or hard physical exertion.

MINERAL METABOLISM. The requirements for **iron** during pregnancy are considerable and often exceed the amounts available (p. 178). With respect to most other minerals, pregnancy induces little change in their metabolism other than their retention in amounts equivalent to those used for growth of fetal and, to a lesser extent, maternal tissues ([Chaps. 7, p. 139 and 10, p. 235](#)).

During pregnancy, **calcium** and **magnesium** plasma levels decline, the reduction probably reflecting for the most part the lowered plasma protein concentration and, in turn, the consequent decrease in the amount bound to protein. [Bardicéf and colleagues \(1995\)](#), however, concluded that pregnancy is a state of magnesium depletion. They showed that total and ionized magnesium levels were significantly lower in normal pregnancy compared with nonpregnant women. [Fogh-Andersen and Schultz-Larsen \(1981\)](#) demonstrated a small but significant increase in free calcium ion concentration in late pregnancy by correcting for blood pH changes. Serum **phosphate** levels are within the nonpregnant range. The renal threshold for inorganic phosphate excretion is elevated in pregnancy due to increased calcitonin ([Weiss and colleagues, 1998](#)). [Cole and co-workers \(1987\)](#) reported that bone turnover was reduced during early pregnancy, returned toward normal during the third trimester, and increased in postpartum lactating women.

ACID-BASE EQUILIBRIUM

As discussed subsequently (p 186), minute ventilation increases during pregnancy and this causes a respiratory alkalosis by lowering the PCO_2 of blood. A moderate reduction in plasma bicarbonate from 26 to about 22 mmol/L *partially* compensates for this. As a result, there is only a minimal increase in blood pH. This increase shifts the oxygen dissociation curve to the left and increases the affinity of maternal hemoglobin for oxygen (*Bohr effect*), thereby decreasing the oxygen-releasing capacity of maternal blood. Thus, the hyperventilation that results in a reduced maternal PCO_2 facilitates transport of carbon dioxide from the fetus to the mother but *appears to impair* release of oxygen from maternal blood to the fetus. The increase in blood pH, however, although minimal, stimulates an increase in 2,3-diphosphoglycerate in maternal erythrocytes ([Tsai and deLeeuw, 1982](#)). This counteracts the Bohr effect by shifting the oxygen dissociation curve back to the right, facilitating oxygen release to the fetus.

PLASMA ELECTROLYTES

Despite large accumulations during pregnancy of sodium and potassium, the serum concentration of these electrolytes decreases. During normal pregnancy, nearly 1000 mEq of sodium and 300 mEq of potassium are retained ([Lindheimer and colleagues, 1987](#)). Despite that their glomerular filtration is increased, sodium and potassium excretion are unchanged during pregnancy ([Brown and colleagues, 1986, 1988](#)). Thus, their fractional excretion is decreased, and it has been postulated that progesterone counteracts the natriuretic and kaliuretic effects of aldosterone.

HEMATOLOGICAL CHANGES

BLOOD VOLUME

The maternal blood volume increases markedly during pregnancy. In studies of normal women, the blood volumes at or very near term averaged about 40 to 45 percent above their nonpregnant levels ([Pritchard, 1965](#); [Whittaker and associates, 1996](#)). The degree of expansion varies considerably, in some women there is only a modest increase, while in others the blood volume nearly doubles. A fetus is not essential for the development of hypervolemia during pregnancy, for increases in blood volume have been demonstrated in some women with hydatidiform mole ([Pritchard, 1965](#)).

Pregnancy-induced hypervolemia has several important functions:

1. To meet the demands of the enlarged uterus with its greatly hypertrophied vascular system.
2. To protect the mother, and in turn the fetus, against the deleterious effects of impaired venous return in the supine and erect positions.
3. To safeguard the mother against the adverse effects of blood loss associated with parturition.

As shown in [Figure 8-6](#), maternal blood volume starts to increase during the first trimester, expands most rapidly during the second trimester, and then rises at a much slower rate during the third trimester to plateau during the last several weeks of pregnancy.

Increased blood volume results from an increase in both plasma and erythrocytes. Although more plasma than erythrocytes is usually added to the maternal circulation, the increase in volume of erythrocytes is considerable, averaging about 450 mL, or an increase of about 33 percent ([Pritchard and Adams, 1960](#)). The importance of this increase in creating a demand for iron is discussed on page 178.

Moderate erythroid hyperplasia is present in the bone marrow, and the reticulocyte count is elevated slightly during normal pregnancy. This is almost certainly related to the increase in maternal plasma erythropoietin levels ([Chap. 49, p. 1310](#)). These levels increase after 20 weeks, corresponding to when erythrocyte production is most marked ([Harstad and co-workers, 1992](#)).

ATRIAL NATRIURETIC PEPTIDES. This group of biologically active peptides is synthesized and secreted by atrial myocytes. Three separate forms (α , β , γ) have been isolated ([Kangawa and co-workers, 1985](#)). Atrial natriuretic peptide produces significant natriuresis and diuresis. It increases renal blood flow and glomerular filtration rate and decreases renin secretion. The actual mechanism(s) responsible for the natriuresis remains unclear, with evidence consistent for both a hemodynamically induced natriuresis and an inhibitory effect upon tubular sodium reabsorption ([Wakitani and colleagues, 1985](#)). Atrial natriuretic peptides also have been shown to reduce basal release of aldosterone from zona glomerulosa cells and to blunt corticotropin and angiotensin II-stimulated release of aldosterone as well ([Atarashi and associates, 1984](#)). Renin secretion is also inhibited by this peptide. Finally, atrial natriuretic peptides have a direct vasorelaxant action upon vascular smooth muscle stimulated by angiotensin II or norepinephrine.

[Castro and associates \(1994\)](#) summarized several studies done to evaluate plasma levels of atrial natriuretic peptide in normal and hypertensive pregnancy. The mean level rose by 40 percent over nonpregnant values by the third trimester and by 150 percent during the first week postpartum. These investigators hypothesized that atrial stretch receptors sense the expanded blood volume of pregnancy as normal to moderately increased. The marked rise in peptide levels during the first week postpartum is consistent with known hemodynamic changes and suggests that the hormone is involved in postpartum diuresis.

By comparison, [Thomsen and colleagues \(1994\)](#) investigated 10 healthy primigravid twin pregnancies and reported that all atrial natriuretic peptide levels during pregnancy were lower than values at 12 weeks postpartum. At 20, 28, and 32 weeks, plasma peptide levels were lower in twin than in singleton pregnancies. These observations may serve to explain in part the relatively increased plasma volume characteristic of women with twins compared with those with singleton fetuses.

HEMOGLOBIN CONCENTRATION AND HEMATOCRIT. In spite of augmented erythropoiesis, hemoglobin concentration and the hematocrit decrease slightly during normal pregnancy. As a result, whole blood viscosity decreases ([Huisman and colleagues, 1987](#)). Hemoglobin concentration at term averages 12.5 g/dL and in 6 percent of women it is below 11.0 g/dL (see [Fig. 49-1](#) and [Table 49-1](#)). Thus, in most women, a hemoglobin concentration below 11.0 g/dL, especially late in pregnancy, should be considered abnormal and usually due to iron deficiency rather than to hypervolemia of pregnancy.

IRON METABOLISM/IRON STORES. Although the total body iron content averages about 4 g in men, in healthy young women of average size, it is probably half that amount. Commonly, iron stores of normal young women are only about 300 mg ([Pritchard and Mason, 1964](#)). As in men, heme iron in myoglobin and enzymes and transferrin-bound circulating iron together total only a few hundred milligrams. The total iron content of normal adult women ranges from 2.0 to 2.5 g.

IRON REQUIREMENTS. The iron requirements of normal pregnancy total about 1000 mg. About 300 mg are actively transferred to the fetus and placenta and about 200 mg are lost through various normal routes of excretion. These are obligatory losses and occur even when the mother is iron deficient. The average increase in the total volume of circulating erythrocytes of about 450 mL during pregnancy, when iron is available, uses another 500 mg of iron, because 1 mL of normal erythrocytes contains 1.1 mg of iron. Practically all of the iron for these purposes is used during the latter half of pregnancy. Therefore, the iron requirement becomes quite large during the second half of pregnancy, averaging 6 to 7 mg/day ([Pritchard and Scott, 1970](#)). Because this amount is not available from body stores in most women, the desired increase in maternal erythrocyte volume and hemoglobin mass will not develop unless exogenous iron is made available in adequate amounts. In the absence of supplemental iron, the hemoglobin concentration and hematocrit fall appreciably as the maternal blood volume increases. Hemoglobin production in the fetus, however, will not be impaired, because the placenta obtains iron from the mother in amounts sufficient for the fetus to establish normal hemoglobin levels even when the mother has severe iron-deficiency anemia.

The amount of iron absorbed from diet, together with that mobilized from stores, is usually insufficient to meet the demands imposed by pregnancy. This is true even though gastrointestinal tract iron absorption appears to be moderately increased during pregnancy ([Hahn and associates, 1951](#)). If the pregnant woman who is not anemic is not given supplemental iron, serum iron and ferritin concentrations decline during the second half of pregnancy ([Fig. 8-7](#)). The somewhat unexpected early pregnancy increases in serum iron and ferritin are thought to be due to minimal iron demands during the first trimester as well as to a positive iron balance because of amenorrhea. These values, summarized in [Table 8-2](#), show that standard deviations for a given mean value are quite large. For example, in pregnant women with overt anemia and not given supplemental iron, serum ferritin levels can vary from 7 to 22 ng/mL during the third trimester. Also shown in [Figure 8-7](#) is the increase in iron-binding capacity (transferrin) that occurs even when iron deficiency has been eliminated by oral iron supplementation.

BLOOD LOSS. Not all the iron added to the maternal circulation in the form of hemoglobin is necessarily lost from the mother. During normal vaginal delivery and through the next few days, only about half of the erythrocytes added to the maternal circulation during pregnancy are lost from the majority of women. These losses are by way of the placental implantation site, the placenta itself, the episiotomy or lacerations, and in the lochia. On the average, an amount of maternal erythrocytes corresponding to about 500 to 600 mL of predelivery blood is lost during and after vaginal delivery of a single fetus ([Pritchard, 1965](#); [Ueland, 1976](#)). The average blood loss associated with cesarean delivery or with the vaginal delivery of twins is about 1000 mL, or nearly twice that lost with the delivery of a single fetus.

IMMUNOLOGICAL AND LEUKOCYTE FUNCTIONS

Pregnancy has been assumed to be associated with suppression of a variety of humoral and cellular mediated immunological functions in order to accommodate the "foreign" semiallogeneic fetal graft ([Chap 2, p 20](#)). In fact, humoral antibody titers against several viruses—for example, herpes simplex, measles, and influenza A—decrease during pregnancy. The decrease in titers, however, is accounted for by the hemodilutional effect of pregnancy. The prevalence of a variety of autoantibodies is unchanged ([Patton and colleagues, 1987](#)). Furthermore, α -interferon, which is present in almost all fetal tissues and fluids, is most often absent in normally pregnant women ([Chard and co-workers, 1986](#)). There is evidence, as yet unexplained, that polymorphonuclear leukocyte chemotaxis and adherence functions are depressed beginning in the second trimester and continuing throughout pregnancy ([Krause and associates, 1987](#)). It is possible that these depressed leukocyte functions of pregnant women account in part for the improvement observed in some with autoimmune diseases and the possibly increased susceptibility to

certain infections. Thus, both function and absolute numbers of leukocytes appear to be important factors when considering the leukocytosis of normal pregnancy.

The leukocyte count varies considerably during normal pregnancy. Usually it ranges from 5000 to 12,000/uL. During labor and the early puerperium it may become markedly elevated, attaining levels of 25,000 or even more; however, the concentration averages 14,000 to 16,000/uL ([Taylor and co-workers, 1981](#)). The cause for the marked increase is not known, but the same response occurs during and after strenuous exercise. It probably represents the reappearance in the circulation of leukocytes previously shunted out of the active circulation. During pregnancy there is a neutrophilia that consists predominantly of mature forms; however, an occasional myelocyte is found.

Beginning quite early in pregnancy, the activity of **leukocyte alkaline phosphatase** is increased. Such elevated activity is not peculiar to pregnancy but occurs in a wide variety of conditions, including most inflammatory states. **C-reactive protein** is an acute-phase serum reactant. Serum concentrations rise rapidly to 1000-fold in response to tissue trauma or inflammation. [Watts and colleagues \(1991\)](#) measured C-reactive protein sequentially during 81 normal pregnancies to establish normal values. Median C-reactive protein values during pregnancy were higher than values for nonpregnant individuals, and these values were elevated further in labor. In women not in labor, 95 percent of values were 1.5 mg/dL or less, and gestational age did not affect serum levels. Another marker of inflammation, the **erythrocyte sedimentation rate** (ESR) is elevated in normal pregnancy due to elevated plasma globulins and fibrinogen ([Hyttén and Leitch, 1971](#)). This test thus cannot be used to reliably diagnose inflammation during pregnancy. Complement factors **C₃** and **C₄** are significantly elevated during the second and third trimesters of pregnancy ([Gallery and colleagues, 1981](#)).

COAGULATION. In normal pregnancy, the coagulation cascade is in an activated state ([Baker and Cunningham, 1999](#)). Evidence of activation includes increased concentrations of all clotting factors except factors XI and XIII, with increased levels of high-molecular-weight fibrinogen complexes. Considering the substantive physiological increase in plasma volume in normal pregnancy, such increased concentrations represent a marked increase in production of these procoagulants. For example, plasma fibrinogen (factor I) in normal nonpregnant women averages about 300 mg/dL and ranges from about 200 to 400 mg/dL. During normal pregnancy, fibrinogen concentration increases about 50 percent to average about 450 mg/dL late in pregnancy, with a range from 300 to 600. The increase in the concentration of fibrinogen undoubtedly contributes greatly to the striking increase in the *erythrocyte sedimentation rate* discussed earlier ([Ozanne and co-workers, 1983](#)). The end-product of the coagulation cascade is fibrin formation.

High-molecular-weight soluble fibrin-fibrinogen complexes circulate in normal pregnancy and D-dimer levels increase with gestational age ([Lee and associates, 1996](#); [Nolan and colleagues, 1993](#)). The clotting times of whole blood in either plain glass tubes (wetttable surface) or silicone-coated or plastic tubes (nonwetttable surface) do not significantly differ in normal pregnant women. Some of the pregnancy-induced changes in the levels of coagulation factors can be duplicated by the administration of estrogen plus progestin contraceptive tablets.

Normal pregnancy also involves changes in platelets ([Baker and Cunningham, 1999](#)). Although there is little change in platelet count in normal pregnancy, platelet width and volume increase. One explanation for these changes is increased platelet consumption leading to an increased proportion of younger, and therefore, larger platelets. Alterations such as these during normal pregnancy may be equated with continuing low-grade intravascular coagulation. In support of this concept, [Tygart and associates \(1986\)](#) interpreted these observations to represent an increased level of thrombocytopoiesis as a consequence of both dilutional and consumptive stimuli of normal pregnancy.

The end product of the coagulation cascade is fibrin formation, and the main function of the fibrinolytic system is to remove excess fibrin. The inactive precursor plasminogen is activated by serine proteases (plasminogen-activators) which convert plasminogen into plasmin. The activity of these plasminogen-activators is balanced by specific inhibitors present in plasma and platelets. The result of plasmin activity on fibrin is fibrinolysis producing fibrin degradation products such as D-dimers. Studies of the fibrinolytic system in pregnancy have produced conflicting results, although the majority of evidence suggests that fibrinolytic activity is actually reduced in normal pregnancy ([Baker and Cunningham, 1999](#)). It appears that plasminogen-activator inhibitors may be increased in normal pregnancy ([Koh and co-authors, 1993](#)). These potentially conflicting findings—that is, evidence of both increased and decreased fibrinolysis—may reflect the difficulty in interpreting measures of fibrinolysis.

REGULATORY PROTEINS. These are natural inhibitors of coagulation, and deficiencies of any of these factors is referred to as *thrombophilia*. Inherited hypercoagulable states such as protein C, protein S, and antithrombin III deficiencies account for 15 to 20 percent of recurrent thromboembolic episodes ([Chap. 49, p. 1330](#)). [Lockwood \(1999\)](#) has recently reviewed coagulopathies in pregnancy arising from regulatory protein deficiencies.

[Bremme and co-workers \(1992\)](#) reported that **protein C** activity showed no significant trends and remained within normal reference ranges throughout pregnancy. Similarly, in a cross-sectional study of 91 normal pregnant women, [Faught and associates \(1995\)](#) found no significant change in antigenic or functional protein C levels. The discovery of the factor V Leiden mutation as causing **resistance to activated protein C** introduced new variables into thrombophilias. In affected women, measurement of this resistance during pregnancy is difficult and DNA testing is recommended.

[Faught and colleagues \(1995\)](#) also showed that total **protein S** levels remained unchanged, but free protein S levels fell significantly from the first to the second trimester (0.45 to 0.26 U/mL) and stayed depressed throughout gestation. [Gatti and colleagues \(1994\)](#) reported no change in protein S antigen; however, protein S activity decreased early and persisted throughout gestation. [Bremme and associates \(1992\)](#) found that the mean free protein S level significantly decreased from 0.26 U/mL in early pregnancy to 0.14 U/mL at 35 weeks. Oral contraceptives decrease these levels by about 20 percent, leading to speculation that the decrease is hormonally mediated.

Levels of **antithrombin III** are essentially unchanged during normal pregnancy ([Weenink and co-workers, 1982](#)). The levels of **thrombin-antithrombin III complexes**, however, progressively increase ([de Boer and colleagues, 1989](#)). This suggests coagulation activation as is consistent with some observations that fibrinopeptides A and B also are elevated.

CARDIOVASCULAR SYSTEM

During pregnancy and the puerperium there are remarkable changes involving the heart and the circulation. The most important changes in cardiac function occur in the first eight weeks of pregnancy ([McLaughlin and Roberts, 1999](#)). Cardiac output is increased as early as the fifth week of pregnancy and this initial increase is a function of reduced systemic vascular resistance and an increase in heart rate. Between weeks 10 and 20, notable increases in plasma volume occur such that preload is increased. Ventricular performance during pregnancy is influenced by both the decrease in systemic vascular resistance and changes in pulsatile arterial flow. Vascular capacity increases, in part, due to an increase in vascular compliance. As discussed in the following section, multiple factors contribute to these changes in overall hemodynamic function, allowing the cardiovascular system to adjust to the physiological demands of the fetus while maintaining maternal cardiovascular integrity. These changes during the last half of pregnancy are graphically summarized in [Figure 8-8](#), which also shows the important effects of maternal posture on hemodynamic events during pregnancy.

HEART

The resting pulse rate increases about 10 bpm during pregnancy ([Stein and co-workers, 1999](#)). As the diaphragm becomes progressively elevated, the heart is displaced to the left and upward, while at the same time it is rotated somewhat on its long axis. As a result, the apex of the heart is moved somewhat laterally from its position in the normal nonpregnant state, and an increase in the size of the cardiac silhouette is found in radiographs ([Fig 8-9](#)). The extent of these changes is influenced by the size and position of the uterus, toughness of the abdominal muscles, and configurations of the abdomen and thorax. Furthermore, normally pregnant women have some degree of benign pericardial effusion which may increase the cardiac silhouette ([Enein and colleagues, 1987](#)). Variability of these factors makes it difficult to identify precisely moderate degrees of cardiomegaly by simple x-ray studies.

[Katz and co-workers \(1978\)](#) studied left ventricular performance during pregnancy and the puerperium using echocardiography. Both left ventricular wall mass and end-diastolic dimensions increased during pregnancy, as did heart rate, calculated stroke volume, and cardiac output. The changes in stroke volume were directly proportional to end-diastolic volume, implying, at least, that there is little change in the inotropic state of the myocardium during normal pregnancy. [Sadaniantz and associates \(1996\)](#) reported that these changes are not cumulative in subsequent pregnancies. In multifetal pregnancies, however, cardiac output is increased predominantly by **increased inotropic effect** ([Veille and co-workers, 1985](#)). The increased heart rate and inotropic contractility imply that cardiovascular reserve is reduced.

During pregnancy, some of the cardiac sounds may be altered. [Cutforth and MacDonald \(1966\)](#) obtained phonocardiograms at varying stages of pregnancy in 50 normal women and documented the following changes:

1. An exaggerated splitting of the first heart sound with increased loudness of both components; no definite changes in the aortic and pulmonary elements of the

second sound; and a loud, easily heard third sound.

2. A systolic murmur in 90 percent of pregnant women, intensified during inspiration in some or expiration in others, and disappearing very shortly after delivery; a soft diastolic murmur transiently in 20 percent; and continuous murmurs arising from the breast vasculature in 10 percent.

Normal pregnancy induces no characteristic changes in the *electrocardiogram*, other than slight deviation of the electrical axis to the left as a result of the altered position of the heart.

CARDIAC OUTPUT. During normal pregnancy, arterial blood pressure and vascular resistance decrease while blood volume, maternal weight, and basal metabolic rate increase. Each of these events would be expected to affect cardiac output. It is now evident that cardiac output *at rest*, when measured in the lateral recumbent position, increases significantly beginning in early pregnancy ([Duvekot and colleagues, 1993](#); [Mabie and co-workers, 1994](#)). It continues to increase and remains elevated during the remainder of pregnancy ([Fig. 8-10](#)). Typically, cardiac output in late pregnancy is appreciably higher when the woman is in the lateral recumbent position than when she is supine, because in the supine position the large uterus often impedes cardiac venous return. [Ueland and Hansen \(1969\)](#), for example, found cardiac output to increase 1100 mL (20 percent) when the pregnant woman was moved from her back onto her side. When she assumes the standing position after sitting, cardiac output in the pregnant woman falls to the same degree as in the nonpregnant woman ([Easterling and associates, 1988](#)).

During the first stage of labor, cardiac output increases moderately, and during the second stage, with vigorous expulsive efforts, it is appreciably greater ([Fig. 8-10](#)). After the substantively augmented cardiac output in the immediate puerperium, most of the pregnancy-induced increase is lost very soon after delivery.

HEMODYNAMIC VALUES FOR LATE PREGNANCY. [Clark and colleagues \(1989\)](#) conducted studies of maternal cardiovascular hemodynamics that serve to define normal values late in pregnancy ([Table 8-3](#)). Right heart catheterization was performed in 10 healthy nulliparous women at 35 to 38 weeks, and again at 11 to 13 weeks postpartum. Late pregnancy was associated with the expected increases in heart rate, stroke volume, and cardiac output. Systemic vascular and pulmonary vascular resistance both decreased significantly, as did colloid osmotic pressure. Pulmonary capillary wedge pressure and central venous pressure did not change appreciably between late pregnancy and the puerperium. These investigators concluded that normal late pregnancy is not associated with hyperdynamic left ventricular function as determined by Starling function curves (see [Fig. 44-1](#), p. 1183).

FACTORS CONTROLLING VASCULAR REACTIVITY IN PREGNANCY. [Gant and associates \(1973\)](#) conducted a prospective study of vascular reactivity to angiotensin II throughout pregnancy. Normal nulliparas who remained normotensive were refractory to the pressor effects of infused angiotensin II. Conversely, those destined to become hypertensive lost this refractoriness. This clear divergence of sensitivity to angiotensin II was likely the result of significant alterations in a variety of physiological processes that serve to control vascular reactivity to angiotensin II.

RENIN, ANGIOTENSIN II, AND PLASMA VOLUME. The renin-angiotensin-aldosterone axis is intimately involved in renal control of salt and water balance. All components of this system are increased in normal pregnancy ([Gallery and Lindheimer, 1999](#)). Renin is produced both by the maternal kidney and the uteroplacental unit while increased renin substrate (angiotensinogen) is produced by both maternal and fetal liver. This increase in angiotensinogen is due in part to high levels of estrogen production during normal pregnancy. [August and colleagues \(1995\)](#) provided data from first-trimester pregnancies and showed that stimulation of the renin-angiotensin system was important in blood pressure maintenance. [Gant and co-workers \(1974\)](#) and [Cunningham and associates \(1975\)](#) found that various acute volume loads, including normal saline (1000 mL), dextran (500 mL), and packed red blood cells (950 mL), did not alter pressor responsiveness to angiotensin II in normotensive pregnant women. Therefore, the increased refractoriness to angiotensin II characteristic of normal pregnancy is likely the consequence of individual vessel refractoriness to angiotensin II. That is, in the woman destined to develop preeclampsia, or in the woman already acutely ill with preeclampsia, the increased sensitivity to angiotensin II was the result of an alteration in vessel wall refractoriness rather than the consequence of changes in blood volume or circulating renin-angiotensin levels.

PROSTAGLANDINS. Increased production of prostaglandins in normal pregnancy may well play a central role in control of vascular tone, blood pressure, and sodium balance ([Gallery and Lindheimer, 1999](#)). Prostaglandin E₂ synthesis in the renal medulla is markedly increased in late pregnancy and is presumed to be natriuretic. Prostacyclin, the principal prostaglandin of endothelium, is also increased in late pregnancy and functions in regulation of blood pressure as well as coagulation. Prostacyclin has also been implicated to be a factor in the angiotensin resistance characteristic of normal pregnancy ([Friedman, 1988](#)). There has also been considerable interest in the ratio of prostacyclin to thromboxane in maternal urine and blood as this relates to preeclampsia ([Chap. 24, p. 586](#)).

PROGESTERONE AND METABOLITES. A progestin-induced mechanism may modulate prostaglandin-mediated vascular responsiveness to the pressor effects of angiotensin II characteristic of normal human pregnancy. Normally pregnant women lose pregnancy-acquired vascular refractoriness to angiotensin II within 15 to 30 minutes after the placenta is delivered. Moreover, large amounts of intramuscular progesterone given during late labor delay this loss. Conversely, intravenously administered progesterone does not restore angiotensin II refractoriness to women with pregnancy-induced hypertension; however, the infusion of a major progesterone metabolite—5 α -dihydroprogesterone—does. Similarly, infusion of this steroid into five normally pregnant women who had been rendered angiotensin II-sensitive by indomethacin also restored vascular refractoriness ([Everett and associates, 1978a](#)).

CYCLIC AMP. Administration of theophylline to angiotensin II-sensitive pregnant women with early-onset pregnancy-induced hypertension more than doubled the mean effective pressor dose of angiotensin II, restoring the vascular refractoriness characteristic of normal pregnancy ([Everett and co-workers, 1978b](#)). This effect of theophylline likely results from its inhibition of the enzyme *phosphodiesterase*, a principal regulator of intracellular cyclic nucleotide accumulation. Phosphodiesterase activity inhibition would promote the accumulation of cyclic adenosine monophosphate (cAMP) within vascular smooth muscle and should lead to the promotion of vascular smooth muscle relaxation.

CALCIUM ENTRY TO VASCULAR SMOOTH MUSCLE. Reductions in vascular refractoriness to infused angiotensin II have been reported in normal women and several different animals after the administration of various agents that act as calcium-channel blockers ([Anderson, 1987](#); [Hof, 1985](#); [Pasanisi, 1985](#); and their co-workers).

ENDOTHELIN. The endothelins are a recently discovered family of 21-amino-acid peptides. Endothelin-1 is produced in endothelial cells and vascular smooth muscle and regulates local vasomotor tone by causing vasoconstriction ([Levin, 1995](#)). Endothelin-2 and -3 are produced within the kidney and intestine.

There are endothelin receptors in pregnant and nonpregnant myometrium and endothelins have also been identified in amnion, amniotic fluid, decidua, and placental tissue ([Kubota and colleagues, 1992](#); [Sagawa and associates, 1994](#)). Their putative role in human parturition is discussed in detail in [Chapter 11 \(p. 279\)](#).

Endothelin-1 acts in a paracrine fashion and is the most potent vasoconstrictor substance yet identified. Its production is stimulated by angiotensin II, arginine vasopressin, and thrombin. Endothelins in turn stimulate secretion of atrial natriuretic peptide, aldosterone, and catecholamines. They reduce cardiac output, renal blood flow, and glomerular filtration. Endothelins bind to receptors (endothelin A and B), activate phospholipase C, and increase intracellular calcium concentration.

CIRCULATION

The posture of the pregnant woman affects *arterial blood pressure*. Blood pressure in the brachial artery varies when sitting or lying in the lateral recumbent supine position. Usually, arterial blood pressure decreases to a nadir at about midpregnancy and rises thereafter. Diastolic pressure decreases more than systolic ([Fig 8-11](#)).

The antecubital *venous pressure* remains unchanged during pregnancy, but in the supine position the femoral venous pressure rises steadily, from 8 cm H₂O early in pregnancy to 24 cm H₂O at term ([Fig. 8-12](#)). Employing radiolabeled tracers, [Wright and co-workers \(1950\)](#) and others have demonstrated that blood flow in the legs is retarded during pregnancy except when the lateral recumbent position is assumed. This tendency toward stagnation of blood in the lower extremities during the latter part of pregnancy is attributable to the occlusion of the pelvic veins and inferior vena cava by pressure of the enlarged uterus. The elevated venous pressure returns to normal if the pregnant woman lies on her side and immediately after delivery ([McLennan, 1943](#)). From a clinical viewpoint, the retarded blood flow and increased lower extremity venous pressure are of great importance. These alterations contribute to the dependent edema frequently experienced by women as they approach term, and to the development of varicose veins in the legs and vulva, as well as hemorrhoids. They also predispose to deep-vein thrombosis as discussed in [Chapter 46 \(p. 1235\)](#).

SUPINE HYPOTENSION. In late pregnancy with the woman in the supine position, the large pregnant uterus rather consistently compresses the venous system that returns blood from the lower half of the body to the extent that cardiac filling may be reduced and cardiac output decreased. In about 10 percent of women, this causes significant arterial hypotension, sometimes referred to as the *supine hypotensive syndrome* ([Kinsella and Lohmann, 1994](#)). [Bieniarsz and associates \(1968\)](#) observed that in the supine position, the large pregnant uterus may also compress the aorta sufficiently to lower arterial blood pressure below the level of

compression. They demonstrated that the usual measurement of blood pressures in the brachial artery does not provide a reliable estimate of the pressure in the uterine or other arteries that lie distal to aortic compression. When the pregnant woman is supine, uterine arterial pressure is significantly lower than that in the brachial artery. In the presence of systemic hypotension, as occurs with spinal analgesia, the decrease in uterine arterial pressure is even more marked than in arteries above the level of aortic compression ([Chap. 15, p. 372](#)).

BLOOD FLOW IN SKIN. Increased cutaneous blood flow in pregnancy serves to dissipate excess heat generated by increased metabolism.

RESPIRATORY TRACT

The diaphragm rises about 4 cm during pregnancy (see [Fig. 8-9](#)). The subcostal angle widens appreciably as the transverse diameter of the thoracic cage increases about 2 cm. The thoracic circumference increases about 6 cm, but not sufficiently to prevent a reduction in the residual volume of air in the lungs created by the elevated diaphragm. Diaphragmatic excursion is actually greater during pregnancy than when nonpregnant.

PULMONARY FUNCTION. At any stage of normal pregnancy, the amount of oxygen delivered into the lungs by the increase in tidal volume clearly exceeds the oxygen need imposed by the pregnancy. Moreover, the amount of hemoglobin in the circulation, and in turn the total oxygen-carrying capacity, increases appreciably during normal pregnancy, as does cardiac output. As the consequence, *maternal arteriovenous oxygen* difference is decreased.

[Hankins and colleagues \(1999\)](#) used pulmonary and radial artery catheters to directly measure oxygen transport in 10 normal women during the third trimester (36 to 38 weeks) and again 12 weeks postpartum. The oxygen content of arterial blood was significantly lower in the third trimester than in the postpartum period (16 and 12 mL/dL, respectively). Although cardiac output was significantly increased consistent with normal pregnancy, its effects on oxygen delivery were negated by a substantially lower hemoglobin content. Thus, the relative or physiological anemia of pregnancy accounted for the lower arterial oxygen content observed in this study.

The respiratory rate is little changed during pregnancy but the *tidal volume*, *minute ventilatory volume*, and *minute oxygen uptake* increase appreciably as pregnancy advances ([Table 8-4](#)). The *maximum breathing capacity* and *forced or timed vital capacity* are not altered appreciably. The *functional residual capacity* and the *residual volume* of air are decreased as the consequence of the elevated diaphragm. *Lung compliance* is unaffected by pregnancy. *Airway conductance* is increased and *total pulmonary resistance* is reduced, possibly as a result of progesterone action. The critical *closing volume*, or the lung volume at which airways in the dependent parts of the lung begin to close during expiration, has been considered to be higher in pregnancy by some investigators but not by others ([DeSwiet, 1991](#)).

An increased awareness of a desire to breathe is common even early in pregnancy ([Milne and colleagues, 1978](#)). This may be interpreted as dyspnea, which in turn suggests pulmonary or cardiac abnormalities when none exist. The mechanism of physiological dyspnea is thought to be increased tidal volume that lowers the blood PCO₂ slightly, which paradoxically causes dyspnea. The increased respiratory effort and in turn the reduction in PCO₂ during pregnancy is most likely induced in large part by progesterone and to a lesser degree estrogen. The site of progestin action appears to be central through a direct stimulatory effect on the respiratory center.

Although pulmonary function is not impaired by pregnancy, diseases of the respiratory tract may be more serious during gestation. Important factors are undoubtedly the increased oxygen requirements imposed by pregnancy and perhaps an increase in critical closing volume, especially when supine.

URINARY SYSTEM

KIDNEY

A remarkable number of changes are observed in the urinary system as a result of pregnancy ([Table 8-5](#)). *Kidney size* increases slightly during pregnancy. [Bailey and Rolleston \(1971\)](#), for example, found that the kidney was 15 cm longer during the early puerperium than when measured 6 months later. The *glomerular filtration rate (GFR)* and *renal plasma flow (RPF)* increase early in pregnancy, the former as much as 50 percent by the beginning of the second trimester, and the latter not quite so much ([Chesley, 1963](#); [Dunlop, 1981](#)). As shown in [Figure 8-13](#), elevated glomerular filtration has been found by most investigators to persist to term, and this is despite that renal plasma flow decrease during late pregnancy. *Kallikrein*, a tissue protease synthesized in cells of the distal renal tubule, is increased in several conditions associated with increased glomerular perfusion in nonpregnant individuals. [Platts and colleagues \(2000\)](#) studied urinary kallikrein excretion rates during human pregnancy and found increased excretion at 18 and 34 weeks which returned to nonpregnant levels at term. The significance of these normal fluctuations in renal kallikrein excretion rates during pregnancy remains unknown.

Most studies of renal function conducted during pregnancy have been performed while the subjects were supine, a position that late in pregnancy may produce marked systemic hemodynamic changes that lead to alterations in several aspects of renal function. Late in pregnancy, for instance, urinary flow and sodium excretion average less than half the excretion rate in the supine position compared with the lateral recumbent position.

Although posture clearly affects sodium and water excretion in late pregnancy, its impact on glomerular filtration and renal plasma flow is much more variable. For example, [Chesley and Sloan \(1964\)](#) found both to be reduced when the pregnant woman was in the supine position, whereas [Dunlop \(1976\)](#) identified inconsequential reduction. [Pritchard \(1955\)](#) detected decreases while supine compared with lateral recumbency in some, but not most of women studied in late pregnancy. [Ezimokhai and associates \(1981\)](#) reported that the late pregnancy decrease in renal plasma flow is not due simply to a positional effect.

LOSS OF NUTRIENTS. One unusual feature of the pregnancy-induced changes in renal excretion is the remarkably increased amounts of various nutrients in the urine. Amino acids and water-soluble vitamins are lost in the urine of pregnant women in much greater amounts than in nonpregnant women ([Hyttén and Leitch, 1971](#)).

TESTS OF RENAL FUNCTION. During pregnancy the plasma concentrations of creatinine and urea normally decrease as a consequence of their increased glomerular filtration. At times, the urea concentration may be so low as to suggest impaired hepatic synthesis, which sometimes occurs with severe liver disease.

Creatinine clearance is a useful test to estimate renal function in pregnancy provided that complete urine collection is made over an accurately timed period. *Urine concentration tests* may give results that are misleading ([Davison and colleagues, 1981](#)). During the day, pregnant women tend to accumulate water in the form of dependent edema; and at night, while recumbent, they mobilize this fluid and excrete it via the kidneys. This reversal of the usual nonpregnant diurnal pattern of urinary flow causes nocturia, and the urine is more dilute than in the nonpregnant state. Failure of a pregnant woman to excrete concentrated urine after withholding fluids for approximately 18 hours does not signify renal damage. In fact, the kidney in these circumstances functions perfectly normally by excreting mobilized extracellular fluid of relatively low osmolality.

URINALYSIS. *Glucosuria* during pregnancy is not necessarily abnormal. The appreciable increase in glomerular filtration, together with impaired tubular reabsorptive capacity for filtered glucose, accounts in most cases for the glucosuria ([Davison and Hyttén, 1975](#)). [Chesley \(1963\)](#) calculated that for these reasons alone about one sixth of all pregnant women should spill glucose in the urine. Even though glucosuria is common during pregnancy, the possibility of diabetes mellitus should not be ignored when it is identified.

Proteinuria is normally not evident during pregnancy except occasionally in slight amounts during or soon after vigorous labor. [Higby and associates \(1994\)](#) measured protein excretion in 270 normal women throughout pregnancy. Their mean 24-hour excretion was 115 mg, and the upper 95 percent confidence limit was 260 mg/day. There were no significant differences by trimester ([Fig. 8-14](#)). They also showed that albumin excretion is minimal and ranges from 5 to 30 mg/day. [Lopez-Espinoza and colleagues \(1986\)](#) measured serial albumin excretion using a sensitive radioimmunoassay in 14 healthy pregnant women. There was a slight rise from a median of 7 to 18 mg/24 hours from early to late pregnancy, however, albuminuria was not detected using conventional testing methods.

Hematuria, if not the result of contamination during collection, is compatible with a diagnosis of urinary tract disease ([Chap. 47, p. 1259](#)). Difficult labor and delivery, of course, can cause hematuria because of trauma to the lower urinary tract.

HYDRONEPHROSIS AND HYDROURETER. After the uterus rises completely out of the pelvis, it rests upon the ureters, compressing them at the pelvic brim. Increased intraureteral tonus above this level compared with that of the pelvic portion of the ureter has been identified ([Rubi and Sala, 1968](#)). [Schulman and Herlinger \(1975\)](#) found ureteral dilatation to be greater on the right side in 86 percent of pregnant women studied ([Fig. 8-15](#)). The unequal degrees of dilatation may result from a cushioning provided the left ureter by the sigmoid colon and perhaps from greater compression of the right ureter as the consequence of dextrorotation of the uterus. The right ovarian vein complex, which is remarkably dilated during pregnancy, lies obliquely over the right ureter and may contribute significantly to right

ureteral dilatation.

Another possible mechanism causing hydronephrosis and hydroureter is from an effect of progesterone. Major support for this concept was provided by [Van Wagenen and Jenkins \(1939\)](#), who described further ureteral dilatation after removal of the monkey fetus but with the placenta left in situ. The relatively abrupt onset of dilatation in women at midpregnancy is more consistent with ureteral compression from an enlarging uterus rather than a hormonal effect.

Elongation accompanies distention of the ureter, which is frequently thrown into curves of varying size, the smaller of which may be sharply angulated. These so-called kinks are poorly named, because the term connotes obstruction. They are usually single or double curves, which when viewed in the radiograph taken in the same plane as the curve, appear as more or less acute angulations of the ureter ([Fig. 8-15](#)). Another exposure at right angles nearly always identifies them to be more gentle curves rather than kinks. The ureter undergoes not only elongation but frequently lateral displacement by the pressure of the enlarged uterus.

BLADDER

[Thorp and colleagues \(1999\)](#) studied 123 pregnant women throughout pregnancy and the puerperium and found that pregnancy was associated with an increase in urinary incontinence. When women were asked to compare urinary tract function week by week throughout their pregnancies, they reported a steady deterioration in perceived bladder function. Indeed, objective measures of urinary frequency and total daily urinary output increased throughout pregnancy.

There are few significant anatomical changes in the bladder before 12 weeks. From that time onward, however, the increased size of the uterus, together with the hyperemia that affects all pelvic organs, and the hyperplasia of the muscle and connective tissues, elevates the bladder trigone and causes thickening of its posterior, or intraureteric, margin. Continuation of this process to the end of pregnancy produces marked deepening and widening of the trigone. The bladder mucosa undergoes no change other than an increase in the size and tortuosity of its blood vessels.

Using urethrocytometry, [Iosif and colleagues \(1980\)](#) found that bladder pressure in primigravidas increased from 8 cm H₂O early in pregnancy to 20 cm H₂O at term. To compensate for reduced bladder capacity, absolute and functional urethral lengths increased by 6.7 and 4.8 mm, respectively. Finally, to preserve continence, maximal intraurethral pressure increased from 70 to 93 cm H₂O. Still, the majority of women will experience their initial episode of urinary incontinence during pregnancy. Indeed, loss of urine is always high in the differential diagnosis of the woman presenting with a question of ruptured membranes.

Toward the end of pregnancy, particularly in nulliparas in whom the presenting part often engages before labor, the entire base of the bladder is pushed forward and upward, converting the normal convex surface into a concavity. As a result, difficulties in diagnostic and therapeutic procedures are greatly increased. In addition, the pressure of the presenting part impairs the drainage of blood and lymph from the base of the bladder, often rendering the area edematous, easily traumatized, and probably more susceptible to infection. Both urethral pressure and length have been shown to be decreased in women following vaginal but not abdominal delivery ([Van Geelen and co-workers, 1982](#)). These investigators suggest that a weakness of the urethral sphincter mechanism due to pregnancy or delivery may play a role in the pathogenesis of urinary stress incontinence.

Normally there is little residual urine in nulliparas, but occasionally it develops in the multipara with relaxed vaginal walls and a cystocele. Incompetence of the ureterovesical valve may supervene, with the consequent probability of vesicoureteral reflux of urine.

GASTROINTESTINAL TRACT

As pregnancy progresses, the stomach and intestines are displaced by the enlarging uterus. As the result of the positional changes in these viscera, the physical findings in certain diseases are altered. The appendix, for instance, is usually displaced upward and somewhat laterally as the uterus enlarges, and at times it may reach the right flank (see [Fig. 48-1](#), p. 1281).

Gastric emptying and intestinal transit times are delayed in pregnancy because of hormonal or mechanical factors. For example, this may be the result of progesterone or decreased levels of *motilin*, a hormonal peptide known to have smooth-muscle stimulating effects ([Christofides and associates, 1982](#)). [Macfie and colleagues \(1991\)](#) studied gastric emptying times using acetaminophen absorption and found these to be unchanged during each trimester and compared with nonpregnant women. During labor, however, and especially after administration of analgesic agents, *gastric-emptying time* is typically prolonged appreciably. A major danger of general anesthesia for delivery is regurgitation and aspiration of either food-laden or highly acidic gastric contents ([Chap. 15, p. 366](#)).

Pyrosis (heartburn) is common during pregnancy and is most likely caused by reflux of acidic secretions into the lower esophagus ([Chap. 48, p. 1276](#)). The altered position of the stomach probably contributes to its frequent occurrence; however, lower esophageal sphincter tone is also decreased. Intraesophageal pressures are lower and intragastric pressures higher in pregnant women. At the same time, esophageal peristalsis has lower wave speed and lower amplitude ([Ulmsten and Sundstrom, 1978](#)).

The gums may become hyperemic and softened during pregnancy and may bleed when mildly traumatized, as with a toothbrush. A focal, highly vascular swelling of the gums, the so-called *epulis* of pregnancy, develops occasionally but typically regresses spontaneously after delivery. Most evidence indicates that pregnancy does not incite tooth decay.

Hemorrhoids are fairly common during pregnancy. They are caused in large measure by constipation and the elevated pressure in veins below the level of the enlarged uterus.

LIVER

Although the liver in some animals increases remarkably in size during pregnancy, there is no evidence for such an increase during human pregnancy ([Combes and Adams, 1971](#)). Histological evaluation of liver biopsies, including examination with the electron microscope, have shown no distinct changes in liver morphology in normal pregnant women ([Ingerslev and Teilum, 1946](#)).

Some of the laboratory tests used to evaluate hepatic function yield appreciably different results during normal pregnancy. Moreover, some of those changes are similar to those in patients with liver disease. Total *alkaline phosphatase* activity in serum almost doubles during normal pregnancy, but much of the increase is attributable to heat-stable placental alkaline phosphatase isozymes. Serum aspartate transaminase (AST), alanine transaminase (ALT), gamma glutamyl transferase (GGT), and bilirubin levels are slightly lower during pregnancy compared with nonpregnant normal values ([Girling and colleagues, 1997](#)).

[Mendenhall \(1970\)](#) reconfirmed decreased *plasma albumin* concentration, showing it to average 3.0 g/dL late in pregnancy compared with 4.3 g/dL in nonpregnant women. Total albumin is increased, however, because of a greater volume of distribution. The reduction in albumin concentrations, combined with a normal slight increase in plasma globulins, results in a decrease in the albumin-to-globulin ratio similar to that seen in certain hepatic diseases.

Plasma *cholinesterase* activity is reduced during normal pregnancy. The magnitude of the decrease is about the same as the decrease in the concentration of albumin ([Kambam and associates, 1988](#); [Pritchard, 1955](#)). *Leucine aminopeptidase* activity is markedly elevated in serum from pregnant women. The increase results from the appearance of a pregnancy-specific enzyme (or enzymes) with distinct substrate specificities ([Song and Kappas, 1968](#)). Pregnancy-induced aminopeptidase has oxytocinase and vasopressinase activity.

GALLBLADDER

There is considerable alteration of gallbladder function during pregnancy. [Braverman and co-workers \(1980\)](#), using ultrasonography, found impaired gallbladder contraction and high residual volume. It has been suggested that progesterone impairs gallbladder contraction by inhibiting cholecystokinin-mediated smooth muscle stimulation, the primary regulator of gallbladder contraction. Impaired gallbladder contraction leads to stasis, and this, associated with the increased cholesterol saturation of pregnancy, at least partially explains the increased prevalence of cholesterol stones in women who have been pregnant many times.

The effects of pregnancy on maternal bile acid serum concentrations have been incompletely characterized despite the long-acknowledged propensity for pregnancy to cause intrahepatic cholestasis and pruritus gravidarum from retained bile salts ([Chap. 48, p. 1283](#) and [Chap. 54, p. 1431](#)). Cholestasis has been linked to high circulating levels of estrogen, which inhibit intraductal transport of bile acids ([Simon and colleagues, 1996](#)). [Leslie and associates \(2000\)](#), however, compared circulating estrogen levels in normal pregnant women with those of women with cholestasis. They found the latter group to have significantly lower plasma estrogen levels as well as impaired fetal production of dehydro-epiandrosterone (DHEA), which is the precursor to placental estrogen production. The significance of this recent

finding is unclear.

ENDOCRINE SYSTEM

Some of the most important endocrine changes of pregnancy have been discussed elsewhere, especially in [Chapter 6](#).

PITUITARY GLAND

As shown in [Figure 8-16](#), the pituitary gland enlarges during pregnancy by approximately 135 percent compared with nonpregnant controls ([Gonzalez and colleagues, 1988](#)). Although there have been suggestions that it may increase sufficiently to compress the optic chiasma and reduce visual fields, visual changes during normal pregnancy are minimal. [Scheithauer and colleagues \(1990\)](#) have provided evidence that the incidence of pituitary prolactinomas is not increased during pregnancy. When these tumors are large before pregnancy—a macroadenoma is 10 mm or greater—then enlargement during pregnancy is more likely ([Chap 50, p 1353](#)).

The maternal pituitary gland is not essential for maintenance of pregnancy. A number of women have undergone hypophysectomy, completed pregnancy successfully, and have undergone spontaneous labor while receiving glucocorticoids along with thyroid hormone and vasopressin.

GROWTH HORMONE. During the first trimester, serum and amniotic fluid growth hormone concentrations are within nonpregnant values of 0.5 to 7.5 ng/mL ([Kletzky and associates, 1985](#)). Serum values increase slowly from approximately 3.5 ng/mL at 10 weeks to plateau after 28 weeks at approximately 14 ng/mL. Growth hormone in amniotic fluid peaks at 14 to 15 weeks and slowly declines thereafter to reach baseline values after 36 weeks. After delivery, growth hormone is elevated for some time but at levels lower than late pregnancy values ([Spellacy and Buhi, 1969](#)).

PROLACTIN. During the course of human pregnancy, there is a marked increase in the maternal plasma levels of prolactin. In fact, the levels increase 10-fold (to 150 ng/mL) at term compared with normal nonpregnant women. Paradoxically, after delivery, there is a decrease in plasma prolactin concentration even in women who are breastfeeding. During early lactation, there are pulsatile bursts of prolactin secretion apparently in response to suckling. The physiological cause of the marked increase in prolactin prior to parturition is not entirely certain. It is known, however, that estrogen stimulation increases the number of anterior pituitary lactotrophs and may stimulate the release of prolactin from these cells ([Andersen, 1982](#)). Thyroid-releasing hormone acts to cause an increased prolactin level in pregnant compared with nonpregnant women, but the response decreases as pregnancy advances ([Andersen, 1982; Miyamoto, 1984](#)). Serotonin also is believed to increase prolactin, and prolactin-inhibiting factor—dopamine—inhibits its secretion.

The principal function of maternal serum prolactin is to ensure lactation. Early in pregnancy, prolactin acts to initiate DNA synthesis and mitosis of glandular epithelial cells and the presecretory alveolar cells of the breast. Prolactin also increases the number of estrogen and prolactin receptors in these same cells. Finally, prolactin promotes mammary alveolar cell RNA synthesis, galactopoiesis, and production of casein and lactalbumin, lactose, and lipids ([Andersen, 1982](#)). [Kauppila and co-workers \(1987\)](#) found that a woman with an isolated prolactin deficiency failed to lactate after two pregnancies, establishing the absolute necessity of prolactin for lactation but *not* for successful pregnancy outcome.

Prolactin also is found in high concentration in the fetal plasma, attaining highest concentrations during the last 5 weeks of pregnancy ([Winters and associates, 1975](#)). Considerable evidence has accrued that prolactin in fetal plasma is of fetal pituitary origin.

Prolactin is present in amniotic fluid in high concentrations. Levels of up to 10,000 ng/mL are found at 20 to 26 weeks; thereafter, levels decrease and reach a nadir after 34 weeks. Several investigators have presented convincing evidence that the uterine decidua is the site of prolactin synthesis in amniotic fluid ([Chap. 4, p. 81](#)).

The function of amniotic fluid prolactin is not known. Some investigators have suggested that it impairs the transfer of water from the fetus into the maternal compartment, thus preserving fetal extracellular fluid and preventing fetal dehydration during late pregnancy when amniotic fluid is normally hypotonic.

THYROID GLAND

There are important changes in thyroidal economy during pregnancy that are due to three modifications in the regulation of thyroid hormones. First, pregnancy induces a marked increase in circulating levels of the major thyroxine transport protein, thyroxine-binding globulin, in response to high estrogen levels. Second, several thyroidal stimulatory factors of placental origin are produced in excess. Although it is well recognized that hyperthyroidism may develop in women with elevated chorionic gonadotropin due to trophoblastic disease, the role of this hormone in normal pregnancy is still debated. Evidence has accrued that the thyroid is under dual control of both thyrotropin and chorionic gonadotropin during normal and abnormal pregnancy ([Kennedy and Darne, 1991](#)). Third, pregnancy is accompanied by a decreased availability of iodide for the maternal thyroid. This is due to increased renal clearance and losses to the fetoplacental unit during late gestation, and it results in a relative iodine-deficiency state.

During pregnancy there is moderate enlargement of the thyroid caused by hyperplasia of glandular tissue and increased vascularity. [Glinde and colleagues \(1990\)](#) assessed thyroid gland volume from 552 ultrasound examinations. Total gland volume increased from 12.1 mL in the first trimester to 15.0 mL at delivery. This increase was observed in the majority of women. Total volume also was found to be inversely proportional to serum thyrotropin concentrations. As emphasized by [Levy and co-workers \(1980\)](#), normal pregnancy does not typically cause significant thyromegaly, and any goiter in pregnancy should be investigated.

[Glinde and co-workers \(1990\)](#) provided cross-sectional and longitudinal data of maternal thyroid function throughout pregnancy. As shown in [Figure 8-17](#), thyroxine-binding globulin (TBG) increases beginning early in the first trimester, reaches its zenith at about 20 weeks, and stabilizes at approximately double baseline values for the remainder of pregnancy. Total (free and bound) serum thyroxine (T_4) increased sharply between 6 and 9 weeks, and thereafter only slowly, eventually reaching a plateau value at 18 weeks. Importantly, free serum T_4 levels return to normal after the first trimester. The rise in total triiodothyronine (T_3) is more pronounced up to 18 weeks; thereafter, it plateaus.

[Glinde and colleagues \(1990\)](#) further observed that the adjustment of thyroidal output of T_4 and T_3 was not similar for all pregnant women. Specifically, in about a third of women, there was relative hypothyroxinemia, preferential T_3 secretion, and higher (albeit normal) serum thyrotropin levels. These results suggest considerable variability in thyroidal adjustments during normal pregnancy.

The modifications in serum thyroid-stimulating hormone and chorionic gonadotropin as a function of gestational age are also illustrated in [Figure 8-17](#). There is an inverse relationship between the rise in chorionic gonadotropin and diminishing thyrotropin concentrations. Indeed, thyrotropin levels decrease in more than 80 percent of the women, even though levels are in the normal range for nonpregnant women. Thus, high serum chorionic gonadotropin levels are associated with thyroid stimulation, and this is consistent with a thyrotropin-like effect of chorionic gonadotropin.

These many complex alterations in thyroid regulation during pregnancy do not appear to alter maternal thyroid status as measured by metabolic studies. Although basal metabolic rate increases progressively during normal pregnancy by as much as 25 percent, most of this increase in oxygen consumption can be attributed to fetal metabolic activity. If fetal body surface area is considered along with that of the mother, the predicted and observed basal metabolic rates are quite similar.

THYROID-RELEASING HORMONE (TRH). This neurotransmitter is present throughout the brain but in highest concentrations in the hypothalamus. It stimulates synthesis and release of thyrotropin. It is not increased during normal pregnancy, but it does cross the placenta and may stimulate the fetal pituitary to secrete thyrotropin ([Thorpe-Beeston and associates, 1991](#)). Any role in fetal homeostasis is not clear.

FETAL THYROID GLAND. Changes in fetal thyroid physiology are also shown in [Figure 8-17](#). These are discussed in detail in [Chapter 7 \(p. 155\)](#). As the fetal thyroid becomes autonomous about 10 weeks, there is gradual "maturation" that progresses to term. At least during the first trimester, the fetus is dependent on maternal thyroxine. Later, there is minimal transfer of thyroid hormones from the maternal into the fetal compartment ([Burrow and colleagues, 1994](#)). This is likely the consequence of placental thyroxine deiodination. Therefore, after development, fetal thyroid function appears to be independent of maternal thyroid status.

REVERSE TRIIODOTHYRONINE (RT_3). This hormone is formed from the monodeiodination of thyroxine. Its metabolic activity is much less than triiodothyronine. It is predominately a fetal hormone and its level in fetal blood and amniotic fluid is three to five times higher than in maternal blood ([Roti and associates, 1983](#)). This is likely because the conversion of thyroxine to reverse triiodothyronine takes place in fetal membranes and in the placenta.

PARATHYROID GLANDS

The regulation of calcium concentration is closely interrelated to magnesium, phosphate, parathyroid hormone, vitamin D, and calcitonin physiology. Any alteration of one of these factors is likely to change the others.

PARATHYROID HORMONE AND CALCIUM INTERRELATIONSHIPS. Acute or chronic decreases in plasma calcium or acute decreases in magnesium stimulate the release of parathyroid hormone, whereas increases in calcium and magnesium suppress parathyroid hormone levels. The action of this hormone on bone resorption, intestinal absorption, and kidney reabsorption is to increase extracellular fluid calcium and decrease phosphate.

Parathyroid hormone plasma concentrations decrease during the first trimester, and then increase progressively throughout the remainder of pregnancy ([Pitkin and associates, 1985](#)). Increased levels likely result from the lower calcium concentration in the pregnant woman. As discussed earlier, this is due to increased plasma volume, increased glomerular filtration rate, and maternal-fetal transfer of calcium. Ionized calcium is decreased only slightly and [Reitz and co-workers \(1977\)](#) suggest that during pregnancy there is a new "set point" between ionized calcium and parathyroid hormone. Estrogens also appear to block the action of parathyroid hormone on bone resorption, resulting in another mechanism to increase parathyroid hormone during pregnancy. The net result of these actions is a *physiological hyperparathyroidism* of pregnancy, likely to supply the fetus with adequate calcium.

The potential roles of parathyroid hormone-related peptide production in the fetus, placenta, and maternal tissues are discussed in [Chapters 4 to 7](#).

CALCITONIN AND CALCIUM INTERRELATIONSHIPS. The calcitonin-secreting C cells are derived embryologically from the neural crest and are located predominantly in the perifollicular areas of the thyroid gland. Calcium and magnesium increase the biosynthesis and secretion of calcitonin. Various gastric hormones—gastrin, pentagastrin, glucagon, and pancreaticoxymin—and food ingestion also increase calcitonin plasma levels.

The known actions of calcitonin are generally considered to oppose those of parathyroid hormone and vitamin D to protect skeletal calcification during times of calcium stress. Pregnancy and lactation cause profound calcium stress, and during these times, calcitonin levels are appreciably higher than in nonpregnant women ([Weiss and co-workers, 1998](#); [Whitehead and associates, 1981](#)).

VITAMIN D AND CALCIUM INTERRELATIONSHIPS. Vitamin D is a hormone synthesized in the skin or ingested, and it is converted into 25-hydroxyvitamin D₃ by the liver. This is then converted in the kidney, decidua, and placenta to 1,25-dihydroxyvitamin D₃ ([Weisman and co-workers, 1979](#)). This most likely is the biologically active compound, and it stimulates resorption of calcium from bone and absorption from the intestines.

Control and release of 1,25-dihydroxyvitamin D₃ production is unknown, but the conversion of 25-hydroxyvitamin D₃ to 1,25-dihydroxyvitamin D₃ is facilitated by parathyroid hormone and by low calcium and phosphate plasma levels and opposed by calcitonin. Levels of 1,25-dihydroxyvitamin D₃ are increased during normal pregnancy ([Whitehead and associates, 1981](#)).

ADRENAL GLANDS

In normal pregnancy, there is probably very little morphological change in the maternal adrenal glands.

CORTISOL. There is a considerable increase in the serum concentration of circulating cortisol, but much of it is bound by cortisol-binding globulin, or *transcortin*. The rate of adrenal cortisol secretion is not increased, and probably it is decreased compared with the nonpregnant state. The metabolic clearance rate of cortisol, however, is lower during pregnancy because its half-life is nearly twice as long as it is in nonpregnant women ([Migeon and associates, 1957](#)). Administration of estrogen, including most oral contraceptives, causes changes in levels of cortisol and transcortin similar to those of pregnancy.

In early pregnancy, the levels of circulating corticotropin (ACTH) are reduced strikingly. As pregnancy progresses, the levels of corticotropin and free cortisol rise. This apparent paradox is not understood completely. [Nolten and Rueckert \(1981\)](#) have presented evidence that the higher free cortisol levels observed in pregnancy are the result of a "resetting" of the maternal feedback mechanism to higher levels. They further propose that this might result from *tissue refractoriness* to cortisol. Thus, an elevated free cortisol would be needed during pregnancy to maintain homeostasis.

ALDOSTERONE. As early as 15 weeks, the maternal adrenal glands secrete considerably increased amounts of aldosterone. By the third trimester, about 1 mg/day is secreted. If sodium intake is restricted, aldosterone secretion is elevated even further ([Watanabe and co-workers, 1963](#)). At the same time, levels of renin and angiotensin II substrate are normally increased, especially during the latter half of pregnancy. This gives rise to increased plasma levels of angiotensin II, which by acting on the zona glomerulosa of the maternal adrenal glands, accounts for the markedly elevated aldosterone secretion. It has been suggested that the increased aldosterone secretion during normal pregnancy affords protection against the natriuretic effect of progesterone and atrial natriuretic peptide. Progesterone administered to nonpregnant women is associated with a prompt increase in aldosterone excretion ([Laidlaw and colleagues, 1962](#)).

DEOXYCORTICOSTERONE. There is a striking increase in the maternal plasma levels of deoxycorticosterone (DOC) during pregnancy. [Brown and co-workers \(1972\)](#) found that in nonpregnant women and during the first two trimesters of pregnancy, the levels of plasma deoxycorticosterone are less than 100 pg/mL. During the last few weeks of pregnancy, these levels rise to 1500 pg/mL or more. The levels of deoxycorticosterone and its sulfate in fetal blood are appreciably higher than those in maternal blood, which suggests transfer of fetal deoxycorticosterone into the maternal compartment.

DEHYDROEPIANDROSTERONE SULFATE. As discussed in [Chapter 6](#), the levels of *dehydroepiandrosterone sulfate* circulating in maternal blood and excreted in the urine are decreased during normal pregnancy. This is a consequence of increased metabolic clearance through extensive 16 α -hydroxylation in the maternal liver and estrogen formation in the placenta.

ANDROSTENEDIONE AND TESTOSTERONE. Maternal plasma levels of these androgens are increased during pregnancy. This finding is not totally explained by alterations in their metabolic clearance. Maternal plasma androstenedione and testosterone are converted to estradiol in the placenta, which increases their clearance rates. Conversely, there is increased sex hormone-binding globulin in plasma of pregnant women which retards testosterone clearance. Thus, there is an increased plasma production rate of maternal testosterone and androstenedione during human pregnancy. The source of this increased C₁₉-steroid production is unknown but it likely originates in the ovary. Interestingly, little or no testosterone in maternal plasma enters the fetal circulation as testosterone. Even when massive testosterone levels are found in the circulation of pregnant women with androgen-secreting tumors, the testosterone level in umbilical cord venous plasma is likely to be too low to be detected. This finding is the result of the near complete conversion of testosterone to 17 β -estradiol by the trophoblast ([Edman and associates, 1979](#)).

OTHER SYSTEMS

MUSCULOSKELETAL SYSTEM

Progressive *lordosis* is a characteristic feature of normal pregnancy. Compensating for the anterior position of the enlarging uterus, the lordosis shifts the center of gravity back over the lower extremities. There is increased mobility of the sacroiliac, sacrococcygeal, and pubic joints during pregnancy, presumably as a result of hormonal changes. Their mobility may contribute to the alteration of maternal posture, and in turn cause discomfort in the lower portion of the back, especially late in pregnancy. During late pregnancy, aching, numbness, and weakness are occasionally experienced in the upper extremities. This possibly is from the marked lordosis with anterior neck flexion and slumping of the shoulder girdle, which in turn produce traction on the ulnar and median nerves ([Crisp and DeFrancesco, 1964](#)).

EYES

Intraocular pressure decreases during pregnancy, attributed in part to increased vitreous outflow ([Sunness, 1988](#)). Corneal sensitivity is also decreased, with the greatest changes late in gestation. Most pregnant women demonstrate a measurable but slight increase in corneal thickness thought to be due to edema. Consequently, pregnant women may have difficulty with previously comfortable contact lenses. Brownish-red opacities on the posterior surface of the cornea—*Krukenberg spindles*—have also been observed with a higher than expected frequency during pregnancy. Hormonal effects are postulated as the cause of this increased pigmentation. Other than transient loss of accommodation reported with both pregnancy and lactation, visual function is unaffected by pregnancy.

CENTRAL NERVOUS SYSTEM

Women often report problems with attention, concentration, and memory throughout pregnancy and the early postpartum period. Systematic studies of memory in pregnancy, however, are limited and often anecdotal. [Keenan and colleagues \(1998\)](#) longitudinally investigated memory in pregnant women as well as a matched control group. They found a pregnancy-related decline in memory, which was limited to the third trimester. This decline was not attributable to depression, anxiety,

sleep deprivation, or other physical changes associated with pregnancy The observed decline in memory was transient and it quickly resolved following delivery

Beginning as early as about 12 weeks, and extending through the first 2 months postpartum, women experience difficulty going to sleep, frequent awakenings, fewer hours of night sleep, and reduced sleep efficiency ([Swain and colleagues, 1997](#); [Lee and colleagues, 2000](#)). The greatest disruption of sleep occurs postpartum and may contribute to postpartum "blues" and/or depression ([Chap. 53, p. 1421](#)).

TABLE 8-2. Concentrations of Hemoglobin, Serum Iron, Transferrin, and Serum Ferritin during Pregnancy in Women without Overt Anemia and Not Given Dietary Iron Supplementation

Concentration	Nonpregnant (n = 10)	1st Trimester (n = 17)	2nd Trimester (n = 26)	3rd Trimester (n = 17)	At Delivery (n = 33)	Postpartum (n = 27)
Hemoglobin (g/dL)	13.0 ± 0.6	12.2 ± 1.3	10.9 ± 0.8	11.0 ± 0.9	12.4 ± 1.0	11.5 ± 1.0
Serum iron (µg/dL)	90.0 ± 32.9	106.5 ± 24.5	75.3 ± 37.8	56.0 ± 31.0 ^a	57.1 ± 31.2 ^a	56.0 ± 21.8 ^a
Transferrin (µg/dL)	242.1 ± 32.7	244.6 ± 52.7	336.2 ± 72.6 ^a	362.8 ± 55.4 ^a	438.2 ± 80.0 ^a	363.4 ± 40.5 ^a
Serum ferritin (ng/mL)	63.0 ± 34.7	97.4 ± 39.4 ^a	22.2 ± 14.6 ^b	14.7 ± 7.7 ^b	27.6 ± 15.6 ^b	36.0 ± 23.0 ^b

Each value represents the mean ± standard deviation.

Significantly different from nonpregnant value:

^a $P < .05$.

^b $P < .005$.

TABLE 8-3. Central Hemodynamic Changes in 10 Normal Nulliparous Women between 35 and 38 Weeks' Gestation and Again When 11 to 13 Weeks' Postpartum

Factor	Pregnant ^a	Postpartum	Change
Mean arterial pressure (mm Hg)	90 ± 6	86 ± 8	No change
Pulmonary capillary wedge pressure (mm Hg)	8 ± 2	6 ± 2	No change
Central venous pressure (mm Hg)	4 ± 3	4 ± 3	No change
Heart rate (beats/min)	83 ± 10	71 ± 10	±17%
Cardiac output (L/min)	6.2 ± 1.0	4.3 ± 0.9	+43%
Systemic vascular resistance (dyne/sec/cm ⁻⁵)	1210 ± 266	1530 ± 520	-21%
Pulmonary vascular resistance (dyne/sec/cm ⁻⁵)	78 ± 22	119 ± 47	-34%
Serum colloid osmotic pressure (mm Hg)	18.0 ± 1.5	20.8 ± 1.0	-14%
COP-PCWP gradient (mm Hg)	10.5 ± 2.7	14.5 ± 2.5	-28%
Left ventricular stroke work index (g/m/m ²)	48 ± 6	41 ± 8	No change

COP = colloid osmotic pressure; PCWP = pulmonary capillary wedge pressure.

TABLE 8-5. Renal Changes in Normal Pregnancy

Alteration	Change	Clinical Relevance
Increased renal size	Renal length approximately 1 cm greater on x-rays	Postpartum decreases in size should not be mistaken for parenchymal loss
Dilation of pelves, calyces, and ureters	Resembles hydronephrosis on ultrasound or IVP (more marked on right)	Not to be mistaken for obstructive uropathy; retained urine leads to collection errors; upper urinary tract infections are more virulent; may be responsible for "distention syndrome"; elective pyelography should be deferred to at least 12 weeks postpartum
Increased renal hemodynamics	Glomerular filtration rate and renal plasma flow increase ~50 percent	Serum creatinine and urea nitrogen values decrease during normal gestation; > 0.8 mg/dL (> 72 µmol/L) creatinine already suspect; protein, amino acid, and glucose excretion all increase
Changes in acid-base metabolism	Renal bicarbonate threshold decreases; progesterone stimulates respiratory center	Serum bicarbonate and PCO ₂ are 4-5 mEq/L and 10 mm Hg lower, respectively, in normal gestation; PCO ₂ of 40 mm Hg already represents CO ₂ retention
Renal water-handling	Osmoregulation altered: osmotic thresholds for AVP release and thirst decrease; hormonal disposal rates increase	Serum osmolality decreases 10 mOsm/L (serum Na ~ 5 mEq/L) during normal gestation; increased metabolism of AVP may cause transient diabetes insipidus in pregnancy

AVP = vasopressin; IVP = intravenous pyelography.

FIGURE 8-17.

Relative changes in maternal and fetal thyroid function during pregnancy. Maternal changes include a marked and early increase in hepatic production of thyroxine-binding globulin (TBG) and placental production of chorionic gonadotropin (hCG). Increased thyroxine-binding globulin increases serum T_4 concentrations, and chorionic gonadotropin has thyrotropin-like activity and stimulates maternal T_4 secretion. The transient hCG-induced increase in serum from T_4 inhibits maternal secretion of thyrotropin. Except for minimally increased free thyroxine (free T_4) levels when hCG peaks, these levels are essentially unchanged. (From [Burrow and colleagues, 1994](#), with permission.)

SECTION III - PREGNANCY PLANNING AND ANTEPARTUM MANAGEMENT

9. Preconceptional Counseling

In the early part of the 20th century, women with medical problems were often unable to conceive or were advised not to. Medical breakthroughs such as the discovery of insulin and development of effective antihypertensive and other medications subsequently made it possible for such women to contemplate pregnancy. Obstetrical care of the women with medical problems during this time dealt almost exclusively with protecting maternal health, as little was known about pathological influences on fetal development. In the 1960s, research began to focus on the pathophysiology of pregnancy and perinatal outcome. As a result, prenatal care began to extend toward fetal concerns, and interest in perinatal research increased dramatically. Subsequently, the etiology of many pathological maternal and fetal conditions was elucidated, and intensive research clarified genetic origins of many diseases. At the same time, effective contraception was developed, and many women were now postponing pregnancy and limiting family size, while at the same time striving to optimize the outcome of each pregnancy. Thus, the focus of obstetrical care has changed once again, from treating maternal and fetal diseases to predicting and preventing them.

In 1990, the Public Health Service published *Healthy People 2000*, a guide for a nationwide preventive medicine program drafted by leading scholars and designed to address the highest priority health-care issues. The major goals of this program are to increase the span of healthy life, to reduce health disparities between individuals, and to improve access to preventive services. Preventive medicine for obstetrics figures prominently in this plan, and 3 of the 18 indicators selected for monitoring community health status reflect obstetrical care: infant mortality is number 1, low birthweight is number 14, and first-trimester prenatal care is number 16. A specific goal of the program is to increase to at least 60 percent the proportion of primary-care providers who provide preconceptional care and counseling.

Preconceptional counseling is preventive medicine for obstetrics. All factors that could potentially affect perinatal outcome are identified, the woman is advised of her risks, and a strategy is provided to reduce or eliminate the pathological influences made evident by her family, medical, or obstetrical history and/or specific testing. The 1989 Public Health Service Expert Panel on the Content of Prenatal Care stated that "the preconceptional visit may be the single most important health care visit when viewed in the context of its effect on pregnancy." This chapter reviews a variety of data confirming that preconceptional counseling has a measurable positive impact on pregnancy outcome, describes the components of preconceptional counseling, and provides specific guidelines for the preconceptional management of a variety of medical, obstetrical, and genetic disorders.

BENEFITS OF PRECONCEPTIONAL COUNSELING

Randomized trials of the efficacy of preconceptional counseling are scarce; furthermore, in many cases, withholding such counseling would be considered unethical. Maternal and perinatal outcomes also are dependent upon the interaction of maternal, fetal, and environmental factors, and it is difficult to ascribe pregnancy outcome to one specific intervention. Nevertheless, there have been several prospective and case-control trials that clearly demonstrate that preconceptional counseling improves pregnancy outcomes.

UNINTENDED PREGNANCY

To be effective, counseling about potential pregnancy risks and strategies to prevent them must be provided before conception. By the time most women realize they are pregnant, 1 to 2 weeks after the first missed period, the fetal spinal cord has already formed and the heart is beating ([Moore, 1983](#)). Many prevention strategies, for example, folic acid to prevent neural-tube defects, are ineffective if initiated at this time. The [Centers for Disease Control and Prevention \(1999\)](#) estimates that up to half of all pregnancies are unplanned, and there is evidence that these may be at greatest risk.

[Adams and colleagues \(1993\)](#) conducted a population-based survey of almost 12,500 women in four states and found that women with unintended pregnancies were more likely than those with planned pregnancies to have an indication for preconceptional counseling. [Hellerstedt and co-workers \(1998\)](#) conducted a telephone survey of nearly 7200 pregnant women which showed that women with unintended pregnancies were more likely to have high-risk behaviors such as cigarette smoking and less likely to use vitamins daily. [Jack and associates \(1995\)](#) administered a comprehensive risk survey to 136 women at the time of a negative pregnancy test. The majority did not want to be pregnant, half reported a medical or reproductive risk that could adversely affect pregnancy, half reported a genetic risk, and a fourth reported risks for human immunodeficiency virus (HIV) infection and hepatitis B, as well as alcohol or recreational drug use.

An important measure of the effectiveness of preconceptional counseling is therefore its influence in reducing the number of unintended pregnancies. [Moos and colleagues \(1996\)](#) instituted a preconceptional care program for reproductive-age health department patients in 1985. Of 1378 women presenting for prenatal care, the 456 exposed to preconceptional counseling had a 50 percent greater likelihood of describing their pregnancies as intended when compared with 309 women who had health care but no counseling. They had a 65 percent greater likelihood when compared with women with no health care prior to pregnancy.

CHRONIC MEDICAL DISORDERS

DIABETES Because maternal and fetal pathology associated with hyperglycemia is well known, diabetes is the prototype of a medical disorder for which preconceptional counseling is beneficial. Diabetes-associated risks to both mother and fetus are discussed in [Chapter 51](#). Many of these complications can be avoided if conception occurs when glucose control is regulated ([Jovanovic and colleagues, 1981](#)). Such control requires that glucose control be either chronically well regulated—always a goal, but difficult to achieve—or that the woman make necessary changes before conceiving. Preconceptional counseling educates her about risks, and provides a program designed to reduce these risks before pregnancy.

PERINATAL MORBIDITY AND MORTALITY The utility of preconceptional counseling in preventing diabetes-related complications at all stages of pregnancy has been confirmed. [Figure 9-1](#) summarizes major studies in which the incidence of fetal anomalies in diabetic women who received preconceptional counseling are compared with the incidence in women who did not. Without exception, all studies showed that counseling is associated with fewer malformations.

[Dunne and co-workers \(1999\)](#) recently reviewed the impact of preconceptional counseling on diabetes-related neonatal morbidity other than birth defects. Women who received preconceptional counseling presented earlier for prenatal care, had lower hemoglobin A_{1c} levels, and were less likely to smoke during pregnancy. These women had no deliveries before 30 weeks compared with 17 percent in the uncounseled group; they had fewer macrosomic infants (25 versus 40 percent); had no growth-restricted infants (versus 8.5 percent); experienced no neonatal deaths (versus 6 percent); and their infants had 50 percent fewer admissions to the intensive care nursery unit than diabetic women without counseling (17 versus 34 percent).

MATERNAL AND ECONOMIC MORBIDITY Preconceptional counseling reduces obstetrical complications and health-care costs in diabetic women. In a prospective multicenter observational trial from five Michigan centers, [Herman and colleagues \(1999\)](#) confirmed these. Diabetics with counseling reported for prenatal care 3 weeks earlier than uncounseled women, had lower hemoglobin A_{1c} levels, were significantly less likely to require hospitalization for diabetes control during pregnancy (8 versus 68 percent), and required significantly fewer days of hospitalization (4.5 versus 15.7). They were also less likely to have hypoglycemic episodes, they had fewer episodes of diabetic ketoacidosis, they had no hypertensive complications, and their postpartum stay was 2 days shorter. These improved outcomes were associated with savings of \$34,000 in direct medical costs per patient who had counseling.

EPILEPSY Offspring of women with epilepsy are two to three times more likely to have structural anomalies than those of unaffected women; offspring exposed to anticonvulsants are at even higher risk ([Chang and McAuley, 1998](#); [Yerby, 1993](#)). These risks are detailed in [Chapter 38 \(p. 1012\)](#). Preconceptional counseling usually includes the recommendation to switch to the least teratogenic drug regimen, or possibly even discontinue medication before conception. The [American Academy of Neurology \(1998\)](#) recommends that reproductive-age epileptic women undergo preconceptional counseling, and that they conceive while taking folic acid and the least teratogenic monotherapeutic antiseizure medication. [Biale and Lewenthal \(1984\)](#) performed a retrospective case-control study evaluating the effects of preconceptional folic acid supplementation in epileptic women taking anticonvulsants. They found that 10 of 66 (15 percent) unsupplemented pregnancies resulted in offspring with congenital malformations, whereas none of 33 neonates of supplemented women had anomalies.

OTHER CHRONIC DISEASES [Cox and co-workers \(1992\)](#) reviewed subsequent pregnancy outcomes of 1075 couples who received preconceptional counseling. Pregnancy outcomes for 240 women with hypertension, renal disease, thyroid disease, asthma, and heart disease were significantly improved if they had received counseling. Indeed, 80 percent of those counseled gave birth to a normal infant in that pregnancy, compared with 40 percent in the previous gestation.

GENETIC DISEASES

Birth defects are currently the leading cause of infant mortality and account for 20 percent of all infant deaths. These can be avoided with primary, secondary, or tertiary prevention strategies (Czeizel, 1995). The preferred strategy is *primary prevention*—avoidance of causal factors—which is becoming possible for more congenital diseases as their etiologies are discovered. *Secondary prevention*—identifying and terminating affected pregnancies—is an alternate strategy for single-gene disorders and other defects that cannot be prevented. Benefits of preconceptional counseling are usually measured by comparing the incidence of new cases before and after the initiation of a counseling program. A few examples of congenital conditions clearly benefitted by counseling are provided.

NEURAL-TUBE DEFECTS The incidence of these defects is 1 to 2 per 1000 live births, and they are second only to cardiac anomalies as the most frequent structural fetal malformation (Chap. 36, p. 958). Because some neural-tube defects are related to a specific mutation in the methylene tetrahydrofolate reductase gene (677C>T), the effects can be largely overcome by periconceptional folic acid supplementation (Ou and associates, 1996; van der Put and colleagues, 1995). The Medical Research Council on Vitamin Study Research Group (1991) conducted a randomized double-blind study at 33 centers in seven countries. The result showed that women with a previously affected child who took preconceptional folic acid reduced their recurrence risk by 72 percent. Czeizel and Dudas (1992) subsequently showed that supplementation reduced the *a priori* risk of a first occurrence.

PHENYLKETONURIA (PKU) This disorder is an inborn error of phenylalanine metabolism. It is an example of a disease in which the fetus is not at risk to inherit the disease, but may be damaged by the effects of maternal genetic disease. For such conditions, preconceptional counseling regarding strategies to improve the intrauterine environment constitutes primary prevention and may significantly reduce fetal morbidity. Affected individuals eating an unrestricted diet have abnormally high blood phenylalanine levels. This amino acid readily crosses the placenta to damage developing fetal organs, and neural tissue is particularly vulnerable (Chap. 36, p. 952). With preconceptional counseling, and adherence to a phenylalanine-restricted diet before pregnancy, the incidence of fetal malformations is dramatically reduced (Guttler and colleagues, 1990; Koch and associates, 1990). The Maternal Phenylketonuria Collaborative Study evaluated the effectiveness of preconceptional care in preventing PKU¹-related fetal defects (Rouse and co-workers, 1997). Almost 300 women with PKU were counseled and began a low phenylalanine diet before pregnancy. Compared with infants whose mothers had poor control, infants of women achieving good control had a lower incidence of microcephaly (6 versus 15 percent), neurological abnormalities (4 versus 14 percent), and cardiac defects (none versus 16 percent). The percentage of women treated preconceptionally increased from 7 to 51 from 1984 to 1994 (Platt and colleagues, 2000).

TAY SACHS DISEASE This is a severe autosomal recessive neurodegenerative disorder leading to death in childhood. The effectiveness of preconceptional counseling in reducing genetic disease has been most clearly demonstrated in Tay Sachs disease. In the early 1970s, there were approximately 60 new cases in the United States each year, primarily in individuals of Jewish heritage. An intensive worldwide campaign was initiated to counsel Jewish people, to identify carriers through genetic testing, to provide prenatal testing for high-risk couples—secondary prevention, and even to help heterozygote carriers choose unaffected mates—primary prevention! The outcome of this preconceptional counseling initiative has been monitored by the National Tay-Sachs Disease and Allied Disorders Association (Kaback and colleagues, 1993). Within 8 years of its inception, nearly 1 million young adults around the world had been tested and counseled and the incidence of new Tay Sachs cases has plummeted to 3 to 5 new cases per year. Currently, most new cases are in the non-Jewish population.

THALASSEMIAS Currently, 250 million people—4.5 percent of the world population—carry a gene for a hemoglobinopathy, and 300,000 affected infants are born each year (Angastiniotis and colleagues, 1995). Some of the more important thalassemia syndromes are discussed in Chapter 49 (p. 1321). Some of these could be avoided by both primary and secondary prevention (Fucharoen and associates, 1991; Wong, 1985). In endemic areas such as Mediterranean countries, counseling and other prevention strategies have reduced the incidence of new cases by at least 80 percent (Angastiniotis and Model, 1998). Mitchell and colleagues (1996) summarized experiences of a long-standing counseling program aimed at Montreal high school students at risk. Over 20 years, 25,274 students of Mediterranean origin were counseled and tested for β -thalassemia. Within a few years of initiation of the preconceptional program, all high-risk couples who requested prenatal diagnosis had already been counseled through the program, and no affected children have been born since that time.

PRECONCEPTIONAL COUNSELORS

Practitioners providing routine health maintenance for reproductive-age women have the best opportunity to provide preventive counseling. Gynecologists, internists, family practitioners, and pediatricians can provide counseling at the annual examination. The occasion of a negative pregnancy test is a good time for counseling. Jack and associates (1995) administered a comprehensive preconceptional risk survey to 136 women who had a negative pregnancy test in an ambulatory general practice clinic. Almost 95 percent of these women reported at least one problem which could affect a future pregnancy. Examples include medical or reproductive problems (52 percent), genetic risks (50 percent), risk for human immunodeficiency virus (30 percent), risk for hepatitis B and illegal substances (25 percent), alcohol risk (17 percent), and nutritional risk (54 percent).

Basic preconceptional advice regarding diet, alcohol use, smoking, illicit drug use, vitamin intake, exercise, and other influences can be provided by the primary-care provider, including the obstetrician-gynecologist. The counselor should be knowledgeable about relevant medical diseases or surgery, reproductive disorders, or genetic conditions. Medical records must be obtained if necessary, and the counselor must be able to interpret data provided by other specialists for both the woman and her future progeny. The practitioner who is uncomfortable providing counseling for a complex medical or genetic disorder should refer the woman or couple to a counselor with special expertise.

PATIENT HISTORY

Counseling begins with a thorough review of the medical, obstetrical, social, and family histories. Useful information is more likely obtained with specific questions about each aspect of the history. Such an interview may take 30 minutes to an hour. Some important information can be obtained by questionnaire, ideally at a routine prepregnancy visit. Questionnaires are commercially available which address medical and surgical history; reproductive history, including outcomes of each prior pregnancy; medication use and drug allergies; family history of medical or genetic diseases and reproductive abnormalities; racial or ethnic origin; social risk factors—alcohol, illicit drugs, smoking, high-risk sexual behavior, and spousal abuse; environmental risk factors—such as exposure to pesticides or dry-cleaning chemicals; and home environment and stress inducers. Answers are reviewed with the patient so that necessary follow-up is done by obtaining appropriate medical records or by consulting family members.

While most patients can provide some information regarding their history, their understanding may be limited. Maternal reports of familial genetic abnormalities may be especially inaccurate. Several studies have shown that women often fail to report a birth defect in the family or report it incorrectly. Romitti and associates (1997) interviewed 345 women who had a relative with a birth defect and 380 women without such a history. They verified their responses about family history by contacting relatives. Only 30 percent of all of these women correctly reported birth defects history. Rasmussen and colleagues (1990) used the Atlanta Birth Defects Registry to identify 4929 women whose child had a verified birth defect. When contacted, only 60 percent accurately reported the defect. It is thus important to verify the type of reported defect by reviewing pertinent medical records. The woman or couple is also asked to contact her affected relatives for additional information.

REPRODUCTIVE HISTORY

Reproductive history includes previous attempts at conception, any infertility, and abnormal pregnancy outcomes including miscarriage, ectopic pregnancy, or recurrent pregnancy loss. Reproductive history of first-degree relatives may also be helpful—for example, with recurrent pregnancy loss, other family members with the same history increases the risk of a familial translocation or another chromosome rearrangement. History suggesting incompetent cervix or uterine anomaly should prompt the appropriate evaluation.

The need for assisted reproductive technologies to become pregnant is noted. For example, as discussed in Chapter 36, preliminary data suggest that intracytoplasmic sperm injection (ICSI) is associated with certain poor outcomes (Bowen and colleagues, 1998). Cryopreservation of embryos may also slightly increase risks.

Risk factors for recurrent preterm delivery, preeclampsia, placental abruption, and repeat cesarean delivery are summarized elsewhere in this book, along with suggestions for their prevention.

SOCIAL HISTORY

MATERNAL AGE At both ends of the reproductive years, maternal age impacts pregnancy outcome.

TEENAGE PREGNANCY According to the National Center for Health Statistics (Smith and colleagues, 1999), women between ages 15 and 19 account for about 13 percent of all births. Teenagers are more likely to be anemic, and are at increased risk to have growth-restricted infants, preterm labor, and a higher infant mortality

([Fraser and associates, 1995](#)). Because most teen pregnancies are unplanned, they rarely present for preconceptional counseling. Counseling in early pregnancy can still be helpful. Teenagers are usually still growing and developing, and thus have greater caloric requirements than older women. The normal or underweight teenager should be advised to increase caloric intake by 400 kcal/day. Nonjudgmental questioning may elicit a history of substance abuse. As with all good prenatal care, common complications are reviewed.

PREGNANCY AFTER 35 Currently, about 10 percent of pregnancies occur in women in this age group. The older woman is more likely to request preconceptional counseling, either because she has postponed pregnancy and now wishes to optimize her outcome, or she does so prior to infertility treatment. In the past, the indelicate term *elderly gravida* was used to arbitrarily define women over 35. Although hopefully the term has been discarded, the occurrence of certain age-related adverse pregnancy outcomes do begin increasing at this age.

Early studies suggested that women over 35 are at increased risk for obstetrical complications as well as perinatal morbidity and mortality. For the older woman who has a chronic illness or who is in poor physical condition, these risks likely are valid. For the normal weight, physically fit woman without medical problems, however, the risks are much lower than previously reported.

The importance of socioeconomic and health status is illustrated by two studies of pregnancy outcome in different populations of older women. [Berkowitz and co-workers \(1990\)](#) described outcomes of almost 800 private-patient nulliparas over 35 whom they cared for at Mount Sinai Hospital in New York City. They reported only slightly increased risks for gestational diabetes, pregnancy-induced hypertension, placenta previa or abruption, and cesarean delivery. These women did not have an increased risk for preterm delivery, growth-restricted infants, or perinatal death. In contrast, our observations from Parkland Hospital ([Cunningham and Leveno, 1995](#)) of nearly 900 women over 35 showed a significantly increased incidence of hypertension, diabetes, abruption, preterm delivery, stillbirth, and placenta previa ([Fig. 9-2](#)). Not surprisingly, this group also had higher perinatal mortality rates. The disparate outcomes in these two groups of women likely is attributable to socioeconomic status, which influences access to health care and health status.

Some pregnancy outcomes in older women may be influenced by parity; for example, labor abnormalities are more common in older nulliparas. [Bobrowski and Bottoms \(1995\)](#) reviewed pregnancy outcomes in 8746 women and found that both age and parity influenced the incidence of diabetes, labor disorders, and cesarean delivery.

Maternal mortality is higher in women age 35 and older, but improved medical care may ameliorate this risk. [Buehler and colleagues \(1986\)](#) reviewed maternal deaths in the United States from 1974 through 1982. From 1974 through 1978, older women had a fivefold increased relative risk of maternal death compared with younger women. By 1982, however, the mortality rates for older women had decreased by 50 percent. They concluded that this was probably due to improvements in health care.

Maternal age-related fetal risks stem from iatrogenic preterm delivery required for some maternal complications that include hypertension and diabetes, from spontaneous preterm delivery, and from an increased incidence of aneuploidy. Although most researchers have found that maternal age significantly influences only the incidence of aneuploidy, our observations suggest otherwise. [Hollier and colleagues \(2000\)](#) studied 3885 infants with congenital malformations in nearly 103,000 pregnancies at Parkland Hospital. As shown in [Figure 9-3](#), the risk for all nonchromosomal abnormalities increased significantly with maternal age. Club foot was increased significantly after 35 and heart disease after 40. In addition, increased paternal age is associated with increased birth defects due to new autosomal dominant mutations ([Chap. 36, p. 951](#)). Finally, while dizygotic twinning increases with maternal age, the most important cause of multiple gestation in these women currently is infertility treatment.

RECREATIONAL DRUGS AND SMOKING Fetal risks associated with alcohol, marijuana, cocaine, amphetamines, and heroin are discussed in [Chapter 38](#). Alcohol-related mental retardation is currently the only mental retardation syndrome amenable to primary prevention. The key to preventing this and other types of drug-related fetal damage is to have the woman provide an honest assessment of her usage. Questions should be nonjudgmental. The alcoholic can be identified by asking the well-studied TACE questions, which correlate with DSM-III-R criteria for lifetime alcohol diagnoses ([Chang and associates, 1998](#)). This is a series of four questions concerning: *tolerance* to alcohol, being *annoyed* by comments about their drinking, attempts to *cut down*, and a history of drinking early in the morning—the *eye opener*.

Smoking affects fetal growth in a dose-dependent manner. It increases risks for preterm labor, fetal-growth restriction, and low birthweight as well as attention deficit hyperactivity disorder (ADHD) and behavioral and learning problems when school-age is reached ([American College of Obstetricians and Gynecologists, 1999](#)). It also increases the risk of pregnancy complications related to vascular insufficiency, such as uteroplacental insufficiency and placental abruption ([Chap. 25, p. 621](#)). The extent of cigarette use should be determined and the woman provided with a prepregnancy program to reduce or eliminate smoking.

ENVIRONMENTAL EXPOSURES While everyone is exposed to environmental substances, only a few increase pregnancy risk. These exposures include infectious organisms—for example, neonatal nurses have potential exposure to cytomegalovirus or respiratory syncytial virus, and day-care workers may be exposed to parvovirus and rubella. Pregnant industrial workers may be exposed to chemicals such as heavy metals or organic solvents. Patients living in rural areas may be exposed to potentially harmful chemicals through pesticide use or contaminated well water. When harmful prenatal exposure is likely, the woman planning conception should remove herself from the agent before conception and throughout gestation.

LIFESTYLE AND WORK HABITS

A number of personal and work habits and lifestyle issues may have an impact on pregnancy outcome.

DIET Pica for ice, laundry starch, or clay and dirt is often associated with anemia. Many vegetarian diets are protein deficient, but can be corrected by increasing egg and cheese consumption. As discussed in [Chapter 48 \(p. 1298\)](#), **obesity** is associated with a number of maternal complications such as hypertension, preeclampsia, gestational diabetes, thrombophlebitis, labor abnormalities, postterm pregnancy, cesarean delivery, and operative complications ([Wolfe, 1998](#)). It is also associated with adverse fetal outcome. [Cnattingius and co-workers \(1998\)](#) evaluated 167,750 women in Sweden and found that those with a body mass index over 30 were at increased risk for late fetal death and preterm delivery before 32 weeks. [Waller and colleagues \(1994\)](#) have shown that offspring of obese women are at increased risk for spina bifida, ventral wall defects, and intestinal malformations.

In addition to nutritional deficiencies, **anorexia** and **bulimia** increase the risk for associated problems such as electrolyte disturbances, cardiac arrhythmias, and gastrointestinal pathology ([Becker and associates, 1999](#)). In a study of 23 pregnancies in 15 women previously treated for anorexia nervosa or bulimia, [Stewart and colleagues \(1987\)](#) reported that those whose anorexia was not in remission at the time of conception had worsening of symptoms during pregnancy. They also gained less weight and had lighter infants.

EXERCISE There are no data to suggest that exercise is deleterious during pregnancy. Most pregnant women can continue to exercise throughout gestation, although their prepregnancy routine may need to be altered. For example, pregnancy may cause balance problems and joint relaxation may predispose to orthopedic injury. The [American College of Obstetricians and Gynecologists \(1994\)](#) guidelines for exercise in pregnancy are shown in [Table 9-1](#).

DOMESTIC ABUSE Pregnancy can exacerbate interpersonal problems. There is increased risk from an abusive partner during pregnancy. As discussed in [Chapter 43 \(p. 1171\)](#), one in six women is abused during pregnancy ([Eisenstat and Bancroft, 1999](#)). The interviewer should inquire about risk factors for domestic violence, and should offer intervention as appropriate. Abuse is more likely in women whose partners abuse alcohol or drugs, are recently unemployed, and have a poor education or low income, and a history of arrest ([Grisso and colleagues, 1999](#); [Kyriacou and associates, 1999](#)).

FAMILY HISTORY

The most thorough method for obtaining such a history is to construct a pedigree using symbols shown in [Figure 9-4](#). The health and reproductive status of these "blood relatives" are reviewed for medical illnesses, mental retardation, birth defects, infertility, and pregnancy loss. Certain racial, ethnic, or religious backgrounds may indicate increased risk for certain recessive disorders. Family histories are not always accurate, but any concerns should be verified.

CHRONIC MEDICAL DISEASES

Preconceptional counseling should address historical risk factors for both mother and fetus. General questions to be answered include how pregnancy will affect maternal health, and how the high-risk condition will affect the fetus. Almost any medical, obstetrical, or genetic condition warrants some consideration prior to pregnancy. These conditions are discussed in general terms of maternal and fetal risk, suggestions for prepregnancy evaluation are offered, and counseling advice is

provided. More detailed information on each disease, as well as other diseases not mentioned, are found elsewhere in this book.

DIABETES

Substantive risks to mother and fetus are increased with overt diabetes ([Chap. 51](#)). Maternal risks include retinal, renal, and cardiac damage, urinary infections, diabetic ketoacidosis, and cesarean delivery. Hypertension is common and the diabetic woman with renal disease is at especially high risk for preeclampsia. Fetal risks include increased perinatal mortality, a variety of malformations, growth disturbances, iatrogenic preterm delivery, and neonatal metabolic instability. The embryo is particularly susceptible to teratogenic effects of hyperglycemia, and many malformations occur early before pregnancy is recognized ([Reece and Hobbins, 1986](#)). Neural-tube defects and cardiac and renal anomalies occur two to five times more often in diabetic pregnancies ([American Diabetes Association, 1995](#)). Sacral agenesis and holoprosencephaly are rare malformations that are seen commonly in the fetuses of severely diabetic women ([Barr and colleagues, 1983](#); [Passarge and co-workers, 1966](#)).

Because poor glucose control early in pregnancy may be teratogenic, the prepregnancy visit should include a review of diabetic control and provocative factors. Baseline glucose control and end-organ damage should be assessed to include renal and cardiac function and retinopathy. Counseling is provided concerning effects of poor control on fetal malformations as estimated from hemoglobin A_{1c} levels ([Table 9-2](#)). Pregnancy outcome risks in women with renal involvement are discussed later. In most cases of advanced renal insufficiency, pregnancy should be postponed until kidney transplantation.

The important elements of the preconceptional visit have been summarized by the [American Diabetes Association \(1996\)](#) and include an emphasis on patient education. Glucose control is achieved with diet, exercise, and insulin. Until very recently, oral hypoglycemic agents were not recommended and women planning pregnancy usually switch to insulin 2 to 3 months before conception. Folic acid in a dose of 400 ug/day should be ingested prior to conception, and if there is personal or family history of neural-tube defects then 4 mg/day is prescribed.

RENAL DISEASE

Exacerbation of renovascular hypertension, along with superimposed preeclampsia, are concerns for women with any form of renal disease. As discussed in [Chapter 47 \(p. 1262\)](#), although controversial whether pregnancy increases renal damage or hastens permanent dysfunction, it appears more likely with severe disease. [Jones and Hayslett \(1996\)](#) analyzed 82 pregnancies in 67 women and found that a third of those whose serum creatinine was higher than 2 mg/dL had an accelerated decline in renal function during pregnancy. As shown in [Table 9-3](#), there is evidence that some forms of renal disease have a worse prognosis for pregnancy. These are discussed in more detail in [Chapter 47](#).

Regarding fetal risks, there may be associated vascular dysfunction that predisposes to growth restriction, preterm delivery, and perinatal mortality and morbidity. Worsening hypertension or superimposed preeclampsia increase the risk of iatrogenic preterm delivery. Angiotensin-converting enzyme inhibitors are associated with fetal renal tubular dysgenesis and renal failure ([Chap. 38, p. 1014](#)). The best predictor of perinatal outcome is the serum creatinine level ([Table 9-4](#)).

If pregnancy is planned, angiotensin-converting enzyme inhibitors should be discontinued and hypertension controlled with other drugs considered safe in pregnancy ([Chap. 45, p. 1217](#)). Women with severe or end-stage renal disease may choose to await renal transplantation before considering pregnancy.

HYPERTENSION

Although usually not as significant, risks for adverse pregnancy outcomes with chronic hypertension are similar to those for renal disease. Hypertension may worsen during pregnancy, with increased maternal morbidity. The need for additional drug therapy and iatrogenic preterm delivery also is increased. These risks generally parallel the degree of hypertension, and pregnancy-associated risks are discussed in [Chapter 45 \(p. 1212\)](#). In general, evaluation is done to search for obvious causes of hypertension. Renal and cardiac functions are assessed. Although most women have essential hypertension, a correctable cause will occasionally be discovered and ideally treated before conception. In many cases, obesity is a co-factor that can be altered by weight loss. Other benefits accrue from weight loss, and in addition to reduced blood pressure, there is reduced ventricular mass, incidence of hyperinsulinemia, diabetes, and hypertriglyceridemia ([Himeno and associates, 1999](#); [Sjostrom and co-workers, 1999](#)).

EPILEPSY

The most important pregnancy-associated risk to the epileptic woman is increased seizure activity. This is discussed in [Chapter 53 \(p. 1408\)](#). Most studies cite increased seizures in about a third of women during pregnancy. These may be related to reduced drug levels resulting from physiological changes of pregnancy with increased volume of distribution. The most important change appears to be increased drug clearance from induction of hepatic, plasma, and placental enzymes, along with significantly increased glomerular filtration rate. Moreover, nausea and vomiting causes skipped doses while pain and hyperventilation in labor lower the seizure threshold. A preventable cause of increased seizure activity is self-discontinuation of medication in the belief that the medication could harm the fetus. Counseling and preconceptional change in medication can prevent this. The woman is advised that seizures increase her risk of trauma. There is some evidence that uncontrolled seizures, often with associated hypoxia and hypotension, cause lesions in the cerebellum and hippocampus with degeneration of Purkinje cells, leading to the development of new seizure foci.

Offspring of epileptic women are at increased risk to have structural malformations. Although a portion of the risk is related to epilepsy itself, the majority of malformations are related to antiepileptic drugs as discussed in detail in [Chapter 38 \(p. 1012\)](#). Seizures during pregnancy may cause a transient reduction in uterine blood flow and fetal oxygenation. Maternal trauma during a seizure also increases fetal risk. Offspring of epileptic women are at increased risk to develop a seizure disorder ([Annegers and co-workers, 1976](#)). Women with febrile convulsions as children are more likely to have children with that disorder. Finally, offspring of fathers with seizure disorders, however, are not at increased risk.

COUNSELING The activity of the seizure disorder is assessed to determine whether antiepileptic medication is needed. If so, the lowest possible effective dose of the least teratogenic single agent is prescribed. In general, the woman taking monotherapy who has been free of seizures for at least 2 years is a candidate for discontinuing medication. A trial of stopping therapy is done in conjunction with a neurologist and is generally not recommended once the woman is pregnant. Up to two thirds of nonpregnant patients who stopped monotherapy remained seizure free for a mean of 35 months ([Callaghan and colleagues, 1988](#)).

CARDIAC DISEASE

CONGENITAL HEART DISEASE With advances in neonatal care and surgical techniques, women with a wide variety of congenital cardiac abnormalities are surviving to reproductive age and many become pregnant. Individual anomalies and their effects on pregnancy are discussed in detail in [Chapter 44](#). Counseling is addressed on a case-by-case basis. The risk of death should be estimated according to the nature of the cardiac disease and the functional cardiac status. Pregnancy-associated mortality correlates loosely with the type of cardiac lesion (see [Table 44-3, p. 1184](#)). Women with pulmonary hypertension of any etiology, complicated aortic coarctation, or Marfan syndrome with aortic involvement have a mortality risk sufficient to warrant recommendation against pregnancy.

CYANOTIC HEART DISEASE These lesions pose the greatest risk in pregnancy of all congenital heart defects. Affected women are at increased risk to develop heart failure, thrombotic complications, arrhythmias, and infections. Maternal mortality and fetal morbidity and mortality rates are significantly increased. [Sawhney and colleagues \(1998\)](#) cited 14 percent stillbirths and 37 percent growth-restricted fetuses. Women with primary pulmonary hypertension or Eisenmenger syndrome have the highest mortality rate, which is 40 to 50 percent. Only 15 percent have liveborns at term ([Weiss and Atanassoff, 1993](#); [Yentis and co-workers, 1998](#)).

[Presbitero and colleagues \(1994\)](#) reviewed 822 pregnancies in 416 women with cyanotic heart disease, excluding Eisenmenger syndrome. The perinatal prognosis with some of these lesions is summarized in [Table 9-5](#). Only 43 percent of pregnancies resulted in live births and 37 percent of those were delivered preterm. Some important predictors of fetal outcome are also listed in [Table 9-5](#).

ABNORMALITIES REQUIRING ANTICOAGULATION A number of cardiac conditions discussed in [Chapter 44](#) require anticoagulation because of increased risk for thromboembolic events. The most common is mechanical valve placement. When the woman is not pregnant, warfarin anticoagulation is generally preferred; however, these derivatives are teratogenic ([Chap. 38, p. 1014](#)). If possible, the woman attempting pregnancy should be switched to heparin therapy. Excessive anticoagulation increases the risk for bleeding complications and failure to achieve adequate anticoagulation is associated with prosthetic valve thrombosis.

COUNSELING Cardiac function is carefully evaluated with standard methods, including echocardiography and coronary angiography and radionuclide studies if necessary. Surgical records are reviewed, and all medications evaluated for fetal safety. If possible, warfarin is discontinued. In the case of a congenital defect, a

pedigree should be obtained to define the fetal risk. Women with a significant risk of mortality should be advised to reconsider pregnancy. If the woman is a potential candidate for cardiac transplantation, she may wish to reconsider pregnancy until this is accomplished. In all cases, the condition is optimized, and cardiovascular training is instituted.

THROMBOEMBOLISM

There is an increased risk of recurrent thromboembolism during pregnancy ([Chap. 46, p. 1240](#)). An exact risk is difficult to provide, but it may be as high as 10 percent ([American College of Obstetricians and Gynecologists, 2000](#); [Tengborn and colleagues, 1985](#)). Some factors modify the risk of thromboembolism. For example, women over age 35 have a twofold increased incidence compared with younger women ([Greer, 1999](#)). This may be related to the development of venous insufficiency after the first event ([Bergqvist and colleagues, 1990](#)). Older women who smoke more likely have cigarette-induced vascular damage. Older women are more likely obese and this too increases the risk for recurrence ([McCall and co-workers, 1997](#)). A risk factor of great importance is a family history of thromboembolic events which may suggest the possibility of hereditary thrombophilia as discussed next.

THROMBOPHILIAS

Most of these disorders are inherited anticoagulation deficiencies that include protein C or protein S deficiency, antithrombin III deficiency, activated protein C resistance (factor V Leiden mutation), hyperhomocystinemia (methylene tetrahydrofolate reductase mutation), and the prothrombin 20210G?A mutation. In addition, acquired coagulation defects include antiphospholipid antibodies to include the lupus anticoagulant and anticardiolipin antibodies. These are discussed in greater detail in [Chapters 46 \(p. 1234\) and 52 \(p. 1390\)](#).

Briefly, a wide variety of pregnancy complications may occur in these women. In addition to arterial and venous thromboembolism leading to pulmonary embolism and cerebral infarction, there is a greater risk of abortion, early preeclampsia, fetal-growth restriction, and stillbirth. The prevalence and risks for thromboembolism for some of these thrombophilias are listed in [Table 9-6](#). This risk data should be considered preliminary because much of them were derived from high-risk families.

The woman with a history of thromboembolism and an associated inherited thrombophilia should be counseled considering her increased risk of recurrence, and that pregnancy may complicate attempts at prophylaxis. She is counseled also about lifelong risks and the possibility of chronic prophylaxis. Many nonpregnant women taking prophylaxis are given warfarin; as discussed earlier, this is teratogenic and heparin substituted if possible when pregnancy is attempted.

CONNECTIVE-TISSUE DISEASES

These disorders include systemic lupus erythematosus, rheumatoid arthritis, ankylosing spondylitis, Sjogren's syndrome, and scleroderma. They are autoimmune collagen-vascular disorders that are discussed in greater detail in [Chapter 52](#). Pregnancy-associated risks for each disorder vary widely in severity and range from minimal to life threatening. For example, rheumatoid arthritis usually improves during pregnancy; however, 90 percent of women experience a relapse within 6 months of delivery ([Ostensen, 1999](#)). Women with ankylosing spondylitis often have increased back pain resulting from weight gain and lordosis, but otherwise do well. Lupus tends to be more serious and may have adverse effects on both mother and fetus.

Complications are higher for women with long-standing disease, nephritis, hypertension, antiphospholipid antibodies, and a previous pregnancy loss ([Meng and Lockshin, 1999](#); [Ostensen, 1999](#)). Flares result in worsening hypertension and proteinuria. With scleroderma, symptoms from Raynaud phenomenon may improve during pregnancy, but esophageal reflux from hypomotility usually gets worse. Women with diffuse scleroderma are at increased risk to have renal involvement and hypertension that is severe ([Steen, 1999](#)). Women with the lupus anticoagulant or anticardiolipin antibody have the worst outcomes. Anti-Ro antibody (anti SS-A) is associated with neonatal lupus—which generally resolves within the first year of life, and congenital heart block—which is permanent and has significant morbidity. If the woman has already had a child with congenital heart block, the recurrence risk approximates 15 percent ([Meng and Lockshin, 1999](#)). Maternal complications, especially severe hypertension and renal disease, increase the occurrence of adverse perinatal outcomes.

COUNSELING The clinical course is carefully reviewed. Organ damage is assessed, specifically, renal function. The prognosis for women with significant renal disease is based on the degree of renal insufficiency as shown in [Tables 9-3 and 9-4](#). Many medications commonly prescribed for collagen-vascular disorders, for example, corticosteroids, nonsteroidal anti-inflammatory agents, and analgesics, pose no increased fetal risk. In severe cases, potent immunosuppressive agents may be used, and although most are not believed to endanger the fetus, there are theoretical concerns about their safety ([Chap. 38, p. 1029](#)). Angiotensin-converting enzyme inhibitors may be teratogenic and are discontinued in the woman attempting pregnancy.

PSYCHIATRIC DISORDERS

Pregnancy can be stressful to any woman. It is not surprising that it increases the risk of relapse or return of dysphoric symptoms ([Chap. 53, p. 1420](#)). Some relapses are due to self-discontinuation of medication in the belief that it is harmful to the fetus. Symptoms also may be influenced by fluctuating hormone levels, increased stress, and disruption of eating and sleeping patterns as well as other normal activities. Inadequate prenatal care and co-existing substance abuse also play a role ([Kelly and colleagues, 1999](#)). The risk of severe postpartum depression or psychosis is especially increased in women with preexisting psychiatric disorders. Up to 15 percent of these women experience symptoms of depression in the first 3 months after delivery, and postpartum psychosis occurs in 1 to 2 per 1000 ([Pederson, 1999](#)). The incidence of postpartum psychosis in women with bipolar disorder is as high as 25 percent. Women who experienced postpartum psychosis in a previous pregnancy have a recurrence risk of 50 to 75 percent ([Pederson, 1999](#)). Women with a history of major depression, premenstrual syndrome, or previous *postpartum blues* are also at increased risk ([Pariser and co-workers, 1997](#)). Conversely, pregnancy does not appear to increase the risk of relapse in schizophrenia ([Robinson and collaborators, 1999](#)).

FETAL RISK In general, the wide variety of psychiatric medications have not been associated with major birth defects or developmental fetal abnormalities ([Chap. 38, p. 1026](#)). Several types of mental illness are heritable. While the average lifetime risk of developing schizophrenia is 0.8 percent, children with one schizophrenic parent have a 12 percent risk; those with two schizophrenic parents have a 40 percent risk; siblings of schizophrenics have a 10 percent risk ([Kinney, 1997](#)). The average lifetime risk of bipolar disorder is estimated to be 0.5 to 1.0 percent ([McInnis and DePaulo, 1997](#)). If either parent has bipolar disorder, the risk for the offspring increases to 15 percent ([McInnis and DePaulo, 1997](#)). This may be higher if the mother was affected ([McMahon and colleagues, 1995](#)). Offspring of parents with affective disorders are also at risk for attention deficit hyperactivity disorder ([Smith and co-workers, 1997](#)).

COUNSELING Close coordination with the psychiatric counselor is helpful when the woman with a major mental disorder wants to attempt pregnancy. The clinical course is reviewed, including an assessment of all medications. A pedigree may allow an assessment of fetal risk for mental illness. Confounding factors such as alcohol, drug, or cigarette abuse; social problems; or other medical illnesses are considered. When medication is needed, the woman is placed on the drug(s) with the fewest associated risks and at the lowest efficacious dose.

GENETIC DISEASES

Women whose ethnic background, race, or personal or family history place them at increased risk to have a fetus with a genetic disease should receive appropriate counseling. This includes the possibility of prenatal diagnosis (see [Chapters 36 and 37](#)). Women who have a genetic disease usually require additional counseling about their own risks, as genetic conditions are often associated with unique medical problems which may be adversely affected by pregnancy or which can adversely affect pregnancy outcome. Such women should be counseled by someone knowledgeable about genetics and about the effects of pregnancy on the genetic disease in question. They often benefit from consultation with other specialists—for example, anesthesiologists, cardiologists, or surgeons. A variety of genetic resources can be accessed for detailed information about many inherited disorders.

IMMUNIZATIONS

Preconceptional counseling includes assessment of immunity to rubella and hepatitis B. Depending on health status, travel plans, and time of year, other immunizations may be in order (see [Table 10-9, p. 92](#)). Vaccines consist of either toxoids (tetanus); killed bacteria or viruses (influenza, pneumococcus, hepatitis B, meningococcus, rabies); or attenuated live viruses (measles, mumps, polio, rubella, chickenpox, yellow fever). Immunization during pregnancy with toxoids or killed bacteria or viruses has not been associated with adverse fetal outcomes ([Chutivongse and colleagues, 1995](#); [Czeizel and co-workers, 1999](#)). Alternatively, live virus vaccines are not recommended during pregnancy, and should ideally be given at least 3 months before attempts to conceive. Women inadvertently given measles, mumps, rubella, or chickenpox vaccines during pregnancy, however, are not necessarily advised to seek pregnancy termination. Most reports indicate that immunizations to these agents pose only a theoretical risk to the fetus (Centers for Disease Control, 1989).

DIAGNOSTIC RADIATION EXPOSURE

Many women seek early postconceptional counseling because of inadvertent x-ray exposure. As discussed in [Chapter 42 \(p. 1150\)](#), there is no evidence that diagnostic radiation increases the risk of adverse outcomes for the fetus or for the child, including through adulthood (Boice and Miller, 1999; [Doll and Wakeford, 1997](#)).

ELECTROMAGNETIC ENERGY

There is no evidence in humans or animals that exposure to various electromagnetic fields such as high-voltage power lines, electric blankets, microwave ovens, and cellular phones causes adverse fetal effects (O'Connor, 1999; Robert, 1999). This is discussed further in [Chapter 44](#).

TABLE 9-1. Exercise Guidelines for Pregnancy and the Postpartum Period

1. During pregnancy, women can continue to exercise and derive health benefit even from mild to moderate exercise routines. Regular exercise at least three times per week is preferable to intermittent activity.
2. Women should avoid exercise in the supine position. This position is associated with decreased cardiac output in most pregnant women because the remaining cardiac output is preferentially distributed away from splanchnic beds (including the uterus) during vigorous exercise. Prolonged periods of motionless standing should also be avoided.
3. Women should be aware of the decreased oxygen available for aerobic exercise during pregnancy. They should be encouraged to modify exercise intensity according to symptoms. Pregnant women should stop exercising when fatigued and not exercise to exhaustion. Weight-bearing exercises may under some circumstances be continued at intensities similar to those before pregnancy. Non-weight-bearing exercises, such as cycling or swimming, minimize the risk of injury and facilitate continuation of exercise.
4. Morphological changes in pregnancy should serve as a relative contraindication to types of exercise in which loss of balance could be detrimental to maternal or fetal well-being, especially in the third trimester. Any type of exercise involving the potential for even mild abdominal trauma should be avoided.
5. Pregnancy requires an additional 300 kcal/d to maintain metabolic homeostasis. Thus, women who exercise during pregnancy should be particularly careful to ensure an adequate diet.
6. Pregnant women who exercise in the first trimester should augment heat dissipation by ensuring adequate hydration, appropriate clothing, and optimal environmental surroundings.
7. Many of the physiological and morphological changes of pregnancy persist 4 to 6 weeks postpartum. Thus, prepregnancy exercise routines should be resumed gradually and based on physical capability.

TABLE 9-3. Pregnancy Outcomes Associated with Specific Chronic Renal Diseases

Renal Disease	Effects
Chronic glomerulonephritis and focal glomerulosclerosis	There may be an increased incidence of hypertension late in gestation, but unusually no adverse effects if renal function is preserved and hypertension absent before gestation. Some disagree, believing that coagulation changes of pregnancy exacerbate these diseases, especially IgA nephropathy, focal glomerulosclerosis, and membranoproliferative glomerulonephritis.
Systemic lupus erythematosus	Expect more problems than most glomerular diseases, but prognosis is most favorable if disease is in remission for at least 6 months before conception.
Periarteritis nodosa and scleroderma	Associated with maternal deaths; reactivation of quiescent scleroderma can occur during pregnancy and postpartum; therapeutic abortion should be considered. Fetal prognosis is poor.
Diabetic nephropathy	Pregnancy does not accelerate functional loss; increased covert bacteriuria; high incidence of heavy proteinuria and hypertension late in gestation.
Chronic pyelonephritis (tubulointerstitial disease)	Bacteriuria in pregnancy may lead to acute exacerbations, but otherwise is well tolerated.
Polycystic disease	There is controversy concerning whether functional impairment, often minimal in childbearing years, is accelerated by pregnancy.
Urolithiasis	Ureteral dilatation and stasis do not seem to affect natural history; infections are more frequent; stents have been successfully placed during gestation.
Previous urological surgery	Depending on indication, other urogenital tract malformations may be present, urinary infections increase, and functional decrements have been observed. Cesarean delivery may be necessary to avoid disruption of the continence mechanism if artificial sphincters or neourethras are present.

10. Prenatal Care

Organized prenatal care in the United States was introduced largely by social reformers and nurses ([Merkatz and colleagues, 1990](#)). In 1901, Mrs. William Lowell Putnam of the Boston Infant Social Service Department began a program of nurse visits to women enrolled in the home delivery service of the Boston Lying-in Hospital. This work was so successful that an outpatient prenatal clinic was established in 1911, and women were urged to enroll as early in pregnancy as possible. Former authors of *Williams Obstetrics* were early supporters of prenatal care. Nicholas J. Eastman credited the movement to organized prenatal care with having "done more to save mothers' lives in our time than any other single factor."

OVERVIEW OF PRENATAL CARE

By the end of the 20th century, prenatal care has become one of the most frequently used health services in the United States. In 1998, there were more than 41 million prenatal visits; the median number was 12.4 visits per pregnancy, and as shown in [Figure 10-1](#), many women had 17 or more visits. The United States Public Health Service (1992) goal for the year 2000 was for at least 90 percent of American women to commence prenatal care in the first trimester. As shown in [Table 10-1](#), 84 percent of American women had begun prenatal care in the first trimester by 1998. This measure of obstetrical care, after showing little improvement in the 1980s, has risen for nine consecutive years with a 10 percent total gain during the 1990s ([Ventura and colleagues, 2000](#)). In 1998, all but 1.2 percent of women received some prenatal care. Over the last decade, the largest gains in timely prenatal care occurred among minority groups ([Fig. 10-2](#)), but disparity continues.

The number of women with significant obstetrical and medical risk factors or complications identifiable during prenatal care is summarized in [Table 10-2](#). Almost a fourth have significant, identifiable, *treatable complications*. [Kogan and colleagues \(1998\)](#) analyzed prenatal care in 54 million live births between 1981 and 1995 in the United States and found a major increase in prenatal care use and especially in "intensive" prenatal care, defined as more than nine prenatal visits. They attributed this increase in intensive prenatal care to the expansion of Medicaid eligibility for pregnant women and to the development of maternal-fetal medicine as a specialty coupled with widespread use of ultrasonography.

INADEQUATE PRENATAL CARE

The [Centers for Disease Control and Prevention \(2000a\)](#) analyzed 1989-1997 birth certificate data to examine the extent to which women received delayed or no prenatal care. They then used the 1997 Pregnancy Risk Assessment Monitoring System (PRAMS) data for 13 states to assess these same reasons. [PRAMS¹](#) is an ongoing, state-based surveillance system that randomly samples birth certificates and collects information from mothers on pregnancy-related behaviors and experiences. They found that half of women with delayed or no prenatal care wanted to begin care earlier. Reasons for inadequate prenatal care varied by social/ethnic group, age, and method of payment. The most common reason was "I didn't know that I was pregnant." The second most common cited barrier was "I didn't have enough money or insurance to pay for my visits." The third was inability to get an appointment. [Roberts and colleagues \(1998\)](#) identified additional reasons that included problems finding child care, lack of transportation, and the tendency for parous women to ascribe less importance to prenatal care.

RECENT DEVELOPMENTS

In 1986, the Department of Health and Human Services convened an expert panel to review the content of prenatal care ([Rosen, 1991](#)). This was in response to a report by the Institute of Medicine and National Institutes of Health on the importance of prenatal care in reducing the incidence of low-birthweight infants as a national agenda. The panel concluded that many medical conditions (such as diabetes mellitus), as well as personal behaviors (alcohol abuse) associated with bad pregnancy outcomes could be identified and modified *prior to conception*. Because health during pregnancy depends on health before pregnancy, it is logical that preconceptional care should be an integral part of prenatal care ([Chap. 9](#)).

Systematic health care beginning long before pregnancy undoubtedly proves quite beneficial to the physical and emotional well-being of the prospective mother and her child-to-be. As the consequence of such a program, many acquired diseases and developmental abnormalities will be recognized before pregnancy. Thus, appropriate steps can be taken to eradicate these, or at least to minimize deleterious effects. A striking example is the diabetic women who can be advised of the benefits for the embryo-fetus to be achieved from near normalization of blood glucose levels before conception ([Chap. 51, p. 1368](#)).

The panel also recommended that the number of prenatal visits be reduced in women at no apparent risk. They suggested that such women would best be served by return visits targeted at specific times, for example, alpha-fetoprotein screening at 16 weeks. We have used such an approach for all pregnancies at Parkland Hospital since late 1988 ([Table 10-3](#)). Parous women with normal obstetrical histories are seen even less frequently. In this schedule, limited visits in the first 6 months are targeted to specific purposes. [Kogan and colleagues \(1994\)](#) studied over 9000 women with prenatal care given as recommended by the Expert Panel. They concluded that such care reduced the incidence of low-birthweight infants. [Ward and associates \(1996\)](#) found that such a scheme reduced routine visits, but the increase in urgent clinic visits offset this, so that the total number of visits was unchanged. As reviewed by [Clement and co-workers \(1999\)](#), there have been four randomized trials comparing different schedules of prenatal visits and all found reduced schedules to be safe in terms of the physical outcomes of the mothers and infants.

EFFECTIVENESS OF PRENATAL CARE

In an extensive review, [Fiscella \(1995\)](#) could not find conclusive evidence that prenatal care improved birth outcomes. Others have also raised concern about the effectiveness of prenatal care because during the 1980s and 1990s, when utilization of prenatal care substantively increased, the rates of low birthweight and preterm birth in the United States worsened ([Kogan and colleagues, 1998](#)).

In counterpoint, however, should prenatal care be judged solely on the basis of its effect on birth outcomes? The impact of prenatal care on maternal health, a major focus of prenatal care when it was invented in the early years of the 20th century, has been dramatic. The recognition in the United States that maternal mortality was appallingly high was a slow process until about 1920 ([Loudon, 1992](#)). The maternal mortality rate in 1920 was 690 per 100,000 births and this had fallen to 50 per 100,000 by 1955, in association with many developments in health care for women and infants, of which prenatal care was but one component. The effectiveness of prenatal care cannot be gauged in isolation from the remainder of the obstetrical care system that has subsequently developed in this country and elsewhere. Indeed, and as the following statement from the 7th edition of [Williams Obstetrics \(1929\)](#) indicates, prenatal care was originally but one part of an organized health care program for pregnant women:

One of the few creditable achievements of American obstetrics consists in the development of so-called "Prenatal Care." The term has a wider application than the words imply, and may be defined as such supervision and care of the pregnant, parturient and puerperal woman as will enable her to pass through the dangers of pregnancy and labor with the least possible risk ... the first step in such a program consists in organizing the obstetrical dispensary [sic, prenatal clinic] and indoor service [sic, intrapartum] as a single unit.

Thus, in this context, prenatal care was not an end in itself but a systematic *gateway* to coordinated intrapartum and postpartum care and often even beyond into a woman's later life.

[Rooks \(1998\)](#), using prevention of low birthweight as an example, emphasized that most of the risk factors for this outcome also require maternal behavior modification. The presumption is largely that psychosocial interventions during prenatal care have limited value in modifying maternal behavior. There are few systematic studies of behavior modification during pregnancy. [Olds and colleagues \(1997\)](#) have published a series of well-designed experiments examining the effects of psychosocial interventions during the prenatal period and the first 24 months of postnatal life ([Earls, 1998](#)). These studies have shown that such interventions can increase birthweight, prevent preterm birth, reduce child abuse and neglect, and also reduce antisocial behavior later in life ([Olds and associates, 1986, 1997, 1998](#)). Studies such as these suggest that the benefits and limitations of prenatal care should be measured not only in the context of immediate pregnancy outcomes, but also in the context that prenatal care can be a gateway to behavior modification for both mothers and their children. Put another way, measuring the effects of prenatal care should encompass more than counting the number of prenatal visits in relation to birth outcomes.

PROCEDURES FOR PRENATAL CARE

The [American Academy of Pediatrics and the American College of Obstetricians and Gynecologists \(1997\)](#) have defined prenatal care as follows: "A comprehensive antepartum care program that involves a coordinated approach to medical care and psychosocial support that optimally begins before conception and extends throughout the antepartum period." The content of such comprehensive care includes assessments during preconception, at initial presentation for pregnancy care, and during follow-up prenatal visits. Each of these components is discussed in the following section.

PRECONCEPTIONAL CARE

A comprehensive preconceptional care program has the potential to assist women who want to get pregnant by reducing risks, promoting healthy lifestyles, and improving readiness for pregnancy. In 1989, the Expert Panel on the Content of Prenatal Care suggested that the negative pregnancy test encounter was an opportunity for preconceptional care. This is discussed in detail in [Chapter 9](#).

INITIAL PRENATAL EVALUATION

Prenatal care should be initiated as soon as there is a reasonable likelihood of pregnancy. This may be as early as a few days after a missed menstrual period, especially for the woman who desires pregnancy termination, but it should be no later than the second missed period for anyone. The major goals are:

1. To define the health status of the mother and fetus.
2. To determine the gestational age of the fetus.
3. To initiate a plan for continuing obstetrical care.

Components of the initial visit are summarized in [Table 10-4](#). The initial plan for subsequent care may range from relatively infrequent routine visits to that of prompt hospitalization because of serious maternal or fetal disease.

PRENATAL RECORD. Use of a standardized prenatal record within a perinatal health care system greatly facilitates antepartum and intrapartum management. Such a record is used by the Parkland Hospital Obstetrics Service. The [American Academy of Pediatrics and the American College of Obstetricians and Gynecologists \(1997\)](#) have provided an excellent prototypical prenatal record.

DEFINITIONS. There are several definitions pertinent to establishment of an accurate prenatal record:

- **Primipara:** a woman who has been delivered only once of a fetus or fetuses who reached viability. Therefore, completion of any pregnancy beyond the stage of abortion ([Chap. 33, p. 856](#)) bestows parity upon the mother.
- **Multipara:** a woman who has completed two or more pregnancies to viability. It is the number of pregnancies reaching viability, and not the number of fetuses delivered, that determines *parity*. Parity is not greater if a single fetus, twins, or quintuplets were delivered, nor lower if the fetus or fetuses were stillborn.
- **Nulligravida:** a woman who is not now, and never has been pregnant.
- **Gravida:** a woman who is or has been pregnant, irrespective of the pregnancy outcome. With the establishment of the first pregnancy, she becomes a primigravida, and with successive pregnancies a multigravida.
- **Nullipara:** a woman who has never completed a pregnancy beyond an abortion. She may or may not have been pregnant or have had a spontaneous or elective abortion(s).
- **Parturient:** a woman in labor.
- **Puerpera:** a woman who has just given birth.

In certain clinics it is customary to summarize past obstetrical history by a series of digits connected by dashes. The first digit refers to the number of term infants, the second to the number of preterm infants, the third to the number of abortions, and the fourth to the number of children currently alive. For example, a woman who is para 6-1-2-6 has had six term deliveries, one preterm delivery, two abortions, and she currently has six children alive.

NORMAL DURATION OF PREGNANCY. The mean duration of pregnancy calculated from the first day of the last normal menstrual period is very close to 280 days, or 40 weeks. [Kortenoever \(1950\)](#), in an analysis of 7504 pregnancies, found the average duration to be 282 days. A mean value of 281 days was calculated from the data of the Obstetrical Statistical Cooperative for 77,300 women who underwent spontaneous labor and whose infants weighed at least 2500 g.

It is customary to estimate the expected date of delivery by adding 7 days to the date of the first day of the last normal menstrual period and counting back 3 months (Naegele rule). For example, if the last menstrual period began on September 10, the expected date of delivery would be June 17. It is apparent that pregnancy is erroneously considered to have begun about 2 weeks before ovulation if the duration is so calculated. Nonetheless, clinicians conventionally calculate *gestational age* or *menstrual age* from the first day of the last menstrual period, to identify temporal events in pregnancy. Embryologists and other reproductive biologists more often employ *ovulatory age* or *fertilization age*, both of which are typically 2 weeks shorter. [Bracken and Belanger \(1989\)](#) tested the accuracy of various "pregnancy wheels" provided by three pharmaceutical companies and found that such devices were remarkably prone to error. Specifically, incorrect delivery dates were predicted in 40 to 60 percent of estimates, with a 5-day error being typical.

It has become customary to divide pregnancy into three equal *trimesters* of approximately 3 calendar months. Historically, the first trimester extended through the completion of 14 weeks, the second through 28 weeks, and the third included the 29th through 42nd weeks of pregnancy. Put another way, trimesters can be obtained by division of 42 into three periods of 14 weeks each. There are certain major obstetrical problems that cluster in each of these time periods. For example, most spontaneous abortions take place during the first trimester, whereas practically all cases of hypertensive disorders due to pregnancy become clinically evident during the third trimester.

The clinical use of trimesters to describe the duration of a specific pregnancy fosters imprecision and should be abandoned. For example, it is inappropriate in cases of uterine hemorrhage to categorize the problem temporally as "third-trimester bleeding." Appropriate management for the mother and her fetus will vary remarkably, depending upon whether the bleeding is encountered early or late in the third trimester ([Chap. 25, p. 620](#)). **Precise knowledge of the age of the fetus is imperative for ideal obstetrical management!** Therefore, expert attention must be given to this important measurement. The clinically appropriate unit of measure is *weeks of gestation completed*. Increasingly, clinicians designate gestational age using completed weeks and days, for example, 33 3/7 weeks for 33 completed weeks and 3 days.

HISTORY. For the most part, the same essentials go into appropriate history-taking from the pregnant woman as elsewhere in medicine. The history is obtained unhurriedly in a private setting to establish the good rapport so necessary for a successful outcome. **Detailed information concerning past obstetrical history, if any, is crucial because many prior pregnancy complications tend to recur in subsequent pregnancies.**

The *menstrual history* is extremely important. The woman who spontaneously menstruates regularly every 28 days or so is most likely to ovulate at midcycle. Thus, the gestational age (menstrual age) becomes simply the number of weeks since the onset of the last menstrual period. If her menstrual cycles were significantly longer than 28 to 30 days, ovulation more likely occurred well beyond 14 days; or if the intervals were much longer and irregular, chronic anovulation is likely to have preceded some of the episodes of vaginal bleeding identified as menses. **Without regular, predictable, cyclic, spontaneous menses that suggest ovulatory cycles, accurate dating of pregnancy by physical examination is difficult.**

It is important to ascertain whether or not *steroidal contraceptives* were used before the pregnancy. It is now common, but not necessarily recommended, for women who sustain regularly recurring withdrawal bleeding while using oral contraceptives to cyclically stop their use and to conceive without any further menstrual-like bleeding. Ovulation, however, may not have resumed 2 weeks after the onset of the last withdrawal bleeding, but instead, it may have occurred at an appreciably later but highly variable date. Predicting the time of ovulation in this circumstance is difficult.

The possibility of the presence of an *intrauterine device* should be ascertained, because certain pregnancy complications are increased by its presence in utero ([Chap. 58, p. 1539](#)).

PSYCHOSOCIAL SCREENING. The [American College of Obstetricians and Gynecologists \(1999b\)](#) has reviewed the importance of psychosocial screening during

prenatal care. The College concluded that addressing psychosocial issues is an essential step toward improving women's health and birth outcomes. Shown in [Table 10-5](#) is a psychosocial screening tool developed by the Healthy Start Program of the Florida Department of Health and which is recommended for this purpose.

SMOKING DURING PREGNANCY. Except in teenagers, smoking has declined from 19.5 percent of pregnant women in 1989 to 12.9 percent in 1998 ([Ventura and colleagues, 2000](#)). As discussed in [Chapter 38 \(p. 1019\)](#), smoking cessation during pregnancy, including use of nicotine gum and transdermal nicotine patches has been reviewed by the [American College of Obstetricians and Gynecologists \(1997c\)](#). [Cnattingius and co-workers \(1999\)](#) studied the effects of smoking cessation on recurrent preterm birth in a population-based cohort of 243,858 Swedish women delivered between 1983 and 1993. Cessation of smoking between pregnancies was associated with reduction in the risk of recurrent preterm delivery.

ALCOHOL AND STREET DRUGS DURING PREGNANCY. Alcohol use is substantially underreported on the birth certificate; according to these data just 1.1 percent of women reported any alcohol use in 1998 ([Ventura and colleagues, 2000](#)). According to the Centers for Disease Control and Prevention, however, about 15 percent of women used alcohol during pregnancy in 1995 ([Ebrahim and associates, 1998](#)). This was down from 23 percent in 1988. The [American College of Obstetricians and Gynecologists \(1994b\)](#) has reviewed screening for alcohol abuse, as well as street drugs, during pregnancy ([Chap. 38, p. 1030](#)).

DOMESTIC VIOLENCE SCREENING. The term "domestic violence" usually refers to violence against adolescent and adult females within the context of family or intimate relationships ([American College of Obstetricians and Gynecologists, 1999a](#)). Such violence has been increasingly recognized as a major public health problem. [Gazmararian and colleagues \(1996\)](#) reported that the prevalence of domestic violence during pregnancy in most studies was 4 percent to 8 percent. The [American College of Obstetricians and Gynecologists \(1999a\)](#) has provided methods for screening for domestic violence, and recommends their use at the first prenatal visit, then again at least once per trimester, and again at the postpartum follow-up. The [American College of Obstetricians and Gynecologists \(1998b\)](#) concluded that mandatory reporting to governmental agencies cannot be justified at this time.

OBSTETRICAL EXAMINATION. The cervix is visualized employing a speculum lubricated with warm water. Bluish-red passive hyperemia of the cervix is characteristic, but not of itself diagnostic, of pregnancy. Dilated, occluded cervical glands bulging beneath the exocervical mucosa, so-called *nabothian cysts*, may be prominent. If the cervix is dilated appreciably, fetal membranes may be visualized through the cervical canal, implying at least that expulsion of the products of conception may be imminent. Next, in order to identify cytological abnormalities a Pap smear is obtained and specimens for identification of *Neisseria gonorrhoeae* and possibly *Chlamydia trachomatis* are obtained.

A moderate amount of white mucoid discharge is normal. The presence of foamy yellow liquid in the vagina is strongly suggestive of *Trichomonas*, whereas the presence of a curdlike discharge is consistent with *Candida infection*. Treatment of trichomoniasis and candidiasis is discussed on page 244.

The speculum is removed and the digital pelvic examination is completed by palpation, with special attention given to the consistency, length, and dilatation of the cervix; to the fetal presenting part, especially if late in pregnancy; to the bony architecture of the pelvis; and to any anomalies of the vagina and perineum, including cystocele, rectocele, and relaxed or torn perineum. The vulva and contiguous structures are also carefully inspected. All cervical, vaginal, and vulvar lesions are evaluated further by appropriate use of colposcopy, biopsy, culture, or dark-field examination. The perianal region should be visualized and digital rectal examination done to identify hemorrhoids or other lesions.

Between 18 and 32 weeks' gestation, there is good correlation between the gestational age of the fetus in weeks and the height of the uterine fundus in centimeters, when measured as the distance over the abdominal wall from the top of the symphysis pubis to the top of the fundus, with the bladder empty. It is important for the examiner to document the height of the fundus.

PHYSICAL EXAMINATION. The thorough physical examination should include evaluation of the teeth, so that repair of carious teeth can be undertaken promptly. When varicose veins are identified, frequent postural drainage should be urged and elastic support stockings provided.

LABORATORY TESTS. Recommended routine laboratory tests are shown in [Table 10-4](#). The Institute of Medicine recommended that a national policy of universal screening be developed for human immunodeficiency virus (HIV) testing with patient notification, as a routine of prenatal testing. In a joint statement, the [American College of Obstetricians and Gynecologists \(1999c\)](#) and the American Academy of Pediatrics supported this recommendation. If a woman declines testing, this should be noted in the prenatal record. All pregnant women should also be screened for hepatitis B virus infection.

HIGH-RISK PREGNANCIES. There are major categories for increased risk that can be identified and given appropriate consideration in pregnancy management. These include:

1. Preexisting medical illness.
2. Previous poor pregnancy outcome, such as perinatal mortality, preterm delivery, fetal-growth restriction, malformations, placental accidents, or maternal hemorrhage.
3. Evidence of maternal undernutrition.

SUBSEQUENT PRENATAL VISITS

RETURN VISITS. Traditionally the timing of subsequent prenatal examinations has been scheduled at intervals of 4 weeks until 28 weeks, and then every 2 weeks until 36 weeks, and weekly thereafter ([Table 10-6](#)). As shown in [Table 10-3](#), fewer visits are acceptable in uncomplicated pregnancies. Conversely, women with complicated pregnancies often require return visits at 1- to 2-week intervals.

FETAL HEART SOUNDS. In essentially all pregnancies, the fetal heart can first be heard between 16 and 19 weeks when carefully listened for with a DeLee fetal stethoscope ([Chap. 2, p. 28](#)). The ability to hear unamplified fetal heart sounds will depend upon several factors, including patient size and the examiner's hearing acuity. [Herbert and co-workers \(1987\)](#) reported that the fetal heart was audible by 20 weeks in 80 percent of women. By 21 weeks audible fetal heart sounds were present in 95 percent, and by 22 weeks in all.

FUNDAL HEIGHT. Measurement of the height of the uterine fundus above the symphysis can provide useful information. [Jimenez and co-workers \(1983\)](#) demonstrated that between 20 and 31 weeks the fundal height in centimeters equaled the gestational age in weeks. [Quaranta and associates \(1981\)](#) and [Calvert and colleagues \(1982\)](#) reported essentially identical observations up to 34 weeks' gestation. *The bladder must be emptied before making the measurement.* [Worthen and Bustillo \(1980\)](#), for example, demonstrated that at 17 to 20 weeks, fundal height was 3 cm higher with a full bladder.

GESTATIONAL AGE. One of the most important determinations at prenatal examinations is assessment of fetal age. Fortunately, it is possible to identify this with considerable precision through an appropriately timed, carefully performed clinical examination, coupled with knowledge of the time of onset of the last menstrual period. When this date and fundal height are repeatedly in temporal agreement, the duration of gestation can be firmly established. When gestational age cannot be clearly identified, sonography is of considerable value.

Later in pregnancy, precise knowledge of gestational age may be of considerable importance, because a number of pregnancy complications may develop, for which the optimal treatment will depend on fetal age. For example, with the development of preeclampsia at 38 weeks, very often delivery is most beneficial to both mother and fetus. If the duration of gestation is only 28 weeks when preeclampsia develops, however, attempts at conservative management and delay of delivery may be more beneficial.

UNIVERSAL ULTRASONOGRAPHY SCREENING. There is continuing controversy concerning the issue of universal screening of all pregnancies with ultrasonography ([Chap. 41, p. 1113](#)). Routine ultrasound is not currently recommended in low-risk pregnancies by the [American College of Obstetricians and Gynecologists \(1997b\)](#).

PRENATAL SURVEILLANCE. At each return visit steps are taken to determine the well-being of both the mother and her fetus. Certain information, obtained by history and examination, is especially important.

Fetal

- Heart rate(s).
- Size—actual and rate of change.
- Amount of amniotic fluid.
- Presenting part and station (late in pregnancy).
- Activity.

Maternal

- Blood pressure—actual and extent of change.
- Weight—actual and amount of change.
- Symptoms, including headache, altered vision, abdominal pain, nausea and vomiting, bleeding, fluid from vagina, and dysuria.
- Height in cm of uterine fundus from symphysis.
- Vaginal examination late in pregnancy often provides valuable information:
 - Confirmation of the presenting part.
 - Station of the presenting part ([Chap. 13, p. 311](#)).
 - Clinical estimation of pelvic capacity and its general configuration ([Chap. 3, p. 58](#)).
 - Consistency, effacement, and dilatation of the cervix.

SUBSEQUENT LABORATORY TESTS. If the initial results were normal, most of the procedures need not be repeated. Hematocrit (or hemoglobin) determination and syphilis serology if it is prevalent in the population, should be repeated about 28 to 32 weeks.

Determination of maternal serum alpha-fetoprotein concentration at 16 to 18 weeks (15 to 20 weeks is acceptable) is recommended to screen for open neural-tube defects and some chromosomal anomalies. Precise knowledge of gestational age is paramount for accuracy of this screening test ([Chap. 37, p. 979](#)).

SPECIFIC PRENATAL NEEDS. A variety of needs or problems specific to individual women are discernible during the initial prenatal encounter if they have not already been addressed during preconceptional evaluation. Middle-school age adolescents (11 to 15 years old) are at increased risk for preterm birth as well as a variety of psychosocial problems. For example, [Satin and colleagues \(1994\)](#) in a study of 16,500 nulliparous women delivered at Parkland Hospital, found that preterm birth was increased significantly in 1622 pregnancies in these girls. Others have reported similar findings ([Amini and associates, 1996](#)).

ANCILLARY PRENATAL TESTS

GESTATIONAL DIABETES. For women at risk for gestational diabetes, screening is recommended between 24 and 28 weeks ([Chap. 51, p. 1362](#)).

CHLAMYDIA TRACHOMATIS. Universal testing of all pregnant women for chlamydial infection is not recommended ([American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 1997](#)). In high-risk women of low socioeconomic means, infection at 24 weeks was associated with a two- to threefold incidence of preterm birth ([Andrews and colleagues, 2000](#)).

BACTERIAL VAGINOSIS. Routine screening for bacterial vaginosis is not recommended ([American College of Obstetricians and Gynecologists, 1998a](#)). [Carey and co-workers \(2000b\)](#), in a study sponsored by the National Institute of Child Health and Human Development, randomized 1953 women from the general obstetrical population with asymptomatic bacterial vaginosis to receive two 2-g doses of metronidazole or placebo at 16 to 24 weeks' gestation. Treatment did not reduce preterm birth. In this same trial, metronidazole treatment increased the risk of preterm birth in women with asymptomatic trichomonal infection ([Carey and co-workers, 2000a](#)). Screening for bacterial vaginosis may be considered in women at high-risk for preterm labor ([Chap. 27, p. 699](#)).

FETAL FIBRONECTIN. Determination of this protein in vaginal fluid has been used to forecast preterm delivery in women with contractions ([Chap. 27, p. 702](#)). The Committee on Obstetric Practice of the [American College of Obstetricians and Gynecologists \(1997a\)](#) does not recommend the routine screening of the general obstetric population.

GROUP B STREPTOCOCCUS. Eradication of this organism during labor substantively decreases early-onset neonatal sepsis ([Chap. 56, p. 1471](#)). Currently, however, there is no clear consensus regarding screening cultures for streptococcal colonization. The [American College of Obstetricians and Gynecologists Committee on Obstetrics \(1996\)](#) and the [Centers for Disease Control and Prevention \(1996\)](#) recommend either of two strategies. The first is to treat pregnant women with chemoprophylaxis based solely on risk factors without screening cultures. The second is to perform screening cultures at 35 to 37 weeks, and to offer intrapartum treatment with penicillin if the culture is positive. At Parkland Hospital, women with risk factors for neonatal group B infection are given intrapartum intravenous ampicillin and all infants are administered aqueous penicillin G in the delivery room. This regimen has virtually eliminated neonatal group B infections ([Wendel and colleagues, 2000](#)).

SCREENING FOR GENETIC DISEASES. This screening can be offered based on family history or the ethnic or racial background of the couple ([American College of Obstetricians and Gynecologists, 1995b](#)). Examples include testing for Tay-Sachs disease for people of Eastern European Jewish or French Canadian ancestry; β -thalassemia for those of Mediterranean, Southeast Asian, Indian, Pakistani, or African ancestry; α -thalassemia for people of Southeast Asian or African ancestry; and sickle cell anemia for people of African, Mediterranean, Middle Eastern, Caribbean, Latin American, or Indian descent. Screening for cystic fibrosis may be offered to those with a family history of this disease. This is discussed in detail in [Chapter 36](#).

NUTRITION

Meaningful studies of nutrition in human pregnancy are exceedingly difficult to design. For ethical reasons, experimental dietary deficiency must not be produced deliberately. In those instances in which severe nutritional deficiencies have been induced as a consequence of social, economic, or political disaster, coincidental events often have created many variables, the effects of which are not amenable to quantification. Some past experiences suggest, however, that in otherwise healthy women a state of near starvation is required to establish clear differences in pregnancy outcome.

During the severe European winter of 1944-1945, nutritional deprivation of known intensity prevailed in a well-circumscribed area of the Netherlands occupied by the German military ([Stein and associates, 1972](#)). At the lowest point, rations reached 450 kcal/day, with generalized undernutrition rather than selective malnutrition. [Smith \(1947\)](#) analyzed the outcomes of pregnancies that were in progress during this 6-month famine. Median infant birthweights decreased about 250 g and rose again after food became available. This indicated that birthweight can be significantly influenced by starvation during later pregnancy. The perinatal mortality rate, however, was not altered, nor was the incidence of malformations significantly increased. The frequency of pregnancy "toxemia" was found to decline during this "hunger winter."

Evidence of impaired brain development has been obtained in some animal fetuses whose mothers had been subjected to intense dietary deprivation. These studies stimulated interest in the subsequent intellectual development of young adults in the Netherlands whose mothers had been starved during pregnancy. The comprehensive study by [Stein and co-workers \(1972\)](#) was made possible because all males at age 19 underwent compulsory examination for military service. It was concluded that severe dietary deprivation during pregnancy caused no detectable effects on subsequent mental performance.

Maternal weight gain during pregnancy does influence birthweight of the infant. [Abrams and Laros \(1986\)](#) studied the effect of maternal weight gain on birthweight in

2946 pregnancies with term deliveries. Only eight women did not gain weight. Multiple regression analysis controlling for maternal age, race, parity, socioeconomic status, cigarette consumption, and gestational age was done. As shown in [Figure 10-3](#), maternal weight gain affected birthweight; underweight women delivered smaller infants whereas the opposite was true for overweight women. The mean weight gain during pregnancy was 33 lb (15 kg). An important finding in this study was that weight gain does not appear requisite for fetal growth in obese women.

Information on maternal weight gain is collected on the birth certificate ([Ventura and colleagues, 2000](#)). In 1998, as shown in [Figure 10-4](#), the majority of women (64 percent) gained 26 lb or more during pregnancy. The median weight gain was 30.5 lb. Maternal weight gain had a positive correlation with birthweight, and women with the greatest risk of delivering a low-birthweight infant (< 2500 g) were those with weight gains less than 16 lb. Indeed, 1 of 7 women who gained less than 16 lb delivered an infant weighing less than 2500 g. This incidence was 1 of 5 in African-American women.

RECOMMENDATIONS FOR WEIGHT GAIN

For the first half of the 20th century, it was recommended that weight gain during pregnancy be limited to less than 20 lb (9.1 kg). It was believed that such restriction would prevent pregnancy hypertensive disorders and fetal macrosomia resulting in operative deliveries. By the 1970s, however, women were encouraged to gain at least 25 lb (11.4 kg) to prevent preterm births and fetal growth restriction. In 1990, the Institute of Medicine recommended a weight gain of 25 to 35 lb (11.5 to 16 kg) for women with normal prepregnancy body mass index (BMI). This index is easily calculated using the chart shown in [Figure 48-8](#) (p. 1299). Weight gains recommended according to prepregnancy body mass index categories are shown in [Table 10-7](#). The [American Academy of Pediatrics and the American College of Obstetricians and Gynecologists \(1997\)](#) have endorsed these guidelines.

[Feig and Naylor \(1998\)](#) from Canada have challenged these recommendations for a population-wide strategy of liberal weight gain in industrial nations. They called this a potentially harmful policy that encourages women to overeat during pregnancy, and without addressing other causes of low-birthweight infants such as poor prenatal care, adolescent pregnancy, drug abuse, and heavy smoking. They preferred the recommendation by the Committee on Medical Aspects of Food Policy in the United Kingdom, which a pregnant woman with a normal BMI² should gain 15 to 25 lb during pregnancy ([Report of the Panel on Dietary Reference Values, 1991](#)).

[Hyttén \(1991\)](#) reviewed data from over 20 years and observed that total weight gain throughout pregnancy in healthy primigravidas eating without restrictions is approximately 12.5 kg (27.5 lb). Normal physiological events cumulatively account for about 9 kg as fetus, placenta, amniotic fluid, uterine and breast hypertrophy, increased blood volume, and retained extracellular and extravascular fluid. The remainder of the 12.5 kg appears to be mostly maternal storage fat.

[Hyttén and Leitch \(1971\)](#) examined the rate of weight gain during the second half of pregnancy in normal nulliparous women. The rate between 20 weeks and delivery was about 1 lb/wk, with a wide range ([Fig. 10-5](#)). Similar results were obtained by [Petitti and co-workers \(1991\)](#) in both African-American and white women who delivered infants with birthweights of 3000 g or more. In both groups, weight gain from 8 to 20 weeks was about 0.7 lb/wk and about 1 lb/wk from 20 weeks to delivery. [Hickey and colleagues \(1995\)](#) reported slightly higher values of 1 lb/wk in the second and third trimesters.

Several possible disadvantages of excessive weight gain as a consequence of the fetus-infant being heavier must be considered. [Parker and Abrams \(1992\)](#) examined the associations between maternal weight gain outside the recommendations of the Institute of Medicine in 6690 singleton births. The average prepregnancy weight was 57 kg (125 lb), and the average maternal weight gain was 15.2 ± 5.2 kg (33.4 ± 11.4 lb) in these predominantly Caucasian and Asian women. Less than half gained weight within the Institute's recommendations for their BMI². Weight gains within the recommendations reduced the risk of adverse outcomes studied. Conversely, low weight gains for a given habitus were associated with small-for-gestational age infants. There have been several other studies in which less weight gain than recommended was found to be associated with preterm or low-birthweight infants ([Abrams and Selvin, 1995](#); [Hickey and colleagues, 1995](#); [Siega-Riz and associates, 1994](#)). [Parker and Abrams \(1992\)](#) showed that excessive weight gains were linked to large-for-gestational age infants and correspondingly increased cesarean delivery rates (16 versus 22 percent). [Witter and colleagues \(1995\)](#) reported that the risk of cesarean delivery increases linearly with pregnancy weight gain, independent of birthweight. [Johnson and Yancey \(1996\)](#) emphasize that the consequences of the recommendations of the Institute of Medicine to increase pregnancy weight gain have been incompletely assessed.

Not all the weight put on during pregnancy is lost during and immediately after parturition ([Hyttén, 1991](#)). The normal woman who gains 12.5 kg (27.5 lb) in pregnancy is about 4.4 kg (9 lb) above her prepregnant weight when she goes home postpartum. [Schauberger and co-workers \(1992\)](#) studied prenatal and postpartum weights in 795 women delivered in Wisconsin. Average weight gain was 13.0 ± 4.8 kg (28.6 ± 10.6 lb). As shown in [Figure 10-6](#), the majority of maternal weight loss (about 5.5 kg or 12.1 lb) was at delivery and in the ensuing 2 weeks (about 4 kg or 8.8 lb). An additional 2.5 kg (5.5 lb) was lost between 2 weeks and 6 months postpartum. The average total weight loss was 12.2 ± 4.6 kg (26.8 ± 10.1 lb), resulting in an average retained weight of 1.4 ± 4.8 kg (3 ± 10.5 lb) due to pregnancy. Overall, the more weight gained during pregnancy, the more that was lost postpartum. Parous women retained more of their pregnancy weight, but the interval between pregnancies was not linked to long-term obesity. The effects of breast feeding on maternal weight loss was negligible.

SUMMARY OF WEIGHT GAIN. Perhaps the most remarkable finding about weight gain in pregnancy is that a wide range is compatible with good clinical outcomes and that departures from "normality" are very nonspecific for any adverse outcome in a given individual.

RECOMMENDED DIETARY ALLOWANCES

Periodically the Food and Nutrition Board of the National Research Council recommends dietary allowances for women, including those who are pregnant or lactating. Their latest recommendations are summarized in [Table 10-8](#). Recommended daily allowances are not intended for application to individuals, but as guides to the needs of populations and groups, because individuals undoubtedly vary widely in their requirements. Certain prenatal vitamin-mineral supplements may lead to intakes well in excess of these allowances. This is not readily apparent to either the consumer or physician issuing the prescription, because label information is expressed in terms of the Food and Drug Administration (FDA) *U.S. Recommended Daily Allowances*, which are substantially different for several nutrients ([Institute of Medicine, 1990](#)). Moreover, the use of excessive supplements (for example, 10 times the recommended daily allowances), which often are self-prescribed by a substantial portion of the general public, has led to concern about nutrient toxicities during pregnancy. Nutrients that can potentially exert toxic effects include iron, zinc, selenium, and vitamins A, B₆, C, and D. Vitamin and mineral intake more than twice the recommended daily dietary allowance shown in [Table 10-8](#), should be avoided during pregnancy ([American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 1997](#)).

PRENATAL VITAMIN AND MINERAL SUPPLEMENTATION. Up until the recommendation for folate supplementation to prevent neural-tube defects, iron was the only known nutrient for which requirements during pregnancy could not be met by diet alone ([Institute of Medicine, 1990](#)). A daily supplement of 30 mg of elemental iron is the recommended prophylaxis for iron deficiency in women at low risk for nutritional deficiency. Ingestion on an empty stomach will facilitate iron absorption for prophylaxis or treatment of iron-deficiency anemia ([Chap. 49, p. 1309](#)). In 1997, the FDA³ specified that iron preparations containing 30 mg or more of elemental iron per dosage had to be packaged as individual doses (e.g., blister packages). This regulation is targeted at preventing accidental iron poisoning in children.

Routine multivitamin supplementation is not recommended by the [American Academy of Pediatrics and the American College of Obstetricians and Gynecologists \(1997\)](#), unless the maternal diet is questionable or if she is at nutritional risk. The latter includes multiple gestation, substance abuse, complete vegetarians, epileptics, and women with hemoglobinopathies. In these high-risk women, daily multivitamin-mineral supplementation is recommended beginning in the second trimester. The suggested composition of this multivitamin-mineral supplement is 30 to 60 mg iron, 15 mg zinc, 2 mg copper, 250 mg calcium, 10 ug (400 IU) vitamin D, 50 mg vitamin C, 2 mg vitamin B₆, 300 ug folate, and 2 ug vitamin B₁₂ ([Institute of Medicine, 1992](#)).

CALORIES. As shown in [Figure 10-7](#), pregnancy requires an additional 80,000 kcal, which are accumulated primarily in the last 20 weeks. A daily caloric increase of 300 kcal throughout pregnancy is recommended by the [National Research Council \(1989\)](#). Calories are necessary for energy, and whenever caloric intake is inadequate, protein is metabolized for energy rather than being spared for its vital role in fetal growth and development. Total physiological requirements during pregnancy are not necessarily the sum of ordinary nonpregnant requirements plus those specific to pregnancy. For example, the additional energy required during pregnancy may be compensated in whole or in part by reduced physical activity ([Hyttén, 1991](#)).

PROTEIN. To the basic protein needs of the nonpregnant woman are added the demands for growth and repair of the fetus, placenta, uterus, and breasts, and increased maternal blood volume. During the last 6 months of pregnancy, about 1 kg of protein is deposited, amounting to 5 to 6 g/day ([Hyttén and Leitch, 1971](#)). Amino acids in maternal plasma have been incompletely studied other than to observe a marked fall in the concentrations of ornithine, glycine, taurine, and proline ([Hyttén, 1991](#)). Exceptions during pregnancy are glutamic acid and alanine, which rise in concentration.

It is desirable that the majority of the protein be supplied from animal sources, such as meat, milk, eggs, cheese, poultry, and fish, because they furnish amino acids in optimal combinations. Milk and milk products have long been considered nearly ideal sources of nutrients, especially protein and calcium, for pregnant or lactating women.

MINERALS. The intakes recommended by the [National Research Council \(1989\)](#) for a variety of minerals are presented in [Table 10-8](#). Practically all diets that supply sufficient calories for appropriate weight gain will contain enough minerals to prevent deficiency if iodized salt is used.

IRON. The reasons for increased iron requirements during pregnancy are discussed in [Chapter 8 \(p. 178\)](#). Of the approximately 300 mg of iron transferred to the fetus and placenta and the 500 mg incorporated, if available, into the expanding maternal hemoglobin mass, nearly all is used after midpregnancy. During that time, iron requirements imposed by pregnancy and maternal excretion total about 7 mg per day ([Pritchard and Scott, 1970](#)). Very few women have sufficient iron stores to supply this amount, and the diet seldom contains enough iron to meet this demand.

Iron supplementation is practiced commonly in the United States and elsewhere, although the merits of this practice continue to be questioned by some. Indeed, the U.S. Preventive Services Task Force (1993) takes a neutral stance, presumably because maternal anemia has not been proved to cause adverse pregnancy outcomes. This is illogical because it cannot be an advantage to enter a delivery in an anemic state when obstetrical hemorrhage is an ever-present threat.

[Scott and co-workers \(1970\)](#) established that as little as 30 mg of elemental iron supplied in the form of a simple iron salt such as ferrous gluconate, sulfate, or fumarate taken regularly once each day throughout the latter half of pregnancy, provided sufficient iron to meet the requirements of pregnancy and to protect any preexisting iron stores. This amount should also provide for the iron requirements of lactation. The pregnant woman may benefit from 60 to 100 mg of iron per day if she is large, has twin fetuses, is late in pregnancy, takes iron irregularly, or has a somewhat depressed hemoglobin level. The woman who is overtly anemic from iron deficiency responds well to 200 mg of iron per day in divided doses ([Chap. 49, p. 1310](#)).

Because iron requirements are slight during the first 4 months of pregnancy, it is *not* necessary to provide supplemental iron during this time. Withholding iron supplementation during the first trimester of pregnancy avoids the risk of aggravating nausea and vomiting. Ingestion of iron at bedtime also appears to minimize the possibility of an adverse gastrointestinal reaction. Iron-containing medication must be kept out of the reach of small children.

CALCIUM. The pregnant woman retains about 30 g of calcium, most of which is deposited in the fetus late in pregnancy ([Pitkin, 1985](#)). This amount of calcium represents only about 2.5 percent of total maternal calcium, most of which is in bone, and which can readily be mobilized for fetal growth. Moreover, [Heaney and Skillman \(1971\)](#) demonstrated increased calcium absorption by the intestine and progressive retention throughout pregnancy. According to [Pitkin \(1985\)](#), bound calcium levels, but not ionized calcium, fall slightly in maternal plasma as albumin concentration decreases ([Chap. 8, p. 176](#)).

PHOSPHORUS. The ubiquitous distribution of phosphorus ensures an adequate intake during pregnancy. Plasma levels of inorganic phosphorus do not differ appreciably from nonpregnant levels.

ZINC. Severe zinc deficiency may lead to poor appetite, suboptimal growth, and impaired wound healing. Profound zinc deficiency may cause dwarfism and hypogonadism. It may also lead to a specific skin disorder, *acrodermatitis enteropathica*, which is due to a rare, severe congenital zinc deficiency. Although zinc-deficient animal fetuses may have increased central nervous system malformations, the role of zinc in human pregnancy outcome is less clear ([Goldenberg and associates, 1995](#)).

Zinc in plasma is only about 1 percent of total body zinc. Moreover, plasma zinc is almost entirely bound to several plasma proteins and amino acids. Therefore, low plasma concentrations are generally the consequence of changes in concentration of the various binders in plasma rather than true zinc depletion ([Swanson and King, 1983](#)). Even though the concentration is reduced, the total zinc plasma pool of normally pregnant women is actually increased as the consequence of the large increase in pregnancy-induced plasma volume. [Goldenberg and colleagues \(1995\)](#) provided zinc supplementation (25 mg) in a randomized study of 580 indigent women beginning at a mean of 19 weeks. Plasma zinc levels were slightly and significantly higher in women supplemented. Infants born to zinc-supplemented women were slightly larger (mean 125 g) and had a slightly larger head circumference (mean increase 4 mm). Although the level of zinc supplementation that is safe for pregnant women has not been clearly established, recommended daily intake during pregnancy is 15 mg ([Table 10-8](#)).

IODINE. The use of iodized salt by all pregnant women is recommended to offset the increased need for fetal requirements and increased maternal renal losses. Iodine intake has been thought to be adequate in the United States, but it has declined substantially in the past 15 years ([Utiger, 1999](#)). Interest in increasing dietary iodine during pregnancy was heightened by a recent report linking subclinical maternal hypothyroidism to significant mental retardation in the children of such women ([Haddow and colleagues, 1999](#)).

Severe maternal iodine deficiency predisposes offspring to endemic cretinism, characterized by multiple severe neurological defects ([Chap. 50, p. 1345](#)). In parts of China and Africa where this condition is endemic, iodide supplementation very early in pregnancy prevents cretinism ([Cao and colleagues, 1994](#)). Iodine ingestion in pharmacological amounts during pregnancy may depress thyroid function and induce a sizable fetal goiter. The consumption of large amounts of seaweed by food faddists may do the same.

MAGNESIUM. Deficiency as the consequence of pregnancy has not been recognized. Undoubtedly, during prolonged illness with no magnesium intake, the plasma level might become critically low, as it would in the absence of pregnancy. We have observed magnesium deficiency during pregnancy complicated by the consequences of previous intestinal bypass surgery. [Sibai and co-workers \(1989\)](#) randomized 400 normotensive primigravid women to placebo tablets or 365 mg elemental magnesium supplementation from 13 to 24 weeks. Supplementation did not improve any measures of pregnancy outcome.

COPPER. Enzymes that contain copper, such as cytochrome oxidase, play key roles in many oxidative processes and hence in the production of most of the energy required for metabolism. Pregnancy has a major effect on maternal copper metabolism, with marked increases in serum ceruloplasmin and plasma copper. Copper deficiency has not been documented in humans during pregnancy. No studies of copper supplementation of pregnant women have been reported, although several prenatal supplements currently marketed provide 2 mg of copper per tablet.

SELENIUM. This is an essential component of the enzyme glutathione peroxidase, which catalyzes the conversion of hydrogen peroxide to water. Selenium is an important defensive component against free radical damage. Its deficiency has been identified in a large area of the People's Republic of China, where there is a severe geochemical deficiency. Deficiency is manifested by a frequently fatal cardiomyopathy in young children and women of childbearing age. Conversely, selenium toxicity due to oversupplementation has also been observed. There is no reported need to supplement selenium in American women during pregnancy.

CHROMIUM. Chromium is believed to play a physiological role as a co-factor for insulin, facilitating the initial attachment of the hormone to its peripheral receptors. The extent to which chromium is important in human nutrition remains uncertain, and there are no data suggesting that supplementation is advisable during pregnancy.

MANGANESE. This serves as a co-factor for enzymes such as the glycosyltransferases, which are necessary for the synthesis of polysaccharides and glycoproteins. Manganese deficiency has not been observed in human adults, and supplements are not indicated during pregnancy.

POTASSIUM. The concentration of potassium in maternal plasma decreases by about 0.5 mEq/L by midpregnancy ([Brown and colleagues, 1986](#)). Potassium deficiency develops in the same circumstances as when the woman is not pregnant. Prolonged nausea and vomiting may lead to hypokalemia and metabolic alkalosis. A previously rather common cause, the use of diuretics, has nearly disappeared.

SODIUM. Deficiency during pregnancy is most unlikely unless diuretics are prescribed or dietary sodium intake is reduced drastically. In general, salting food to taste will provide an abundance of sodium. Plasma sodium concentration normally decreases a few mEq during pregnancy; however, sodium excretion is unchanged, and averages 100 to 110 mEq/day ([Brown and colleagues, 1986](#)).

FLUORIDE. The value of supplemental fluoride during pregnancy has been questioned. [Horowitz and Heifetz \(1967\)](#) investigated the prevalence of caries in temporary and permanent teeth of children with the same postnatal exposure to optimally fluoridated water but different patterns of prenatal exposure. They concluded that there were no additional benefits from maternal ingestion of fluoridated water if the offspring ingested such water from birth.

[Glenn and associates \(1982\)](#) reported a remarkably lower incidence (99 percent) of caries in children whose mothers ingested 2.2 mg of sodium fluoride daily during pregnancy, compared with those whose mothers used only fluoridated water. Fluoride supplementation during pregnancy has not been endorsed by the American Dental Association ([Institute of Medicine, 1990](#)).

Supplemental fluoride ingested by the lactating woman does not increase the fluoride concentration in her milk ([Ekstrand, 1981](#)).

VITAMINS. Most evidence concerning the importance of vitamins for successful reproduction has been obtained from animal experiments. Typically, severe deficiency has been produced in the animal by withholding the vitamin completely, beginning long before the time of pregnancy; or by giving a very potent vitamin antagonist. The administration of some vitamins in great excess to pregnant animals has been shown to exert deleterious effects on the fetus and newborn.

The increased requirements for vitamins during pregnancy shown in [Table 10-8](#) in practically all circumstances can be supplied by any general diet that provides adequate amounts of calories and protein. The exception is folic acid during times of unusual requirements, such as pregnancy complicated by protracted vomiting, hemolytic anemia, or multiple fetuses.

FOLIC ACID. In the United States, approximately 4000 pregnancies are affected by neural-tube defects each year and more than half of these could be prevented with daily intake of 400 ug of folic acid throughout the periconceptional period ([Centers for Disease Control and Prevention, 1999](#)). Since 1992, the Public Health Service has recommended that all women capable of becoming pregnant consume 400 ug of folic acid daily throughout their childbearing years. The [Food and Drug Administration \(1996\)](#) later established standards fortifying cereal and grain products such as cereal, bread, rice, and pasta with folic acid. By putting 140 ug of folic acid into each 100 g of grain products, it was estimated that the folic acid intake of the average American woman of childbearing age would increase 100 ug per day.

There is evidence that this policy is contributing to a rise in serum folate levels ([Lawrence and associates, 1999](#)). There is also controversy over how much folic acid supplementation is enough to prevent neural-tube defects ([Mills, 2000](#)). Thus, it is unknown what lowest folic acid dose will prevent the estimated 50 percent of defects related to folic acid metabolism. [Daly and colleagues \(1997\)](#) contend that delivery of 200 ug daily by food fortification is effective against neural-tube defects and safer for the general population. The importance of a national food-fortification program is underscored by experiences in England and Wales where such a program is not used ([Kadir and colleagues, 1999](#)). Despite a large increase in sale of over-the-counter and prescription folic acid supplements in the 1990s in England and Wales, the rate of neural-tube defects has not changed. One explanation is that supplement sales likely do not represent the actual consumption of folic acid.

In 1997, the March of Dimes contracted the Gallup Organization to conduct a random-digit-dialed telephone survey of a national sample of 2001 women aged 15 to 45 years to assess knowledge about folic acid use ([Centers for Disease Control and Prevention, 1999](#)). Less than a third of women of childbearing age consume a daily supplement containing folic acid. Surprisingly, only 13 percent of women knew that folic acid helps prevent birth defects, and only 7 percent knew that folic acid should be taken before pregnancy. The March of Dimes will invest up to \$10 million for a 3-year national folic acid education program.

VITAMIN A. Dietary intake of vitamin A in the United States appears to be adequate to meet the needs of most pregnant women ([American College of Obstetricians and Gynecologists, 1998d](#)). Routine supplementation during pregnancy is thus not recommended. A small number of case reports suggest an association with birth defects and very high doses of 10,000 to 50,000 IU daily during pregnancy. These malformations are similar to those produced by the vitamin A derivative isotretinoin (Accutane), which is a proven teratogen in humans ([Chap. 38, p. 1015](#)). Beta-carotene, the precursor of vitamin A found in fruits and vegetables, has not been shown to produce vitamin A toxicity.

VITAMIN B₁₂. The level of vitamin B₁₂ in maternal plasma decreases variably in otherwise normal pregnancies ([Chap. 49, p. 1312](#)). This is mostly from a reduction in plasma transcobalamins and is prevented only in part by supplementation. Vitamin B₁₂ occurs naturally only in foods of animal origin. It is now established that *strict vegetarians* may give birth to infants whose vitamin B₁₂ stores are low. Moreover, because breast milk of a vegetarian mother most likely contains little vitamin B₁₂, the deficiency may become profound in the breast-fed infant ([Higginbottom and associates, 1978](#)). Excessive ingestion of vitamin C can also lead to a functional deficiency of vitamin B₁₂.

VITAMIN B₆. Most clinical trials in pregnant women have failed to demonstrate any benefits of vitamin B₆ supplements ([Institute of Medicine, 1990](#)). For women at high risk for inadequate nutrition—e.g., substance abuse, adolescents, and those with multiple gestations—a daily supplement containing 2 mg is recommended.

VITAMIN C. The recommended dietary allowance for vitamin C during pregnancy is 70 mg/day, or about 20 percent more than when nonpregnant ([Table 10-8](#)). A reasonable diet should readily provide this amount. The maternal plasma level declines during pregnancy while the cord level is higher, a phenomenon observed with most water-soluble vitamins.

PRAGMATIC NUTRITIONAL SURVEILLANCE

Although the science of nutrition continues in its perpetual struggle to identify the ideal amounts of protein, calories, vitamins, and minerals for the pregnant woman and her fetus, those directly responsible for their care may best discharge their duties as follows:

- In general, advise the pregnant woman to eat what she wants in amounts she desires and salted to taste.
- Make sure that there is ample food to eat, especially in the case of the socioeconomically deprived woman.
- Ensure that she is gaining weight, with a goal of about 25 to 35 pounds in women with a normal body mass index.
- Periodically, explore the food intake by dietary recall. In this way, the occasional nutritionally absurd diet will be discovered.
- Give tablets of simple iron salts that provide at least 30 mg of iron daily. Give folate supplementation before and in the early weeks of pregnancy.
- Recheck the hematocrit or hemoglobin concentration at 28 to 32 weeks to detect any significant decrease.

COMMON CONCERNS

EXERCISE. In general, it is not necessary for the pregnant woman to limit exercise, provided she does not become excessively fatigued or risk injury to herself or her fetus. The current enthusiasm for jogging also has attracted a number of pregnant women. In fact, several women, even late in pregnancy, have run safely in marathons.

[Clapp \(1989\)](#) reported that 18 conditioned pregnant women actually improved their metabolic efficiency during exercise. Specifically, the amount of oxygen required to complete a treadmill exercise actually *decreased* during pregnancy! [Pivarnik and co-workers \(1990\)](#) used invasive hemodynamic monitoring and compared cardiovascular responses of seven healthy women to aerobic exercise (cycle or treadmill) during late pregnancy and again 3 months postpartum. Oxygen consumption, heart rate, stroke volume, and cardiac output all increased appropriately in response to exercise. [Pivarnik and associates \(1994\)](#) later showed that pregnant women who exercised regularly had significantly larger blood volumes.

The effects have been described of maternal exercise on pregnancy outcomes, including spontaneous abortion, the course of labor, and birthweight ([Clapp and Capeless, 1990](#); [Clapp and Little, 1995](#)). Continuation of aerobic exercise at intensities between 50 and 85 percent of their maximum capacity in 47 recreational runners and 40 aerobic dancers during the periconceptional period had no effect on the incidence of spontaneous abortion. Well-conditioned women who perform aerobics or run regularly were found to have shorter active labors and fewer cesarean deliveries, less meconium-stained amniotic fluid, and less fetal distress in labor. Continuation of regular aerobic or running exercise programs, however, did result in reduced birthweight (average 310 g) that primarily affected neonatal fat mass. Continuing regular exercise throughout pregnancy has even been observed to positively alter early neonatal behavior ([Clapp and co-workers, 1999](#)).

The [American College of Obstetricians and Gynecologists \(1994a\)](#) recommends that women who are accustomed to aerobic exercise before pregnancy should be allowed to continue this during pregnancy. They caution against starting new aerobic exercise programs or intensifying training efforts. For example, in women who were previously sedentary, aerobic activity more strenuous than walking is not recommended.

With some pregnancy complications, the mother and her fetus may benefit from a very sedentary existence. For example, women with hypertensive disorders due to pregnancy benefit from being sedentary ([Chap. 24, p. 595](#)), as do women pregnant with two or more fetuses ([Chap. 30, p. 795](#)), women suspected of having a growth-restricted fetus ([Chap. 29, p. 755](#)), and those with severe heart disease ([Chap. 44, p. 1186](#)).

EMPLOYMENT. The legal and social movements in the United States to provide equality of opportunity in the workplace have reached women who are or might become pregnant. [Annas \(1991\)](#) reviewed the legal issues involved with employment during pregnancy. Importantly, the United States Supreme Court buttressed the

Pregnancy Discrimination Act of 1978 by ruling in 1991 that federal law prohibits employers from excluding women from job categories on the basis that they are or might become pregnant. More than 120 nations around the world currently provide paid maternity leave and health benefits by law, including most industrialized nations except the United States, Australia, and New Zealand ([Luke and co-authors, 1999](#)). Although the Family and Medical Leave Act (FMLA) was passed in 1993, a recent report to Congress found that because this leave is without pay, women eligible for leave did not take it for financial reasons. It is estimated that nearly half of women of childbearing age in the United States are in the labor force. Even larger proportions of socioeconomically less fortunate women are working.

[Manshande and colleagues \(1987\)](#) reported a sevenfold increased incidence of low-birthweight infants in women from Zaire who worked hard in the fields. [Teitelman and co-workers \(1990\)](#) evaluated maternal work activity and pregnancy outcome in 4186 women delivered at Yale-New Haven Hospital. Women were classified according to the type of jobs they held. *Standing* jobs, such as those of a cashier, bank teller, or dentist, required standing in the same position for more than 3 hours per day. *Active* jobs, such as physicians, waitresses, and real estate agents, involved continuous or intermittent walking. *Sedentary* jobs, such as librarian, bookkeeper, or bus driver, required less than an hour of standing per day. They found that pregnant women who work at jobs that require prolonged standing are at greater risk for preterm delivery, but it did not have any effect on fetal growth. [Mozurkewich and colleagues \(2000\)](#) reviewed 29 studies with over 160,000 pregnancies. They confirmed a 20 to 60 percent increase in preterm birth, fetal growth restriction, or hypertension with physically demanding work. [Gabbe and Turner \(1997\)](#) have reviewed work during pregnancy. [Paul \(1997\)](#) reviewed exposure to hazardous occupational agents during pregnancy.

Common sense dictates that any occupation that subjects the pregnant woman to severe physical strain should be avoided. Ideally, no work or play should be continued to the extent that undue fatigue develops. Adequate periods of rest should be provided during the working day. Women with previous pregnancy complications that are likely to be repetitive, such as low-birthweight infants, probably should minimize physical work. The [American Academy of Pediatrics and the American College of Obstetricians and Gynecologists \(1997\)](#) has concluded that women with uncomplicated pregnancies can usually continue to work until the onset of labor. A period of 4 to 6 weeks was recommended before return to work after delivery.

TRAVEL. Travel by the healthy woman has no harmful effect on pregnancy. Travel in properly pressurized aircraft offers no unusual risk, and American Airlines permits unrestricted travel as long as the woman feels well and is not within 7 days of her expected delivery date. Delta Airlines has no travel restrictions, but does recommend that the pregnant woman check with her physician if travel is scheduled after the "eighth month." At least every 2 hours, she should walk about. Perhaps the greatest risk with travel, especially international travel, is the development of a complication remote from facilities adequate to manage the complication.

The [American College of Obstetricians and Gynecologists \(1998c\)](#) has formulated guidelines for use of automobile passenger restraints during pregnancy. There is no evidence that safety restraints increase the chance of fetal injury. Indeed, the leading cause of fetal death in a motor accident is the death of the mother ([Chap. 43, p. 1172](#)). Therefore, pregnant women should be encouraged to wear properly positioned three-point restraints throughout pregnancy while riding in automobiles. The lap belt portion of the restraining belt should be placed under her abdomen and across her upper thighs. The belt should be as snug as comfortably possible. The shoulder belt also should be snugly applied and positioned between the breasts, although no serious harm appears to occur if the breast is compressed during a collision. There is little evidence concerning air-bag use during pregnancy ([Chap. 43, p. 1172](#)). While some reports suggest their safety, we as well as others ([Schultze and associates, 1998](#)) have encountered stillbirths with their deployment.

BATHING. There is no objection to bathing during pregnancy or the puerperium. During the last trimester, the heavy uterus usually upsets the balance of the pregnant woman and increases the likelihood of her slipping and falling in the bathtub. For that reason, showers at the end of pregnancy may be preferable.

CLOTHING. It has generally been recommended that the clothing worn during pregnancy be comfortable and nonconstricting. According to fashion experts, however, pregnancy apparel has changed considerably in recent years ([Morgan, 2000](#)). One clothes designer stated: "It [sic, pregnancy] used to be about covering it up, and now it's about showing it off. Today's maternity chic is body-hugging not body hiding."

The increasing mass of the breasts may make them pendulous and painful, and well-fitting supporting brassieres may be indicated for comfort. Constricting leg wear should be avoided.

BOWEL HABITS. Constipation is common, presumably because of prolonged transit time and compression of the lower bowel by the uterus or by the presenting part of the fetus ([Chap. 48, p. 1277](#)). In addition to the discomfort caused by the passage of hard fecal material, bleeding and painful fissures may develop in the edematous and hyperemic rectal mucosa. There is also greater frequency of *hemorrhoids* and, much less commonly, of prolapse of the rectal mucosa.

Women whose bowel habits are reasonably normal in the nonpregnant state may prevent constipation during pregnancy by close attention to bowel habits, taking sufficient quantities of fluid, and reasonable amounts of daily exercise, supplemented when necessary by a mild laxative, such as prune juice, milk of magnesia, bulk-producing substances, or stool-softening agents.

COITUS. Whenever abortion or preterm labor threatens, coitus should be avoided. Otherwise it has been generally accepted that in healthy pregnant women, sexual intercourse usually is not harmful before the last 4 weeks or so of pregnancy. In interviews with nearly 10,000 women enrolled in a prospective investigation, the Vaginal Infection and Prematurity Study Group found a significantly decreased frequency of sexual intercourse with advancing gestation ([Read and Klebanoff, 1993](#)). By 36 weeks, 72 percent reported intercourse less than once weekly. [Bartellas and colleagues \(2000\)](#) reported that this was due to decreased desire (58 percent) and fear of harm to the pregnancy (48 percent).

Risks from intercourse late in pregnancy have not been clearly delineated. [Grudzinkas and co-workers \(1979\)](#) found no association between gestational age at delivery and the frequency of coitus during the last 4 weeks of pregnancy. [Naeye \(1979\)](#), using data from the Collaborative Perinatal Project, reported that amniotic fluid infections and perinatal mortality were significantly increased if mothers had intercourse once or more weekly in the last month. In the large collaborative study described above by [Read and Klebanoff \(1993\)](#), there was no association with frequent intercourse and preterm delivery. [Ekwo and colleagues \(1993\)](#) interviewed over 1350 women and found that most sexual positions and activities were not associated with adverse outcomes. There was a twofold increased incidence of ruptured membranes with the male-superior position.

On occasion, sexual drive in the face of admonishment against intercourse late in pregnancy has led to sexual practices with disastrous consequences. [Aronson and Nelson \(1967\)](#) described a fatal case of air embolism late in pregnancy as a result of air blown into the vagina during cunnilingus. Other near-fatal cases have been described ([Bernhardt and associates, 1988](#)).

CARE OF THE TEETH. Examination of the teeth should be included in the prenatal general physical examination. Pregnancy is rarely a contraindication to needed dental treatment. The concept that dental caries are aggravated by pregnancy is unfounded.

IMMUNIZATION. There has been some concern over the safety of various immunizations during pregnancy. Current recommendations are summarized in [Table 10-9](#). Immunization in adults has been reviewed by [Foley and Kopelman \(1995\)](#) and [Gardner and Schaffner \(1993\)](#).

SMOKING. Since 1984 the Surgeon General has had warning labels on cigarette packages: "Smoking by pregnant women may result in fetal injury, premature birth, and low birthweight." Information on maternal smoking during pregnancy has been included on the birth certificate beginning in 1989. There has been a progressive decline in reported smoking during pregnancy from 20 percent in 1989 to 13 percent in 1998 ([Ventura and colleagues, 2000](#)). Similar results were observed using the Behavioral Risk Factor Surveillance System survey by the Centers for Disease Control and Prevention ([Ebrahim and co-workers, 2000](#)). It is noteworthy that the prevalence of cigarette smoking nationwide among high school students, in contrast to maternal smoking, increased during the 1990s ([Centers for Disease Control and Prevention, 2000b](#)).

A variety of adverse outcomes have been linked to smoking during pregnancy. Included are low birthweight due to either preterm delivery or fetal growth restriction, infant and fetal deaths, and placental abruption ([Ananth and associates, 1996](#); [Kleinman and colleagues, 1988](#); [Lin and Santolaya-Forgas, 1998](#); [Shah and Bracken, 2000](#); [Ventura and co-workers, 2000](#)). Suggested pathophysiological mechanisms for these adverse pregnancy effects include increased fetal carboxyhemoglobin levels, reduced uteroplacental blood flow, and fetal hypoxia ([Jazayeri and colleagues, 1998](#); [Monheit and co-workers, 1983](#)). To put the smoking problem into a national perspective, in 1998, the 12 percent of American women who reported smoking during pregnancy accounted for one out of five infants weighing less than 2500 g at birth ([Ventura and colleagues, 2000](#)).

The American College of Obstetricians and Gynecologists (1997) has reviewed smoking cessation during pregnancy. The most successful efforts involved interventions that emphasize how to stop smoking. The Food and Drug Administration rates nicotine gum as category C (risk cannot be excluded) and transdermal systems are rated category D (positive evidence of risk). The American College of Obstetricians and Gynecologists (1997c) has concluded, however, that it is reasonable to use these nicotine medications during pregnancy if prior attempts to quit smoking have failed and the smoker is still using 10 to 15 cigarettes per day.

ALCOHOL. Ethanol is a potent teratogen ([Chap. 38, p. 1011](#)). Because alcohol use during pregnancy can cause the fetal alcohol syndrome, the Surgeon General recommends that women who are pregnant or considering pregnancy abstain from using any alcoholic beverages. The fetal alcohol syndrome is characterized by growth restriction, facial abnormalities, and central nervous system dysfunction. **From the evidence available, the best advice to the woman pregnant or about to become pregnant is to not consume alcohol.** It is hoped that the adverse effects of alcohol on pregnancy do not linger after the woman stops drinking.

CAFFEINE. In 1980, the Food and Drug Administration advised pregnant women to limit caffeine intake. The Fourth International Caffeine Workshop concluded shortly thereafter that there was no evidence that caffeine increased teratogenic or reproductive risk ([Dews and colleagues, 1984](#)). In small laboratory animals, caffeine is not a teratogen, but it does potentiate mutagenic effects of radiation and some chemicals if given in massive doses. When infused intravenously into sheep, it decreases uterine blood flow by 5 to 10 percent ([Conover and colleagues, 1983](#)).

Whether consumption of caffeine during pregnancy increases the risk of spontaneous abortion is controversial. [Klebanoff and co-workers \(1999\)](#) used a biological serum marker of caffeine consumption (paraxanthine) to estimate the dose of caffeine in 487 women with spontaneous abortions and in 2087 controls. Only extremely high serum paraxanthine concentrations were associated with abortion. Such high levels were equivalent to drinking more than 5 cups of coffee per day.

ILLICIT DRUGS. Chronic use during pregnancy of illicit drugs, including opium derivatives, barbiturates, and amphetamines, in large doses, is harmful to the fetus. Fetal distress, low birthweight, and serious compromise as the consequence of drug withdrawal soon after birth are well documented. Often the mother who uses hard drugs does not seek prenatal care, and even if she does, she may not admit to the use of such substances. Detection of scars from venipunctures may be the first clue. The management of pregnancy and delivery and successful care of the newborn infant may be extremely difficult.

The effects of a number of illicit drugs are considered in detail in [Chapter 38, \(p. 1030\)](#). The topic was also reviewed by the [American College of Obstetricians and Gynecologists \(1994b\)](#).

MEDICATIONS. Some drugs commonly ingested during pregnancy, and their possible adverse fetal effects, are considered in detail in [Chapter 38](#). **With rare exception, any drug that exerts a systemic effect in the mother will cross the placenta to reach the embryo and fetus.** All physicians should develop the habit of ascertaining the likelihood of pregnancy before prescribing drugs for any woman, because a number of medications in common use can be injurious to the embryo and the fetus. Package inserts provided by pharmaceutical companies and approved by the [FDA](#)⁴ should be consulted before drugs are prescribed for pregnant women. If a drug is administered during pregnancy, the advantages to be gained must clearly outweigh any risks inherent in its use.

NAUSEA AND VOMITING. These are common complaints during the first half of pregnancy. Typically they commence between the first and second missed menstrual period and continue until about 14 weeks. Nausea and vomiting are usually worse in the morning, but may continue throughout the day. [Lacroix and co-workers \(2000\)](#) found that nausea and vomiting was reported by three fourths of pregnant women and lasted an average of 35 days. Half of these had relief by 14 weeks' gestation, and 90 percent by 22 weeks. *Morning sickness* was a misnomer in this study because 80 percent of the women reported that nausea lasted all day.

The genesis of pregnancy-induced nausea and vomiting is not clear and it is discussed in [Chapter 48 \(p. 1275\)](#). While high levels of serum chorionic gonadotropin have been implicated, nausea is likely induced by estrogen levels that parallel gonadotropin levels. [Flaxman and Sherman \(2000\)](#) contend that nausea and vomiting during early pregnancy evolved to protect the developing fetus by encouraging its mother to avoid dangerous foods. There is no scientific evidence for this view.

Seldom is the treatment of nausea and vomiting of pregnancy so successful that the affected expectant mother is afforded complete relief. Fortunately, the unpleasantness and discomfort can usually be minimized. Eating small feedings at more frequent intervals but stopping short of satiation is of value. Because the smell of certain foods often precipitates or aggravates the symptoms, such foods should be avoided as much as possible. Very infrequently vomiting may be so severe that dehydration, electrolyte and acid-base disturbances, and starvation become serious problems. This is termed *hyperemesis gravidarum*, and its management is described in [Chapter 48 \(p. 1275\)](#).

CONSTIPATION. Constipation was discussed under "Bowel Habits" earlier in the chapter, and is covered extensively in [Chapter 48 \(p. 1277\)](#).

BACKACHE. Low back pain to some extent is reported in half of pregnant women. Minor degrees follow excessive strain or fatigue and excessive bending, lifting, or walking. [Orvieto and associates \(1994\)](#) studied 449 women and reported that back pain increased with duration of gestation. Prior low back pain and obesity were risk factors.

Back pain can be reduced by having women squat rather than bend over when reaching down, providing back support with a pillow when sitting down, and avoiding high-heeled shoes. Severe back pain should not be attributed simply to pregnancy until a thorough orthopedic examination has been conducted. Muscular spasm and tenderness, which often are classified clinically as acute strain or fibrositis, respond well to analgesics, heat, and rest. As discussed in [Chapter 50 \(p. 1349\)](#), some women with severe back and hip pain may have *pregnancy-associated osteoporosis* ([Dunne and colleagues, 1993](#)).

In some women, motion of the symphysis pubis and lumbosacral joints, and general relaxation of pelvic ligaments may be demonstrated. In severe cases the pregnant woman may be unable to walk or even remain comfortable without support furnished by a heavy girdle and prolonged periods of rest. Occasionally, anatomical, congenital, or traumatic defects are found. Pain caused by herniation of an intervertebral disc occurs during pregnancy with about the same frequency as at other times.

VARICOSITIES. These generally result from congenital predisposition, and are exaggerated by prolonged standing, pregnancy, and advancing age. Usually varicosities become more prominent as pregnancy advances, as weight increases, and as the length of time spent upright is prolonged. As discussed in [Chapter 8 \(p. 184\)](#), femoral venous pressure increases appreciably as pregnancy advances. The symptoms produced by varicosities vary from cosmetic blemishes on the lower extremities and mild discomfort at the end of the day to severe discomfort that requires prolonged rest with the feet elevated.

The treatment of varicosities of the lower extremities is generally limited to periodic rest with elevation of the legs, elastic stockings, or both. Surgical correction of the condition during pregnancy is generally not advised, although occasionally the symptoms may be so severe that injection, ligation, or even stripping of the veins is necessary in order to allow the pregnant woman to remain ambulatory. In general, these operations should be postponed until after delivery. Vulvar varicosities may be aided by application of a foam rubber pad suspended across the vulva by a belt of the type used with a perineal pad. Rarely, large varicosities may rupture, resulting in profuse hemorrhage.

Occasionally, *superficial thrombophlebitis* complicates preexisting varicose veins ([Chap. 46, p. 1235](#)).

HEMORRHOIDS. Varicosities of the rectal veins occasionally first appear during pregnancy. More often, pregnancy causes an exacerbation or recurrence of previous hemorrhoids. Their development or aggravation during pregnancy is undoubtedly related to increased pressure in the rectal veins caused by obstruction of venous return by the large uterus, and to the tendency toward constipation during pregnancy. Usually pain and swelling are relieved by topically applied anesthetics, warm soaks, and agents that soften the stool. Thrombosis of a rectal vein can cause considerable pain, but the clot can usually be evacuated by incising the wall of the involved vein with a scalpel under topical anesthesia.

HEARTBURN. This symptom is one of the most common complaints of pregnant women, and is caused by reflux of gastric contents into the lower esophagus. The increased frequency of regurgitation during pregnancy most likely results from the upward displacement and compression of the stomach by the uterus combined with relaxation of the lower esophageal sphincter. In most pregnant women, symptoms are mild and relieved by a regimen of more frequent but smaller meals and avoidance of bending over or lying flat. Antacid preparations may provide considerable relief. Aluminum hydroxide, magnesium trisilicate, or magnesium hydroxide, alone or in combination, should be used in preference to sodium bicarbonate. The pregnant woman who tends to retain sodium can become edematous as the result of ingestion of excessive amounts of sodium bicarbonate. Management for symptoms that do not respond to these simple measures is discussed in [Chapter 48 \(p. 1276\)](#).

PICA. There has been considerable historical interest in the alleged cravings (pica) of pregnant women for strange foods and, at times, nonfoods such as ice (pagophagia), starch (amylphagia), or clay (geophagia). The desire for dry lump starch, clay, chopped ice, or even refrigerator frost has been considered by some to be triggered by severe iron deficiency. Although some women crave these items, and although the craving is usually ameliorated after correction of iron deficiency, not all pregnant women with pica are necessarily iron deficient. Certainly, if strange "foods" dominate the diet, iron deficiency will be aggravated or it will develop eventually.

[Golden \(2000\)](#) reviewed the history of pica during pregnancy and traces its roots to medical legend beginning in the 16th century. For example, there is the legend of a 16th-century woman who craved a bite from the arm of a baker and refused all other food. To accommodate her pica, her husband paid the baker to permit the woman to take three bites. After enduring only two, he backed out of the agreement and she subsequently gave birth to triplets, and one was stillborn. This tale was cited up until the 1940s to support the popular belief that the longings of pregnant women should not be denied and that to refuse their demands was to put a child at risk.

We are of the view that pica is more legend than reality. For example, it is commonly believed that pregnant women crave pickles. In fact, during more than 25 years of observation of hospitalized pregnant women for various complications in the Parkland Hospital High-Risk Pregnancy Unit, only one woman demanded pickles be available at her bedside. It is probably time to end obstetrical credence for tales of unusual longings attributable to pregnancy.

PTYALISM. Women during pregnancy are occasionally distressed by profuse salivation. The cause of this ptyalism sometimes appears to be stimulation of the salivary glands by the ingestion of starch. This cause should be looked for and eradicated if found. Most cases are unexplained.

FATIGUE. Early in pregnancy, most women complain of fatigue and desire for excessive periods of sleep. The condition usually remits spontaneously by the fourth month of pregnancy and has no special significance. It may be due to the soporific effect of progesterone(s).

HEADACHE. This symptom is a frequent complaint early in pregnancy. A few cases may result from sinusitis or ocular strain caused by refractive errors. In the vast majority, however, no cause can be demonstrated. Treatment is largely symptomatic. By midpregnancy, most headaches decrease in severity or disappear. The pathological significance of headaches as the consequence of hypertensive disorders that develops later in pregnancy is considered in [Chapter 24 \(p. 570\)](#). Persistent or severe headaches of other origins, for example, migraine, are discussed in [Chapter 53 \(p. 1406\)](#).

LEUKORRHEA. Pregnant women commonly develop increased vaginal discharge, which in many instances is not pathological. Increased mucus formation by cervical glands in response to hyperestrogenemia is undoubtedly a contributing factor. If the secretion is troublesome, the woman may be advised to douche with water mildly acidified with vinegar.

Occasionally, troublesome leukorrhea is the result of an infection caused by *Trichomonas vaginalis* or *Candida albicans*.

TRICHOMONIASIS. In as many as 20 percent of women, *T. vaginalis* can be identified during prenatal examination. Symptomatic infection is much less prevalent, and vaginitis is characterized by foamy leukorrhea with pruritus and irritation. Trichomonads are demonstrated readily in fresh vaginal secretions as flagellated, pear-shaped, motile organisms that are somewhat larger than leukocytes.

Metronidazole has proved effective in eradicating *T. vaginalis*. The drug may be administered orally or vaginally. When ingested by the mother, metronidazole crosses the placenta and enters the fetal circulation. The possibility of teratogenicity from first-trimester exposure has been raised. As discussed in [Chapter 38 \(p. 1021\) Rosa and colleagues \(1987\)](#) found no increased frequency of birth defects in over 1000 women given metronidazole during early pregnancy. The drug is classified as category B by the manufacturer, but the Centers for Disease Control recommend against its use in early pregnancy.

CANDIDIASIS. *C. albicans* can be cultured from the vagina in about 25 percent of women approaching term. Asymptomatic vaginal candidiasis requires no treatment, but may sometimes cause an extremely profuse irritating discharge. Miconazole, clotrimazole, and nystatin are effective for the treatment of candidiasis during pregnancy. Infection is likely to recur, thereby requiring repeated treatment during pregnancy; but it usually subsides at the end of gestation.

BACTERIAL VAGINOSIS. Not an infection in the ordinary sense, bacterial vaginosis is a maldistribution of bacterial populations that comprise normal vaginal flora. Lactobacilli are decreased, and overrepresented species tend to be anaerobic bacteria, including *Gard-nerella vaginalis*, *Mobiluncus*, and some *Bacteroides* species. The Vaginal Infections and Prematurity Study Group ([Hillier and colleagues, 1995](#)) identified the condition in 16 percent of over 10,000 pregnant women studied at 23 to 26 weeks. Its prevalence during pregnancy varies from 10 to 30 percent ([MacDermott, 1995](#)). The issue of vaginosis causing preterm labor remains unresolved ([Chap. 27, p. 699](#)).

Treatment is reserved for symptomatic women who usually complain of a fishy-smelling malodorous discharge. Metronidazole, 500 mg twice daily orally for 7 days, will achieve cure in about 90 percent of cases.

TABLE 10-2. Nonemergent Obstetrical or Medical Risk Factors Detected During Prenatal Care in the United States, 1998

Risk Factor	Births	Percent
Total live births	3,941,553	100
Hypertension due to pregnancy	146,320	3.7
Diabetes	103,691	2.6
Anemia	84,795	2.2
Prior preterm or SGA infant	47,429	1.2
Acute or chronic lung disease	40,190	1.2
Genital herpes	32,969	.8
Chronic hypertension	27,442	.7
Rh sensitization	25,783	.7
Cardiac disease	20,528	.5
Renal disease	11,141	.3
Incompetent cervix	10,704	.3
Hemoglobinopathy	3,202	.1
Total with risk factors	554,194	14

SGA = small for gestational age.

Adapted from Ventura and co-workers (2000).

TABLE 10-3. Prenatal Visit Schedule Used at Parkland Hospital for Nulliparous Women without Medical Risk Factors and Parous Women with Prior Normal Pregnancies^a

Return Visit No.	Nulliparous Women	Parous Women ^b	Purpose of Visit
1	16 wk	16 wk	AFP screening; ultrasound if needed
2	19 wk	22 wk	Assess gestational age; FHT auscultated
3	26 wk	26 wk	Assess gestational age; gestational diabetes screening; anti-D immunoglobulin if needed
4	30 wk	30 wk	Assess fetal size; hematocrit, VDRL and syphilis serology
5	34 wk	36 wk	Assess fetal size, blood pressure
6	36 wk	38 wk	Blood pressure surveillance
7	37 wk	40 wk	Blood pressure surveillance
8	38 wk	41 wk	Blood pressure surveillance; schedule postterm induction for multiparas
9	39 wk		Blood pressure surveillance; Schedule postterm induction
10	40 wk		Blood pressure surveillance; Schedule postterm induction
11	41 wk		Blood pressure surveillance; Schedule postterm induction

AFP = alpha-fetoprotein; FHT = fetal heart tones; VDRL = Venereal Disease Research Laboratory test.

^a Women with risk factors are seen more frequently, typically in specialized obstetrical complication clinics.

^b 18-34 years old and = 1 prior normal pregnancies.

Estimated due date

General physical examination

Laboratory tests: hematocrit (hemoglobin), urinalysis, urine culture, blood grouping, Rh, antibody screen, rubella status, syphilis screen, Pap smear, HbsAg testing; offer HIV testing

Patient education, e.g., use of seatbelts, avoidance of alcohol and tobacco

HbsAg = hepatitis B surface antigen; HIV = human immunodeficiency virus.

From the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (1997), with permission.

TABLE 10-6. Recommended Components of Routine Prenatal Care after the First Visit

Visit intervals	Every 4 wk until 28 wk; then every 2-3 wk until 36 wk and weekly thereafter
Each visit	Assess blood pressure, weight, urine protein and glucose, uterine size, fetal heart rate, fetal movement, contractions, bleeding and membrane rupture; ultrasound is only used for specific indications
15-20 wk	Maternal serum alpha-fetoprotein screening
24-28 wk	Screen for gestational diabetes if indicated
28 wk	Test D-negative women for antibodies; give anti-D immune globulin if indicated

From the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (1997), with permission.

TABLE 10-9. Recommendations for Immunization During Pregnancy

Live virus vaccines

Measles—contraindicated
Mumps—contraindicated
Varicella-zoster—contraindicated

Inactivated bacterial vaccines

Pneumococcal—same as nonpregnant
Meningococcal—same as nonpregnant
Hemophilus—same as nonpregnant
Cholera—risks vs benefits

Hyperimmune globulins

Hepatitis B—postexposure prophylaxis: give along with hepatitis B vaccine initially, then vaccine alone at 1 and 6 mo
Rabies—postexposure prophylaxis
Tetanus—postexposure prophylaxis
Varicella—consider for postexposure within 96 h

Live bacterial vaccine

Typhoid (Ty21a)—risks vs benefits
Poliomyelitis—no longer recommended
Yellow fever—high-risk areas only

Inactivated virus vaccines

Influenza—after first trimester request
Rabies—same as nonpregnant
Hepatitis A and B—same as nonpregnant
Enhanced poliomyelitis (IPV-e)—risk of exposure
Japanese encephalitis—weigh risks vs benefits

Toxoids

Tetanus-diphtheria—same as nonpregnant

Pooled immune serum globulins

Hepatitis A—postexposure prophylaxis
Measles—postexposure prophylaxis

Modified from the Association of Professors of Gynecology and Obstetrics (1999).

SECTION IV - NORMAL LABOR AND DELIVERY

11. Parturition

CLINICAL COURSE OF LABOR

The last few hours of human pregnancy are characterized by uterine contractions that effect dilatation of the cervix and force the fetus through the birth canal. Much energy is expended during this time; hence the use of the term *labor* to describe this process. The myometrial contractions of labor are painful, which is why the term *labor pains* is used to describe this process.

Before these forceful, painful contractions begin, however, the uterus must be prepared for labor. During the first 36 to 38 weeks of gestation, the myometrium is unresponsive; after this prolonged period of quiescence, a transitional phase is required during which myometrial unresponsiveness is suspended and the cervix is softened and effaced. Indeed, there are multiple functional states of the uterus that must be implemented during pregnancy and the puerperium; these are described later and categorized as the uterine phases of parturition.

Myometrial contractions that do not cause cervical dilatation may be observed at any time during pregnancy. These contractions are characterized by unpredictability in occurrence, lack of intensity, and brevity of duration. Any discomfort that they produce is usually confined to the lower abdomen and groin. Near the end of pregnancy, as the uterus undergoes preparation for labor, contractions of this type are more common, especially in multiparas, and sometimes are referred to as false labor. In some women, however, the forceful uterine contractions that effect cervical dilatation, fetal descent, and delivery of the conceptus begin suddenly, seemingly without warning.

MYOMETRIUM

ANATOMICAL AND PHYSIOLOGICAL CONSIDERATIONS. There are unique characteristics of myometrial muscle (and other smooth muscles) compared with skeletal muscle. [Huszar and Walsh \(1989\)](#) point out that these differences create a peculiar advantage for the myometrium in the efficiency of uterine contractions and the delivery of the fetus. First, the degree of shortening of smooth muscle cells with contractions may be one order of magnitude greater than that attained in striated muscle cells. Second, forces can be exerted in smooth muscle cells in any direction, whereas the contraction force generated by skeletal muscle is always aligned with the axis of the muscle fibers. Third, smooth muscle is not organized in the same manner as skeletal muscle; in myometrium, the thick and thin filaments are found in long, random bundles throughout the cells. This arrangement facilitates greater shortening and force-generating capacity of smooth muscle. Fourth, there is the advantage that multidirectional force generation in myometrial smooth muscle permits versatility in expulsive force directionality that can be brought to bear irrespective of the lie or presentation of the fetus.

BIOCHEMISTRY OF SMOOTH MUSCLE CONTRACTIONS. The interaction of myosin and actin is essential to muscle contraction. Myosin (M_r about 500,000) is comprised of multiple light and heavy chains and is laid down in thick myofilaments. The interaction of myosin and actin, which causes activation of ATPase, ATP hydrolysis, and force generation, is effected by enzymatic phosphorylation of the 20-kd light chain of myosin ([Stull and colleagues, 1988, 1998](#)). This phosphorylation reaction is catalyzed by the enzyme *myosin light chain kinase*, which is activated by Ca^{2+} ([Fig. 11-1](#)).

Ca^{2+} binds to calmodulin, a calcium-binding regulatory protein, which in turn binds to and activates myosin light chain kinase. In this manner, agents that act on myometrial smooth muscle cells to cause an increase in the intracellular cytosolic concentration of calcium ($[Ca^{2+}]_i$) promote contraction. Conditions that cause a decrease in $[Ca^{2+}]_i$ favor relaxation. Ordinarily, agents that cause an increase in the intracellular concentration of cyclic adenosine monophosphate (cAMP) or cyclic guanosine monophosphate (cGMP) promote uterine relaxation. It is believed that cAMP and cGMP act to cause a decrease in $[Ca^{2+}]_i$, although the exact mechanism(s) is not defined. The biochemistry and physiology of smooth muscle contractility have been reviewed by [Barany and Barany \(1990\)](#) and by [Sanborn and colleagues \(1994\)](#).

THE THREE STAGES OF LABOR. Active labor is divided into three separate stages. The first stage of labor begins when uterine contractions of sufficient frequency, intensity, and duration are attained to bring about effacement and progressive dilatation of the cervix. The first stage of labor ends when the cervix is fully dilated, that is, when the cervix is sufficiently dilated (about 10 cm) to allow passage of the fetal head. The first stage of labor, therefore, is the stage of cervical effacement and dilatation.

The second stage of labor begins when dilatation of the cervix is complete, and ends with delivery of the fetus. The second stage of labor is the stage of expulsion of the fetus.

The third stage of labor begins immediately after delivery of the fetus, and ends with the delivery of the placenta and fetal membranes. The third stage of labor is the stage of separation and expulsion of the placenta.

CLINICAL ONSET OF LABOR. A rather dependable sign of the impending onset of active labor (provided rectal or vaginal examinations have not been performed in the preceding 48 hours) is the discharge of a small amount of blood-tinged mucus from the vagina. This represents the extrusion of the plug of mucus that had filled the cervical canal during pregnancy, and is referred to as "show" or "bloody show." This is a late sign, because commonly labor is already in progress or likely will ensue during the next several hours to few days. Normally, only a few drops of blood escape with the mucus plug; more substantial bleeding is suggestive of an abnormal cause.

UTERINE CONTRACTIONS CHARACTERISTIC OF LABOR. Unique among physiological muscular contractions, those of uterine smooth muscle of labor are painful. The cause of the pain is not known definitely, but several possibilities have been suggested:

1. Hypoxia of the contracted myometrium (as in angina pectoris).
2. Compression of nerve ganglia in the cervix and lower uterus by the interlocking muscle bundles.
3. Stretching of the cervix during dilatation.
4. Stretching of the peritoneum overlying the fundus.

Compression of nerve ganglia in the cervix and lower uterine segment by the contracting myometrium is an especially attractive hypothesis. Paracervical infiltration with a local anesthetic usually produces appreciable relief of pain during subsequent uterine contractions ([Chap. 15, p. 371](#)).

Uterine contractions are involuntary and, for the most part, independent of extrauterine control. Neural blockage from epidural analgesia does not diminish the frequency and intensity of uterine contractions. Moreover, the myometrial contractions in paraplegic women are normal, though painless, as in women after bilateral lumbar sympathectomy.

Mechanical stretching of the cervix enhances uterine activity in several species, including humans. This phenomenon has been referred to as the *Ferguson reflex* (1941). The exact mechanism by which mechanical dilatation of the cervix causes increased myometrial contractility is not clear. Release of oxytocin was suggested as the cause, but this is not proven. Manipulation of the cervix and "stripping" the fetal membranes is associated with an increase in the levels of prostaglandin F_{2a} metabolite (PGFM) in blood (see [Chap. 20](#)).

The interval between contractions diminishes gradually from about 10 minutes at the onset of the first stage of labor to as little as 1 minute or less in the second stage. Periods of relaxation between contractions, however, are essential to the welfare of the fetus. Unremitting contraction of the uterus compromises uteroplacental blood flow, and ultimately, fetal-placental flow, sufficiently to cause fetal hypoxemia. In the active phase of labor, the duration of each contraction ranges from 30 to 90 seconds, averaging about 1 minute. There is appreciable variability in the intensity of uterine contractions during apparently normal labor, as emphasized by [Schulman and Romney \(1970\)](#). They recorded the amniotic fluid pressures generated by uterine contractions during spontaneous labor; the average was about 40

mm Hg, but varied from 20 to 60 mm Hg ([Chap. 14, p. 355](#)).

DIFFERENTIATION OF UTERINE ACTIVITY. During active labor, the uterus is transformed into two distinct parts. The actively contracting upper segment becomes thicker as labor advances. The lower portion, comprising the lower segment of the uterus and the cervix, is relatively passive compared with the upper segment, and it develops into a much more thinly walled passage for the fetus. The lower uterine segment is analogous to a greatly expanded and thinned-out isthmus of the uterus of nonpregnant women, the formation of which is not solely a phenomenon of labor. The lower segment develops gradually as pregnancy progresses and then thins remarkably during labor ([Figs. 11-2](#) and [11-3](#)). By abdominal palpation, even before rupture of the membranes, the two segments can be differentiated during a contraction. The upper uterine segment is quite firm or hard, whereas the consistency of the lower uterine segment is much less firm. The former is the actively contracting part of the uterus; the latter is the distended, normally much more passive, portion.

If the entire wall of uterine musculature, including the lower uterine segment and cervix, were to contract simultaneously and with equal intensity, the net expulsive force would be decreased markedly. Herein lies the importance of the division of the uterus into an actively contracting upper segment and a more passive lower segment that differ not only anatomically but also physiologically. The upper segment contracts, retracts, and expels the fetus; in response to the force of the contractions of the upper segment, the softened lower uterine segment and cervix dilate and thereby form a greatly expanded, thinned-out muscular and fibromuscular tube through which the fetus can be extruded.

The myometrium of the upper uterine segment does not relax to its original length after contractions; rather, it becomes relatively fixed at a shorter length. The tension, however, remains the same as before the contraction. The upper portion of the uterus, or active segment, contracts down on its diminishing contents, but myometrial tension remains constant. The net effect is to take up slack, maintaining the advantage gained in the expulsion of the fetus, and keeping the uterine musculature in firm contact with the intrauterine contents. As the consequence of retraction, each successive contraction commences where its predecessor left off, so that the upper part of the uterine cavity becomes slightly smaller with each successive contraction. Because of the successive shortening of the muscular fibers with contractions, the upper active uterine segment becomes progressively thickened throughout the first and second stages of labor and tremendously thickened immediately after delivery of the fetus ([Fig. 11-2](#)). The phenomenon of retraction of the upper uterine segment is contingent upon a decrease in the volume of its contents. For the contents to be diminished, particularly early in labor when the entire uterus is virtually a closed sac with only a minute opening at the cervical os, the musculature of the lower segment must stretch. This permits increasingly more of the intrauterine contents to occupy the lower segment, and the upper segment retracts only to the extent that the lower segment distends and the cervix dilates.

The relaxation of the lower uterine segment is not a complete relaxation, but rather the opposite of retraction. The fibers of the lower segment become stretched with each contraction of the upper segment, after which these are not returned to the previous length but rather remain relatively fixed at the longer length; the tension, however, remains essentially the same as before. The musculature still manifests tone, still resists stretch, and still contracts somewhat on stimulation. The successive lengthening of the muscular fibers in the lower uterine segment, as labor progresses, is accompanied by thinning, normally to only a few millimeters in the thinnest part. As a result of the thinning of the lower uterine segment and the concomitant thickening of the upper, the boundary between the two is marked by a ridge on the inner uterine surface, the **physiological retraction ring**. When the thinning of the lower uterine segment is extreme, as in obstructed labor, the ring is very prominent, forming a **pathological retraction ring**. This is an abnormal condition also known as **Bandl ring**, which is illustrated in [Figure 11-2](#) and discussed further in [Chapter 18 \(p. 443\)](#). The existence of a gradient of diminishing physiological activity from fundus to cervix was established from measurements of differences in behavior of the upper and lower parts of the uterus during normal labor.

CHANGE IN UTERINE SHAPE. Each contraction produces an elongation of the uterine ovoid with a concomitant decrease in horizontal diameter. By virtue of this change in shape, there are important effects on the process of labor. First, the decrease in horizontal diameter produces a straightening of the fetal vertebral column, pressing its upper pole firmly against the fundus of the uterus, whereas the lower pole is thrust farther downward and into the pelvis. The lengthening of the fetal ovoid thus produced has been estimated as between 5 and 10 cm. The pressure exerted in this fashion is known as the **fetal axis pressure**. Second, with lengthening of the uterus, the longitudinal fibers are drawn taut and because the lower segment and cervix are the only parts of the uterus that are flexible, these are pulled upward over the lower pole of the fetus. This effect on the musculature of the lower segment and on the cervix is an important factor in cervical dilatation.

ANCILLARY FORCES IN LABOR. After the cervix is dilated fully, the most important force in the expulsion of the fetus is that produced by increased maternal intra-abdominal pressure. This is created by contraction of the abdominal muscles simultaneously with forced respiratory efforts with the glottis closed. This is referred to as "pushing." The nature of the force produced is similar to that involved in defecation, but the intensity usually is much greater. The importance of intra-abdominal pressure in fetal expulsion is most clearly attested to by the labors of women who are paraplegic. Such women suffer no pain, although the uterus may contract vigorously. Cervical dilatation, in large measure the result of uterine contractions acting on a softened cervix, proceeds normally, but expulsion of the infant is accomplished more readily when the woman is instructed to bear down and can do so during a uterine contraction.

Although increased intra-abdominal pressure is required for the spontaneous completion of labor, it is futile until the cervix is fully dilated. Specifically, it is a necessary auxiliary to uterine contractions in the second stage of labor, but pushing accomplishes little in the first stage, except to produce fatigue. Intra-abdominal pressure also may be important in the third stage of labor, especially if the parturient is unattended. After the placenta has separated, its spontaneous expulsion is aided by the mother increasing intra-abdominal pressure.

CERVIX

Before the onset of labor, during the phase of uterine awakening and preparedness, the cervix is softened, which facilitates dilatation of the cervix once forceful myometrial contractions of labor begin.

CHANGES INDUCED IN THE CERVIX WITH LABOR. The effective force of the first stage of labor is the uterine contraction, which in turn exerts hydrostatic pressure through the fetal membranes against the cervix and lower uterine segment. In the absence of intact membranes, the fetal presenting part is forced directly against the cervix and lower uterine segment. As the result of the action of these forces, two fundamental changes—effacement and dilatation—take place in the already softened cervix. For the head of the average fetus at term to pass through the cervix, the cervical canal must dilate to a diameter of about 10 cm; at this time, the cervix is said to be completely (or fully) dilated. There may be no fetal descent during cervical effacement, but most commonly the presenting fetal part descends somewhat as the cervix dilates. During the second stage of labor, descent of the fetal presenting part typically occurs rather slowly but steadily in nulliparas. In multi-paras, however, particularly those of high parity, descent may be very rapid.

CERVICAL EFFACEMENT. The "obliteration" or "taking up" of the cervix is the shortening of the cervical canal from a length of about 2 cm to a mere circular orifice with almost paper-thin edges. This process is referred to as effacement and takes place from above downward. The muscular fibers at about the level of the internal cervical os are pulled upward, or "taken up," into the lower uterine segment, as the condition of the external os remains temporarily unchanged. As illustrated in [Figure 11-4](#), [Figure 11-5](#), [Figure 11-6](#), and [Figure 11-7](#), the edges of the internal os are drawn upward several centimeters to become a part (both anatomically and functionally) of the lower uterine segment. Effacement may be compared with a funneling process in which the whole length of a narrow cylinder is converted into a very obtuse, flaring funnel with a small circular orifice for an outlet. As the result of increased myometrial activity during uterine preparedness for labor, appreciable effacement of the softened cervix sometimes is accomplished before active labor begins. Effacement causes expulsion of the mucus plug as the cervical canal is shortened.

CERVICAL DILATATION. Compared with the body of the uterus, the lower uterine segment and the cervix are regions of lesser resistance. Therefore, during a contraction, these structures are subjected to distention, in the course of which a centrifugal pull is exerted on the cervix ([Figure 11-8](#), [Figure 11-9](#), and [Figure 11-10](#)). As the uterine contractions cause pressure on the membranes, the hydrostatic action of the amnionic sac in turn dilates the cervical canal like a wedge. In the absence of intact membranes, the pressure of the presenting part against the cervix and lower uterine segment is similarly effective. Early rupture of the membranes does not retard cervical dilatation so long as the presenting part of the fetus is positioned to exert pressure against the cervix and lower uterine segment. The process of cervical effacement and dilatation causes the formation of the forebag of the amnionic fluid, which is later described in detail.

LABOR PATTERNS

PATTERN OF CERVICAL DILATATION. Friedman, in his treatise on labor ([1978](#)), stated that "the clinical features of uterine contractions—namely, frequency, intensity, and duration—cannot be relied upon as measures of progression in labor nor as indices of normality. ... Except for cervical dilatation and fetal descent, none of the clinical features of the parturient... appears to be useful in assessing labor progression." The pattern of cervical dilatation that takes place during the course of normal labor takes on the shape of a sigmoid curve. As depicted in [Figure 11-11](#), two phases of cervical dilatation are the latent phase and the active phase. The active phase has been subdivided further as the acceleration phase, the phase of maximum slope, and the deceleration phase ([Friedman, 1978](#)). The duration of the latent phase is more variable and subject to sensitive changes by extraneous factors and by sedation (prolongation of latent phase) and myometrial stimulation

(shortening of latent phase). The duration of the latent phase has little bearing on the subsequent course of labor, whereas the characteristics of the accelerated phase are usually predictive of the outcome of a particular labor. Friedman considers the maximum slope as a "good measure of the overall efficiency of the machine," whereas the nature of the deceleration phase is more reflective of fetopelvic relationships. The completion of cervical dilatation during the active phase of labor is accomplished by cervical retraction about the presenting part of the fetus. After complete cervical dilatation, the second stage of labor commences; thereafter, only progressive descent of the presenting fetal part is available to assess the progress of labor.

PATTERN OF FETAL DESCENT. In many nulliparas, engagement of the fetal head is accomplished before labor begins, and further descent does not occur until late in labor. In others in which engagement of the fetal head is initially not so complete, further descent occurs during the first stage of labor. In the descent pattern of normal labor, a typical hyperbolic curve is formed when the station of the fetal head is plotted as a function of the duration of labor. Active descent usually takes place after cervical dilatation has progressed for some time (Fig. 11-12). In nulliparas, increased rates of descent are observed ordinarily during the phase of maximum slope of cervical dilatation. At this time, the speed of descent increases to a maximum, and this maximal rate of descent is maintained until the presenting fetal part reaches the perineal floor (Friedman, 1978).

CRITERIA FOR NORMAL LABOR. Friedman also sought to select criteria that would delimit normal labor and thereby enable identification of significant abnormalities in labor. The limits, admittedly arbitrary, appear to be logical and clinically useful. The group of women studied were nulliparas and multiparas with no fetopelvic disproportion, no fetal malposition or malpresentation, no multiple pregnancy, and none were treated with heavy sedation or conduction analgesia, oxytocin, or operative intervention. All had a normal pelvis, were at term with a vertex presentation, and delivered average-sized infants. From these studies, Friedman developed the concept of three functional divisions of labor—preparatory, dilatational, and pelvic—to describe the physiological objectives of each division (Fig. 11-12). He found that the preparatory division of labor may be sensitive to sedation and conduction analgesia. Although little cervical dilatation occurs during this time, considerable changes take place in the extracellular matrix (collagen and other connective tissue components) of the cervix. The dilatational division of labor, during which time dilatation is occurring at the most rapid rate, is principally unaffected by sedation or conduction analgesia. The pelvic division of labor begins with the deceleration phase of cervical dilatation. The classical mechanisms of labor, which involve the cardinal movements of the fetus, take place principally during the pelvic division of labor. The onset of the pelvic division is seldom clinically identifiable separate from the dilatational division of labor. Moreover, the rate of cervical dilatation does not always decelerate as full dilatation is approached; in fact, it may accelerate.

RUPTURE OF THE MEMBRANES. Spontaneous rupture of the membranes most often occurs sometime during the course of active labor. Typically, rupture is evident by a sudden gush of a variable quantity of normally clear or slightly turbid, nearly colorless fluid. Less frequently, the membranes remain intact until delivery of the infant. If by chance the membranes remain intact until completion of delivery, the fetus is born surrounded by them, and the portion covering the head of the newborn infant is sometimes referred to as the **caul**. Rupture of the membranes before the onset of labor at any stage of gestation is referred to as **premature rupture of the membranes**.

CHANGES IN THE VAGINA AND PELVIC FLOOR. The birth canal is supported and is functionally closed by a number of layers of tissues that together form the pelvic floor. Its most important structures are the levator ani muscle and the fascia covering its upper and lower surfaces, which for practical purposes may be considered as the pelvic floor (Chap. 3). This group of muscles closes the lower end of the pelvic cavity as a diaphragm and thereby a concave upper and a convex lower surface is presented (see Fig. 3-6). On either side, the levator ani consists of a pubococcygeus and iliococcygeus portion. The posterior and lateral portions of the pelvic floor, which are not filled out by the levator ani, are occupied by the piriformis and coccygeus muscles on either side.

The levator ani varies in thickness from 3 to 5 mm, though its margins encircling the rectum and vagina are somewhat thicker. During pregnancy, the levator ani usually undergoes hypertrophy. By vaginal examination, the internal margin of this muscle can be felt as a thick band that extends backward from the pubis and encircles the vagina about 2 cm above the hymen. On contraction, the levator ani draws both the rectum and vagina forward and upward in the direction of the symphysis pubis and thereby acts to close the vagina. The more superficial muscles of the perineum are too delicate to serve more than an accessory function.

In the first stage of labor, the membranes and presenting part of the fetus serve a role in dilating the upper portion of the vagina. After the membranes have ruptured, however, the changes in the pelvic floor are caused entirely by pressure exerted by the fetal presenting part. The most marked change consists of the stretching of the fibers of the levator ani muscles and the thinning of the central portion of the perineum, which becomes transformed from a wedge-shaped mass of tissue 5 cm in thickness to (in the absence of an episiotomy) a thin, almost transparent membranous structure less than 1 cm in thickness. When the perineum is distended maximally, the anus becomes markedly dilated and presents an opening that varies from 2 to 3 cm in diameter and through which the anterior wall of the rectum bulges. The extraordinary number and size of the blood vessels that supply the vagina and pelvic floor effects a great increase in the amount of blood loss when these tissues are torn.

PLACENTAL SEPARATION. The third stage of labor begins immediately after delivery of the fetus and involves the separation and expulsion of the placenta. After delivery of the placenta and fetal membranes, active labor is completed. As the baby is born, the uterus spontaneously contracts down on its diminishing contents. Normally, by the time the infant is completely delivered, the uterine cavity is nearly obliterated and the organ consists of an almost solid mass of muscle, several centimeters thick above the thinner lower segment. The uterine fundus now lies just below the level of the umbilicus. This sudden diminution in uterine size is inevitably accompanied by a decrease in the area of the placental implantation site (Fig. 11-13). For the placenta to accommodate itself to this reduced area, it increases in thickness, but because of limited placental elasticity, it is forced to buckle. The resulting tension causes the weakest layer of the decidua—the spongy layer, or decidua spongiosa—to give way, and cleavage takes place at that site. Therefore, separation of the placenta results primarily from a disproportion created between the unchanged size of the placenta and the reduced size of the underlying implantation site. During cesarean delivery, this phenomenon may be directly observed when the placenta is implanted posteriorly.

Cleavage of the placenta is greatly facilitated by the nature of the loose structure of the spongy decidua, which may be likened to the row of perforations between postage stamps. As separation proceeds, a hematoma forms between the separating placenta and the remaining decidua. Formation of the hematoma is usually the result, rather than the cause, of the separation, because in some cases bleeding is negligible. The hematoma may, however, accelerate the process of cleavage. Because the separation of the placenta is through the spongy layer of the decidua, part of the decidua is cast off with the placenta, whereas the rest remains attached to the myometrium. The amount of decidual tissue retained at the placental site varies.

Placental separation ordinarily occurs within a very few minutes after delivery. Brandt (1933) and others, based on results obtained in combined clinical and radiographic studies, supported the idea that because the periphery of the placenta is probably the most adherent portion, separation usually begins elsewhere. Occasionally some degree of separation begins even before the third stage of labor, probably accounting for certain cases of fetal heart rate decelerations that occur just before expulsion of the infant.

SEPARATION OF AMNIOCHORION. The great decrease in the surface area of the cavity of the uterus simultaneously causes the fetal membranes (amniochorion) and the parietal decidua to be thrown into innumerable folds that increase the thickness of the layer from less than 1 mm to 3 to 4 mm. The lining of the uterus early in the third stage indicates that much of the parietal layer of decidua parietalis is included between the folds of the festooned amnion and chorion laeve (Fig. 11-14). The membranes usually remain in situ until the separation of the placenta is nearly completed. These are then peeled off the uterine wall, partly by the further contraction of the myometrium and partly by traction that is exerted by the separated placenta, which lies in the thin lower uterine segment or in the upper portion of the vagina. The body of the uterus at that time normally forms an almost solid mass of muscle, the anterior and posterior walls of which, each measuring 4 to 5 cm in thickness, lie in close apposition such that the uterine cavity is almost obliterated.

PLACENTAL EXTRUSION. After the placenta has separated from its implantation site, the pressure exerted upon it by the uterine walls causes it to slide downward into the lower uterine segment or the upper part of the vagina. In some cases the placenta may be expelled from those locations by an increase in abdominal pressure, but women in the recumbent position frequently cannot expel the placenta spontaneously. An artificial means of completing the third stage is therefore generally required. The usual method employed is alternately to compress and elevate the fundus, while exerting minimal traction on the umbilical cord (Chap. 13).

MECHANISMS OF PLACENTAL EXTRUSION. When the central, or usual, type of placental separation occurs, the retroplacental hematoma is believed to push the placenta toward the uterine cavity, first the central portion and then the rest. The placenta, thus inverted and weighted with the hematoma, then descends. Because the surrounding membranes are still attached to the decidua, the placenta can descend only by dragging the membranes along; the membranes then peel off its periphery. Consequently, the sac formed by the membranes is inverted, with the glistening amnion over the placental surface presenting at the vulva. The retroplacental hematoma either follows the placenta or is found within the inverted sac. In this process, known as the **Schultze mechanism** of placental expulsion, blood from the placental site pours into the inverted sac, not escaping externally until after extrusion of the placenta. The other method of placental extrusion is known as the **Duncan mechanism**, in which separation of the placenta occurs first at the periphery, with the result that blood collects between the membranes and the uterine wall and escapes from the vagina. In this circumstance, the placenta descends to the vagina sideways, and the maternal surface is the first to appear at the vulva.

PHYSIOLOGICAL AND BIOCHEMICAL PROCESSES OF PARTURITION

The physiological processes in human pregnancy that results in the initiation of parturition and the onset of labor are not defined. Until recently, it was generally accepted that successful pregnancy in all mammalian species was dependent upon the action of progesterone to maintain uterine quiescence until near the end of gestation. This assumption was supported by the finding that in the majority of mammalian pregnancies studied, **progesterone withdrawal** (whether naturally occurring or surgically or pharmacologically induced) precedes the initiation of parturition. In many of these species, a decline, sometimes precipitous, in the levels of progesterone in maternal plasma normally begins after approximately 95 percent of pregnancy. Moreover, the administration of progesterone to these species late in pregnancy delays the onset of parturition.

In primate pregnancy (including humans), however, progesterone withdrawal does not precede the initiation of parturition. The levels of progesterone in the plasma of pregnant women increase throughout pregnancy, declining only after delivery of the placenta, the tissue site of progesterone synthesis in human pregnancy ([Chap. 6](#)).

PARTURITION THEORIES

Presently, there appear to be two general theorems. Viewed simplistically, these are the retreat from pregnancy maintenance hypothesis and the uterotonin induction of parturition theory. Several combinations of selected tenets of these two postulates are incorporated into the theorems of most investigators. Some researchers also speculate that the mature human fetus, in some undefined fashion, is the source of the initial signal for the commencement of the parturitional process. This has little direct experimental support in human parturition.

Other investigators suggest that one or another uterotonin, produced in increased amounts or in response to an increase in the population of its myometrial receptors, is the proximate cause of the initiation of human parturition. Indeed, an obligatory role for one or more uterotonins is included in most parturition theories, either as a primary or a secondary phenomenon in the final events of childbirth.

CONTEMPORARY HUMAN PARTURITION RESEARCH

Two independent sets of observations have influenced the direction of parturition research during the past 35 years. One was the identification of the mechanisms by which estrogen is synthesized in human pregnancy. By 1960, it was established that human pregnancy is a hyperestrogenic state ([Chap. 6](#)), and that the placenta is virtually the sole tissue site of estrogen formation. At that time, it also was known that the human placenta could not synthesize estrogens de novo, from acetate or cholesterol. In the late 1950s, human placental tissue was shown to convert C₁₉-steroids to estrogens. In the early 1960s, it was established that the fetal adrenal glands produce prodigious amounts of C₁₉-steroids, which are transported in fetal blood to the placenta. In syncytiotrophoblast, these fetal adrenal C₁₉-steroids are metabolized with great efficiency to estrogens. The human placenta, therefore, is an incomplete endocrine organ, at least in the case of estrogen biosynthesis. These several findings were assembled as one part of the concept of a fetal-maternal communication system of human pregnancy ([Siiteri and MacDonald, 1963, 1966](#)).

THE SHEEP MODEL OF PARTURITION. During this same decade, [Liggins and associates \(1967, 1968\)](#) demonstrated that in sheep pregnancy, the fetus provides the initial signal that leads to the timely commencement of parturition. They found that adrenalectomy or hypophysectomy of the sheep fetus in utero caused a delay in the initiation of parturition and delivery. Adrenalectomy or hypophysectomy of the ewe did not cause an alteration in the timing of parturition. Contrarily, the infusion of corticotropin, cortisol, or a synthetic glucocorticosteroid into the sheep fetus earlier in pregnancy caused preterm delivery. Liggins deduced that the sheep fetus provides a signal through interaction of brain-pituitary-adrenal glands, which provide another signal(s) that is transported in fetal blood, and acted upon by placental trophoblasts.

SHEEP FETAL ADRENAL CORTISOL SECRETION AND PLACENTAL STEROID SYNTHESIS. [Liggins and colleagues \(1968, 1973\)](#) as well as [Challis and Lye \(1994\)](#), identified and characterized many of the physiological phenomena of sheep parturition. Near the end of sheep pregnancy, a signal arising in the brain of the fetal sheep promotes the beginning of a coordinated sequence of endocrine phenomena that culminates in **progesterone withdrawal** ([McDonald and Nathanielsz, 1991](#)). The fetal brain parturition signal, presumably corticotropin-releasing hormone (CRH), is transmitted to the fetal pituitary gland via the hypophyseal-portal vessels to stimulate adrenocorticotrophic hormone (ACTH) release from the anterior pituitary gland. An increase in [ACTH¹](#) secretion, together with augmented responsiveness of the fetal adrenal cortices that is acquired with maturation, causes increased fetal adrenal secretion of cortisol ([Myers and colleagues, 1992](#)). In response to increased fetal adrenal cortisol secretion, the expression of cytochrome P-450 17 α -hydroxylase/17,20-lyase (P-450_{17 α} , CYP17) in sheep placenta is increased strikingly at the end of pregnancy. This enzyme catalyzes pregnenolone to eventually produce dehydroepiandrosterone, which in turn is aromatized to estrone. Thus, pregnenolone synthesized in placenta is diverted away from progesterone and toward estrogen.

PROGESTERONE WITHDRAWAL AND RETREAT FROM PREGNANCY MAINTENANCE IN SHEEP PREGNANCY. In some manner that is related to progesterone withdrawal, the continued maintenance of uterine quiescence in sheep pregnancy is withdrawn. Clearly, there is a transition period between the tranquil state of the uterus and the onset of labor in sheep parturition. Specifically, myometrial unresponsiveness is suspended and the uterus is awakened before labor begins.

DIVERGENCE OF ENDOCRINE PROCESSES IN SHEEP AND HUMANS. Crucial differences in key endocrine events in pregnant sheep and women are readily apparent.

1. Progesterone withdrawal marked by a decline in blood progesterone levels does not occur before the initiation of human parturition.
2. There is no profound increase in the levels of cortisol in the human fetus near term as there is in the sheep fetus.
3. The infusion of [ACTH¹](#) or cortisol into the human fetus does not bring about the premature initiation of parturition as it does in the sheep.
4. Glucocorticosteroid treatment in human pregnancy is associated with a pronounced decrease in estrogen formation by inhibiting fetal pituitary [ACTH¹](#) secretion and thus attenuating the supply of fetal adrenal C₁₉-steroid precursors for placental estrogen synthesis.
5. The sheep fetal adrenal glands are not the source of placental estrogen precursors as are the adrenal glands of the human fetus, and estrogen production in sheep pregnancy is small compared with that in humans.
6. The enzyme that diverts pregnenolone to estrogen (17 α -hydroxylase/17,20-desmolase) is expressed in the sheep, but not human placenta.
7. Estrogen is produced very late in pregnancy in the sheep but throughout pregnancy in humans.
8. Plasma levels of progesterone in sheep pregnancy (about 10 ng/mL) are relatively small compared with those in the human (about 160 ng/mL).
9. Intrauterine prostaglandin formation during labor in sheep is at least 20 times that produced in human uterine tissues during labor ([Casey and MacDonald, 1988a; Flower, 1977](#)).

PROGESTERONE METABOLISM/PRODUCTION RATES AND HUMAN PARTURITION. [Little and colleagues \(1966\)](#) found that the metabolic clearance rate of plasma progesterone during human pregnancy is similar to that in men and nonpregnant women. Therefore, the plasma level of progesterone is directly proportional to its production rate.

RETREAT FROM PREGNANCY MAINTENANCE AND HUMAN PARTURITION. The mechanism whereby retreat from pregnancy maintenance occurs in human pregnancy, however, has not been identified. Searches for an alternative form of progesterone deprivation have produced no substantive evidence for alterations in progesterone metabolism, compartmentalization (sequestration) of progesterone, or alterations in progesterone-binding proteins or receptor numbers. Therefore, most investigators have concluded that progesterone withdrawal is not a fundamental component of the initiation of human parturition ([Casey and MacDonald, 1988b](#)).

INHIBITION OF PROGESTERONE ACTION. Progesterone treatment of women does not prevent, delay, or arrest labor at term or preterm ([Casey and MacDonald, 1988b](#)). This finding provides further support for the conclusion that a decrease in progesterone levels, even in specific tissue sites, is not involved in the initiation of human parturition. There is, however, another largely unexplored mechanism by which progesterone action could be subjugated near the end of pregnancy. Progesterone action may be interrupted by a specific agent(s) through a progesterone receptor-independent, gene-specific process ([Casey and associates, 1993b](#)).

[Casey and MacDonald, 1996](#)). The very pinnacle of evolutionary development of systems for the withdrawal of progesterone could be the selective attenuation of some (but not all) progesterone effects, namely the interruption of progesterone action on specific genes. If only the actions of progesterone directly supportive of the maintenance of uterine quiescence were inhibited while other (salutary) actions of progesterone that are not involved directly in uterine contractile responsiveness, such as inhibition of lactogenesis, were preserved until delivery of the placenta, a much more sophisticated endocrine system for the initiation of parturition would have evolved.

Such a putative agent, however, must act in a cell-specific or gene-specific manner through a progesterone receptor-independent process. An endogenous selective agent that inhibits progesterone action could be targeted to alter the expression of specific genes—for example, by modifying progesterone-regulated gene transcription, mRNA stability, or protein function and stability. The specificity of progesterone antagonism could be mediated at:

1. The molecular level (use of specific promoters, by specificity of trans-acting factors).
2. The biochemical level (protein function, enzyme activity).
3. The cellular level (e.g., synthesis or activation of a putative antiprogesterin or its receptor).

Such a gene-specific system for inhibiting progesterone action could provide for highly selective subjugation of selected progesterone actions consistent with an evolutionary hierarchy of humans in reproductive processes. Such a process would explain the failure of administered progesterone to delay or prevent the onset of human parturition at term or preterm. One candidate for this role as selective, gene-specific antiprogesterin has been identified, namely, transforming growth factor- β (TGF- β) ([Casey and MacDonald, 1996](#)).

IS PROGESTERONE ONLY ONE COMPONENT OF A REDUNDANT FAIL-SAFE SYSTEM OF PREGNANCY MAINTENANCE? The possibility also must be considered that the contractile unresponsiveness imposed on the uterus during most of human pregnancy is ensured by multiple processes that act independently and cooperatively to establish uterine quiescence. Progesterone is likely only one of several factors that contribute to the system that maintains myometrial contractile unresponsiveness. Because retreat from continued pregnancy maintenance near the end of pregnancy is pivotal to the preparation of the uterus for labor, an understanding of this phenomenon is central to the solution of the human parturition puzzle.

FETAL CONTRIBUTIONS TO INITIATION OF PARTURITION. It is intellectually satisfying to envision that the fetus, after appropriate maturation of vital organs, provides the initial signal that sets the parturitional process in motion. Teleologically, this seems to be the most logical manner by which parturition could begin in a timely fashion. A signal from the human fetus could be transmitted in one of several ways; but however this is accomplished, the end result must include the suspension of uterine quiescence. Regrettably, such a fetal signal has not been discovered. The fetal sheep signaling system that initiates the parturitional process is believed to proceed via the brain, pituitary gland, adrenal glands, and fetal blood to the placenta. The human fetus also may provide a signal through a fetal blood-borne agent that acts upon trophoblast. It is unlikely, however, that the initial signal for the initiation of parturition is a uterotonic such as oxytocin, prostaglandins, or endothelin-1. Rather, it is more likely that the uterus first must be prepared for labor before a uterotonic can be optimally effective ([Casey and MacDonald, 1994](#)).

FETAL ANOMALIES AND DELAYED PARTURITION. Anomalies of the brain of the fetal calf, fetal lamb, and sometimes the human fetus, delay the normal timing of parturition. With congenital absence of the pituitary gland in the bovine fetus, the gestation period is prolonged by several weeks. Adrenal hypoplasia in the bovine fetus is also associated with a delay in the onset of parturition. If early in pregnancy, the ewe grazes on *Veratrum californicum* or "skunk cabbage," the sheep fetus is characterized by a teratogen-induced cyclopean deformity. The brain anomalies of such a fetus include the absence of vascularization of the fetal pituitary gland from the hypothalamus. The fetal adrenal glands remain hypoplastic and pregnancy continues far beyond term ([Challis and Lye, 1994](#); [Thorburn, 1983](#)).

In 1882, Speigelberg proposed that the signal for the initiation of human parturition also originated in the fetus ([Thorburn, 1993](#)). [Rea \(1898\)](#) observed an association between fetal anencephaly and prolonged human gestation. [Malpas \(1933\)](#) extended these observations and described a human pregnancy with an anencephalic fetus that went to 374 days (53 weeks). He concluded that the association between fetal anencephaly and prolonged human gestation seemed to be attributable to anomalous brain-pituitary-adrenal function in the anencephalic fetus. The adrenal glands of the anencephalic fetus are very small, and at term may be only 5 to 10 percent as large as those of a normal fetus. The smallness of the adrenal glands is caused by failure of development of the fetal zone that normally accounts for most of the human fetal adrenal mass and C₁₉-steroid biosynthesis ([Chap. 6](#)). Finally, in pregnancies in which the fetal adrenal glands are hypoplastic, the onset of labor may be delayed ([Anderson and Turnbull, 1973](#)). These findings were suggestive that in humans, as in sheep, the fetal adrenal glands are important for the timely onset of parturition.

THE HUMAN FETUS AND PARTURITION. There is fragmentary evidence that pregnancies in which there is relative hypoestrogenism—fetal anencephaly or adrenal hypoplasia, or placental sulfatase deficiency—are sometimes associated with prolonged gestation. However, while estrogen may facilitate the development of optimal parturitional processes by increasing the capacity of myometrium to contract and to respond to contractile agents, it is not the signal for the initiation of human parturition.

Other fetal abnormalities that prevent or severely reduce the entry of fetal urine (absence of fetal kidneys) or lung secretions (pulmonary hypoplasia) into amniotic fluid do not cause prolongation of human pregnancy. Thus, a signal from the fetus through the paracrine arm of the fetal-maternal communication system does not appear to be mandated for the initiation of parturition.

UTERINE PHASES OF PARTURITION

Parturition, the bringing forth of young, encompasses all physiological processes involved in birthing: the prelude to, the preparation for, the process of, and the parturient's recovery from childbirth. From the disparate nature of these physiological processes, it is evident that multiple transformations in uterine function must be accommodated in a timely manner during successful pregnancy and parturition. As shown in [Figure 11-15](#), parturition can be arbitrarily divided into four uterine phases which correspond to the major physiological transitions of the myometrium and cervix during pregnancy ([Casey and MacDonald 1993a, 1993c](#); [MacDonald and Casey, 1996](#)).

UTERINE PHASE 0 OF PARTURITION. Beginning even before implantation, a remarkably effective period of myometrial quiescence is imposed on the uterus. This phase of parturition is characterized by myometrial smooth muscle tranquility with maintenance of cervical structural integrity. This is the phase in which the inherent propensity of the myometrium to contract is harnessed. During this phase, which persists for about the first 95 percent of normal pregnancy, myometrial smooth muscle is rendered unresponsive to natural stimuli and relative contractile paralysis is imposed against a host of mechanical and chemical challenges that otherwise would promote emptying of the uterine contents. The myometrial contractile unresponsiveness of phase 0 is so extraordinary that near the end of pregnancy the myometrium must be awakened from this prolonged parturitional diapause in preparation for labor.

During phase 0 of parturition, as the myometrium is maintained in a quiescent state, the cervix must remain firm and unyielding. The maintenance of cervical anatomical and structural integrity is essential to the success of phase 0 of parturition. Premature cervical dilatation, structural incompetence, or both, portend an unfavorable pregnancy outcome that ends most often in preterm delivery ([Chap. 27](#)). Shortening of the cervix, when identified between 24 and 28 weeks of pregnancy, is indicative of increased risk of preterm delivery ([Iams and colleagues, 1996](#)).

UTERINE PHASE 1 OF PARTURITION. To prepare the uterus for labor, the uterine tranquility of phase 0 of parturition must be suspended; this is the time of uterine awakening. The morphological and functional changes in myometrium and cervix that prepare the uterus for labor may be the natural outcome of the suspension of uterine phase 0; but whatever the mechanism, the capacity of myometrial cells to regulate the concentration of cytoplasmic Ca²⁺ is restored; myometrial cell responsiveness is reinstated, uterotonic sensitivity develops, and intercellular communicability is established. As these functional capacities of myometrial smooth muscle to contract are implemented and the cervix is ripened, phase 1 of parturition merges into phase 2, active labor. [Challis and Lye \(1994\)](#) refer to the change in uterine functionality before labor as "activation."

UTERINE MODIFICATION DURING PHASE 1 OF PARTURITION. Specific modifications in uterine function evolve with the suspension of uterine phase 0:

1. A striking increase in myometrial oxytocin receptors.
2. An increase in gap junctions (number and surface area) between myometrial cells.

3. Uterine irritability.
4. Responsiveness to uterotonins.
5. Transition from a contractile state characterized predominantly by occasional painless contractions to one in which more frequent contractions develop.
6. Formation of the lower uterine segment.
7. Cervical softening.

With the development of a well-formed lower uterine segment, the fetal head oftentimes descends to or even through the maternal inlet of the pelvis, a distinctive event referred to as **lightening**. The abdomen of the pregnant woman commonly undergoes a change in shape, an event sometimes described by the mother as "the baby dropped." No doubt there are many other modifications of the uterus late in pregnancy during phase 1, some of which may be integral components of uterine preparedness for labor.

Late in pregnancy, at sometime during phase 1 of parturition, there is a striking—50-fold or more—increase in the number of oxytocin receptors in myometrium ([Fuchs and associates, 1982](#)). This coincides with the increase in uterine contractile responsiveness to oxytocin ([Soloff and co-workers, 1979](#)). Also, prolonged human gestation is associated with a delay in this increase in receptors ([Fuchs and collaborators, 1984](#)).

Also during phase 1, the number and size of gap junctions between myometrial cells increase before the onset of labor, continue to increase during labor, and then decrease quickly after delivery. This is true of spontaneous parturition, both at term and preterm ([Garfield and Hayashi, 1981](#)).

CERVICAL CHANGES OF PHASE 1 OF PARTURITION. The body of the uterus (the fundus) and the cervix, although parts of the same organ, must respond in quite different ways during pregnancy and parturition. On the one hand, it is essential that during most of pregnancy, the myometrium be dilatable but remain quiescent. On the other hand, the cervix must remain unyielding and reasonably rigid. Coincident with the initiation of parturition, however, the cervix must soften, yield, and become more readily dilatable. The fundus must be transformed from the relatively relaxed, unresponsive organ characteristic of most of pregnancy to one that will produce effective contractions that drive the fetus through the yielding (dilatable) cervix and on through the birth canal. Failure of a coordinated interaction between the functions of fundus and cervix portends an unfavorable pregnancy outcome. But despite the apparent reversal of roles between cervix and fundus from before to during labor, it is likely that the processes in both portions of the uterus are regulated by common agents.

COMPOSITION OF THE CERVIX. There are three principal structural components of the cervix: collagen, smooth muscle, and the connective tissue or ground substance. Constituents of the cervix important in cervical modifications at parturition are those in the extracellular matrix and ground substance, the glycosaminoglycans, dermatan sulfate and hyaluronic acid. The smooth muscle content of cervix is much less than that of the fundus, and varies anatomically from 25 to only 6 percent.

CERVICAL SOFTENING. The cervical modifications of phase 1 of parturition principally involve changes that occur in collagen, connective tissue, and its ground substance. Cervical softening is associated with two complementary changes:

1. Collagen breakdown and rearrangement of the collagen fibers.
2. Alterations in the relative amounts of the various glycosaminoglycans.

Hyaluronic acid is associated with the capacity of a tissue to retain water. Near term, there is a striking increase in the relative amount of hyaluronic acid in cervix, with a concomitant decrease in dermatan sulfate. The role for smooth muscle in the cervical softening process is not clear, but may be more important than previously believed. [Rath and colleagues \(1998\)](#) and [Winkler and Rath \(1999\)](#) have addressed this possibility in some detail.

Prostaglandin E₂ and PGF_{2a} applied directly to the cervix induce the maturational changes of cervical softening, that is, modification of collagen and alterations in the relative concentration of the glycosaminoglycans. Prostaglandin suppositories, placed intravaginally adjacent to the cervix, are used clinically to effect cervical softening and used to facilitate the induction of labor ([Chap. 20, 470](#)). In some species, these events can be induced in response to a decline in the levels of progesterone. Yet other compounds may serve as active participants in the activation or orchestration of these coordinated events. Relaxin, for example, acts to effect cervical softening while maintaining the uterus in a quiescent state. If a relaxin-mediated process were operative in human pregnancy, it would represent a very early functional modification of phase 1, and thereby relaxin could be regarded as a participant in implementing uterine phase 1. But despite the enormous importance of cervical softening to the success of parturition, relatively little is known of the precise sequence (or regulation) of the biochemical processes involved.

UTERINE PHASE 2 OF PARTURITION. Phase 2 is synonymous with active labor, that is, the uterine contractions that bring about progressive cervical dilatation and delivery of the conceptus. Phase 2 of parturition is customarily divided into the three stages of labor described earlier in the chapter. The onset of labor is the transition from uterine phase 1 to phase 2 of parturition.

UTERINE PHASE 3 OF PARTURITION. Phase 3 encompasses the events of the puerperium—maternal recovery from childbirth, maternal contributions to infant survival, and the restoration of fertility in the parturient. Immediately after delivery of the conceptus, and for about an hour or so thereafter, the myometrium must be held in a state of rigid and persistent contraction/retraction, which effects compression of the large uterine vessels and thrombosis of their lumens. In this coordinated fashion, fatal postpartum hemorrhage is prevented.

During the early puerperium, a maternal-type behavior pattern develops and maternal-infant bonding begins. The onset of lactogenesis and milk let-down in maternal mammary glands also is, in an evolutionary sense, crucial to the bringing forth of young. Finally, involution of the uterus, which restores this organ to the nonpregnant state, and the reinstatement of ovulation must be accomplished in preparation for the next pregnancy. Four to six weeks usually are required for complete uterine involution; but the duration of phase 3 of parturition is dependent on the duration of breast feeding. Infertility usually persists so long as breast feeding is continued because of lactation (prolactin)-induced anovulation and amenorrhea ([Chap. 58, p. 1548](#)).

A FAIL-SAFE SYSTEM TO MAINTAIN UTERINE QUIESCENCE

The myometrial quiescence of phase 0 of parturition is so remarkable (and ordinarily so successful) that it probably is induced by multiple independent and cooperative biomolecular processes. Individually, some of these processes may be redundant, that is, pregnancy may continue in the absence of one or more processes that normally contribute to the fail-safe system of pregnancy maintenance.

OVERCOMING THE INHERENT PROPENSITY OF THE MYOMETRIUM TO CONTRACT. The phasic myometrial smooth muscle is, inherently, a contractile tissue: strips of myometrium from uteri of nonpregnant women placed in an isotonic water bath contract in a rhythmical fashion without added stimuli, even in the presence of prostaglandin synthase inhibitors ([Crankshaw and Dyal, 1994](#)). Therefore, it is difficult to comprehend how the uterus can be expanded to accommodate a 3500 g fetus, 1 L of amniotic fluid, and 800 g of placenta and fetal membranes without erupting into powerful contractions. The volume capacity of the uterine cavity increases by several orders of magnitude during pregnancy. The uterus increases in size from an organ of about 50 to 70 g to one that weighs more than 1000 g at term. Knowing the incredible force that will be generated during labor, it is amazing that the intrauterine burden of human pregnancy is tolerated with such functional myometrial equanimity.

THE PHYSIOLOGICAL INVESTMENTS IN PHASE 0 OF PARTURITION. The physiological investments that must be made to sustain uterine phase 0 are enormous. It is likely that all manner of biomolecular systems (neural, endocrine, paracrine, and autocrine), calling upon multiple cell-signaling processes, are implemented and coordinated to impose a state of relative uterine unresponsiveness. Moreover, a complementary fail-safe system that protects the uterus against agents that could perturb the tranquil state of phase 0 also must be in place.

The actions of estrogen and progesterone via intracellular receptors; myometrial cell plasma membrane receptor-mediated increases in cyclic adenosine monophosphate (cAMP); the generation of cyclic guanosine monophosphate (cGMP); and other systems (modifications in myometrial cell ion channels) may all be operative in phase 0 of human parturition. If this were the case, it also is possible that a defect (either naturally occurring or pharmacologically induced), however severe, in one component of this system might not necessarily preclude the successful maintenance of pregnancy to term ([Fig. 11-16](#)).

Redundant physiological processes in human pregnancy are well-known. For example, the formation of human placental lactogen (hPL), as well as placental growth-hormone variant, can be completely absent in an otherwise normal pregnancy ([Chap. 6, pp. 113, 115](#)). The near-complete absence of estrogen formation in human pregnancy caused by several different disorders does not preclude successful pregnancy and parturition. Even the administration of an antiprogesterin to near-term pregnant women does not cause the onset of labor.

STEROID HORMONE CONTRIBUTIONS TO PHASE 0 OF PARTURITION. There is a commonly held belief that estrogen causes myometrial contractions and that progesterone attenuates contractile responsiveness. Partly because of this belief, reference is frequently made to the importance of "estrogen:progesterone ratios" (in blood or tissues) to uterine contractility. Most likely this is an oversimplification and quite possibly an incorrect interpretation of the role of these two sex steroid hormones in myometrial function. The plasma levels of estrogen and progesterone in normal human pregnancy are enormous; both are in great excess in terms of the affinity constants for the estrogen and progesterone receptors. For this reason, it is difficult to comprehend how relatively subtle changes in the ratio of the concentrations of these two steroids could modulate physiological processes during human pregnancy. The teleological reason for such high levels of estrogen and progesterone in human pregnancy is not known.

ESTROGEN. Acting directly or indirectly, estrogen promotes a variety of myometrial changes that enhance the capacity of the myometrium to generate powerful contractile force: myometrial cell hypertrophy, myometrial cell contractile potential, uterotonin receptors, and cell-to-cell communicability ([Pepe and Albrecht, 1995](#)). Estrogen does not act directly, however, to cause myometrial contractions; rather, estrogen promotes the capacity for forceful and coordinated contractions. Progesterone (directly or indirectly) seems to impose (probably in concert with other systems) contractile unresponsiveness. For example, estrogen may act to increase gap junctions between myometrial cells and L-type Ca^{2+} channels; but these junctions and channels must be opened to facilitate contractions.

Most likely, estrogen and progesterone act in concert to contribute to the effectiveness of phase 0 of parturition. Estrogen acts in part by promoting progesterone responsiveness. In many responsive tissues, the estrogen receptor—acting via the estrogen response element of the progesterone receptor gene—induces the synthesis of progesterone receptors.

PROGESTERONE. It has been presumed for decades that progesterone action is essential for the successful maintenance of pregnancy. Regrettably, however, neither the biomolecular particulars of this, nor the role of other agents in promoting this tolerant uterine state are clearly defined. Because of its action in other mammalian species, however, it is presumed that progesterone acts to establish and maintain uterine phase 0 of parturition.

STEROID HORMONES AND MYOMETRIAL CELL-TO-CELL COMMUNICATION. Communication is established between myometrial cells by gap junctions that facilitate the passage of current (electrical or ionic coupling) or metabolites (metabolite coupling). Gap junctions are transcellular membrane channels comprised of **connexons**. This is a hexameric assemblage of a specific connexin (the gap junction protein) joined in mirror symmetry with another connexon in the plasma membrane of an adjacent cell ([Fig. 11-17](#)). These pairs of connexons establish a conduit for the exchange of small molecules (M_r less than 1000) and ions between cells. Importantly for myometrial contractile function, both cAMP and Ca^{2+} are transported via these channels. In heart and myometrium, connexin43 (M_r about 43 kd) is the principal gap junction protein. The physiological importance of optimal numbers (area) of functional permeable gap junctions between myometrial cells is believed to be the establishment of electrical synchrony in the myometrium, which effects coordination of contractions and thereby greater force during labor.

Estrogen treatment promotes myometrial gap junction formation in some animals by increasing connexin43 synthesis. The simultaneous administration of antiestrogens prevents this ([Burghardt and colleagues, 1984](#)). Progesterone treatment also negates the stimulatory effect of estrogen on the development of gap junctions in some animals. Conversely, progesterone antagonists lead to the premature development of gap junctions and preterm labor and delivery ([Chwalisz and colleagues, 1991](#)).

In myometrial tissue obtained from pregnant women before labor when the number of gap junctions is small, a spontaneous increase in the number of gap junctions occurs in vitro ([Hayashi and collaborators, 1985](#)). This is suggestive that the excised tissue is relieved from a pregnancy endocrine milieu that prevented gap junction development in vivo. [Chow and Lye \(1994\)](#) found that the level of connexin43 mRNA in human myometrial tissues increased between 37 to 40 weeks before labor and increased further after labor began. Despite that connexin43 protein decreased, gap junctions increased during late pregnancy and labor. They suggested that gap junctional area is regulated by the level of connexin43 mRNA and connexon assembly.

Modifications in gap junctional permeability have been demonstrated in a variety of systems in response to various hormones, neurotransmitters, Ca^{2+} , cAMP, and phorbol esters. In animals, [Cole and Garfield \(1986\)](#) found that adenylyl cyclase activators caused a decrease in the permeability of gap junctions. Similar results were obtained using strips of human myometrial tissues ([Sakai and co-workers, 1992](#)). These findings are suggestive that intercellular myometrial communication via gap junctions may be regulated by the level (synthesis/degradation) of connexin43, the assembly of connexons, and the permeability of the gap junctions produced. These processes appear to be regulated in part by estrogen and progesterone.

STEROID HORMONES AND OXYTOCIN RECEPTORS. Most studies to evaluate the regulation of myometrial oxytocin receptor synthesis have been performed in the rat. Estradiol-17 β treatment either in vivo or in myometrial explants causes an increase in myometrial oxytocin receptors. This action of estradiol-17 β is prevented by simultaneous treatment with progesterone ([Fuchs and colleagues, 1983](#)). Progesterone also may act to increase oxytocin receptor degradation ([Soloff and colleagues, 1983](#)). Estradiol-17 β treatment of sheep uterine tissue in vitro does not cause an increase in oxytocin receptors, but oxytocin and progesterone treatment lowers the level of these receptors ([Sheldrick and Flick-Smith, 1993](#)).

The human oxytocin receptor gene is a single-copy gene on chromosome 3 p26.2. An estrogen response element is not present in this gene. The level of oxytocin receptor mRNA in human myometrium tissues obtained at term is greater than that in uterine tissues of nonpregnant women. Thus, the increase in oxytocin receptor number in myometrium at term may be attributable to increased oxytocin gene transcription ([Fuchs and associates, 1982](#)).

Oxytocin receptors also are present in human endometrium and in decidua at term and these stimulate prostaglandin production ([Fuchs and associates, 1981](#)). Oxytocin receptors also are present in amnion and chorion-decidual tissues ([Benedetto and associates, 1990](#)).

ABSENCE OF PROGESTERONE WITHDRAWAL BEFORE INITIATION OF PARTURITION IN PRIMATE PREGNANCY. Plasma progesterone levels do not decrease before labor in primates ([Challis and Lye, 1994](#)). Plasma levels decline only after delivery of the placenta. Nonetheless, the morphological and functional modifications that prepare the human uterus for labor occur in a timely manner in human pregnancy just as in those species in which progesterone withdrawal is a clearly demonstrable endocrine antecedent of parturition.

A successful human pregnancy has been observed in which the levels of progesterone in maternal plasma were low, particularly so early in pregnancy. Steroid hormone formation was evaluated in a woman homozygous for abetalipoproteinemia, a form of familial hypercholesterolemia caused by a defect in low-density lipoprotein (LDL) apoprotein synthesis ([Parker and associates, 1986](#)). Progesterone synthesis in the human corpus luteum is absolutely dependent upon the use of plasma LDL² cholesterol. Most of progesterone synthesis in human placenta also is accomplished by the uptake and use of maternal plasma LDL, but limited cholesterol synthesis in syncytiotrophoblast is possible ([Chap. 6](#)). LDL is not available for uptake and use by steroidogenic tissues in persons with abetalipoproteinemia. Consequently, after spontaneous ovulation, there was no detectable progesterone in blood of the woman described, but the levels of estradiol-17 β during the postovulatory phase, after the luteinizing hormone surge, were normal. This woman conceived, and her pregnancy progressed to term despite low levels of plasma progesterone, especially in early pregnancy.

PROGESTERONE ADMINISTRATION AND HUMAN PARTURITION. Progesterone administration to pregnant women does not delay the timely onset of parturition or arrest or prevent preterm labor. These findings are indicative that some "hidden" or unique form of progesterone deprivation is not the cause of the suspension of uterine phase 0 processes in human parturition. These observations, however, do not preclude the possibility that some progesterone actions are inhibited by a progesterone receptor-independent, selective antiprogesterin-like mechanism during the initiation of parturition.

PROGESTERONE RECEPTOR ANTAGONISTS AND HUMAN PARTURITION. The steroidal antiprogesterin RU-486 (mifepristone), administered to women during the latter phase of the ovarian cycle, induces menstruation prematurely and is quite effective in the induction of abortion during the first few weeks of human pregnancy. This compound is a classical steroid antagonist, acting at the level of the progesterone receptor. RU-486, however, is progressively less effective in inducing abortion or labor in women as pregnancy advances. Treatment of women near term with RU-486 may facilitate the induction of labor by oxytocin but is largely ineffective in independently causing labor ([Frydman and colleagues, 1988](#)). This is in contrast to the premature induction of labor by RU-486 in those species that normally experience progesterone withdrawal before labor.

PROGESTERONE AND UTERINE PHASE 0 OF PARTURITION: CONCLUSIONS. Based upon these several observations, an obligatory role for progesterone in the

maintenance of human pregnancy can be neither established nor refuted. It seems most likely that the actions of estrogen and progesterone are involved as components of a broader-based fail-safe biomolecular system that implements and maintains phase 0 of human parturition.

CONTRIBUTION OF PLASMA MEMBRANE-MEDIATED MYOMETRIAL CELL-SIGNALING SYSTEMS TO PARTURITIONAL PROCESSES. In addition to intracellular receptor proteins, such as those that mediate the action of sex steroid hormones, myometrial cell signaling also is propagated by plasma membrane-associated receptors. There are three known classes of cell-surface receptors: G-protein linked, ion channel linked, and enzyme linked. Multiple examples of each class of these plasma membrane receptors have been identified in human myometrium, and all three of these cell membrane signaling mechanisms appear to be modified during phase 0 of parturition.

More than 100 heptahelical plasma membrane G-protein-linked receptors have been identified and characterized in the myometrium of pregnant and nonpregnant women. The ligands for the heptahelical receptors are neuropeptides, hormones, and autacoids. Some of these ligands are available to the myometrium during pregnancy in high concentration by several routes—from maternal blood (endocrine), contiguous tissues or adjacent cells (paracrine), or direct synthesis in the myometrial smooth muscle cells (autocrine) (Fig. 11-16). Most of these heptahelical receptors are associated with the activation of adenylyl cyclase. Other heptahelical receptors in myometrium, however, are more commonly associated with G-protein-mediated activation of phospholipase C.

THE G-PROTEINS. These guanine-binding proteins are heterotrimers composed of an alpha (α), beta (β), and gamma (γ) chain. The α -subunit binds GDP (guanine diphosphate) or GTP (guanine triphosphate) with high affinity. The active form (Ga-GTP) regulates effector proteins, namely plasma membrane-bound enzymes such as adenylyl cyclase and phospholipase C, and selected ion channels. Indeed, the hydrolysis of GTP to GDP serves as a "molecular switch" to regulate the activity of the G-protein (Linder and Gilman, 1992). Ga-subunits are classified into four major subfamilies Ga_s (stimulate adenylyl cyclase), Ga_i (inhibits adenylyl cyclase), Ga_q (activates phospholipase C), and Ga₁₂ (regulate Na⁺/K⁺ exchange).

G-PROTEIN SIGNAL TRANSMISSION. The G-proteins are versatile, seemingly capable of more than one type of signal generation even by way of a single heptahelical receptor in the same cell. Consequently, there are multiple metabolic points that serve as regulatory intercepts. The heptahelical receptor-G-protein-effector phenotype of a cell is distinguished by:

1. Its complement of heptahelical receptors.
2. The α -, β -, and γ -subunits.
3. The G-protein-modulated effectors that a given cell expresses.

These phenotypic characteristics of a cell, however, can be modified during development or by metabolic/endocrine processes. It is conceivable, therefore, that the heptahelical receptor-G-protein-effector phenotype of myometrial smooth muscle may be an important determinant of the functional status of the myometrium, that is, the imposition of quiescence (activation of adenylyl cyclase) or the facilitation of contractions (activation of phospholipase C and increased [Ca²⁺]).

Many G-protein-coupled receptors that participate in regulation of myometrial activity have been cloned. These were reviewed recently by Lopez Bernal and TambyRaja (2000).

HEPTAHHELICAL RECEPTORS IN MYOMETRIUM THAT MEDIATE cAMP FORMATION

A number of heptahelical receptors that nominally are associated with Gas-mediated activation of adenylyl cyclase and increased levels of cAMP are present in myometrium. These receptors together with appropriate ligands may act (in concert with sex steroid hormones) as part of a fail-safe system to maintain uterine quiescence, phase 0 of parturition (Price and associates, 2000; Sanborn and colleagues, 1998).

β -ADRENORECEPTORS AND PHASE 0 OF PARTURITION. In studies of adenylyl cyclase and G-protein-linked receptor-mediated processes in the myometrium, the β -adrenergic adrenoreceptors have served as prototypes. Most commonly, the β -adrenergic receptors mediate Ga_s-stimulated increases in adenylyl cyclase, increased levels of cAMP, and myometrial cell relaxation. The rate-limiting factor in the β -receptor system is likely the number of adenylyl cyclase enzyme units or the number of receptors. The number of G-proteins in most systems far exceeds the number of receptors and effector molecules. The role of β -adrenoreceptors in maintaining uterine quiescence in vivo, however, is difficult to evaluate.

LH/hCG RECEPTORS. The heptahelical receptor for LH/hCG has been demonstrated in a number of extragonadal tissues, including myometrial smooth muscle and blood vessels (Lei and co-workers, 1992; Ziecik and colleagues, 1992). Initially, their identification seemed quite aberrant considering the more commonly recognized tissue localization in the ovary and testis. The levels of the LH/hCG receptor in myometrium during pregnancy are greater before than during labor (Zuo and colleagues, 1994). Chorionic gonadotropin acts to activate adenylyl cyclase by way of a plasma membrane receptor-Ga_s-linked system. This causes a decrease in contraction frequency and force and a decrease in tissue-specific myometrial cell gap junctions (Ambrus and Rao, 1994; Eta and co-workers, 1994).

RELAXIN. This peptide hormone is a member of the insulin-like growth factor family of proteins, consisting of an A and B chain (Bogic and associates, 1995; Weiss, 1995). There are two separate human relaxin genes, designated H1 and H2. Relaxin in plasma of pregnant women is believed to originate exclusively by secretion from the corpus luteum. Plasma levels of relaxin are greatest (about 1 ng/mL) at between 8 and 12 weeks, and thereafter decline to lower levels that persist until term. The plasma membrane receptor for relaxin mediates the activation of adenylyl cyclase and promotes myometrial relaxation, but also cervical softening. Consequently, it has not been possible to envision a clear-cut role for this hormone in human parturition.

CORTICOTROPIN-RELEASING HORMONE (CRH³). This heptahelical receptor is present in myometrium during pregnancy. There are multiple isoforms of the receptor in myometrium, and their affinity is modified late in pregnancy (Grammatopoulos and associates, 1994, 1995; Hillhouse and colleagues, 1993). CRH⁴ is synthesized in the placenta, amnion, decidua, and myometrium. As discussed in Chapter 6 (p. 115), plasma levels of CRH increase during early pregnancy, but during the final 6 to 8 weeks of normal pregnancy, they increase in dramatic fashion. Because of this, several investigators have suggested that CRH is involved in the initiation of human parturition. It is not immediately apparent, however, how CRH-induced parturition would come about because CRH acts to increase cAMP formation and it would be expected to promote myometrial smooth muscle relaxation (Jaffe, 1998).

PARATHYROID HORMONE-RELATED PROTEIN (PTH-rP). The PTH/PTH-rP⁵ receptor is a plasma membrane heptahelical receptor. Most often this receptor initiates Ga_s-mediated activation of adenylyl cyclase. PTH-rP is expressed in myometrium, decidua, amnion, and trophoblast. Estrogen and TGF- β treatment of human myometrial cells causes an increase in the levels of PTH-rP mRNA (Casey and associates, 1992; Paspaliaris and associates, 1995). PTH-rP expression in smooth muscle (including uterus) is also increased by stretching (Daifotis and associates, 1992; Yamamoto and colleagues, 1992). Whereas the function of PTH-rP in uterine physiology is not established, it may serve to maximize uterine blood flow during myometrial contractions by its vasorelaxant action (Thiede and colleagues, 1991a, 1991b). PTH-rP also may act on myometrial smooth muscle to facilitate the maintenance of uterine tranquility.

PROSTAGLANDINS. A number of prostaglandin receptors and subtypes, which belong to the large family of heptahelical plasma membrane G-protein-linked proteins, have been identified (Coleman and associates, 1994). The prostaglandin family of receptors is classified according to the specificity of binding of a given receptor to a particular prostaglandin. The receptors (and naturally occurring, preferred ligands) are TP (thromboxane A₂), DP (PGD₂), IP (PGI₂), FP (PGF_{2a}), and EP (PGE₂).

PROSTAGLANDINS AND MYOMETRIAL RELAXATION. While prostaglandins most commonly have been considered as uterotonins, selected prostanoids are sometimes primarily muscle relaxants. Specifically, PGE₂, PGD₂, and PGI₂ cause relaxation of vascular smooth muscle and vasodilatation in many circumstances. Modifications in the relative expression of the various prostaglandin receptors in myometrium at various stages of gestation may account in part for many varied responses of human myometrial tissues to prostaglandins. For example, Breuiller and co-workers (1991) found that prostanoids stimulated adenylyl cyclase activity in myometrium obtained at 32 to 35 weeks, but not in tissue obtained at 39 to 40 weeks.

Yet another variable is caused by the lack of specificity of prostanoids via different receptors. For example, PGE₂ at low concentrations acts to stimulate Ga_s-induced adenylyl cyclase and smooth muscle relaxation. At higher concentrations, PGE₂ may act via Ga_i or Ga_q to inhibit adenylyl cyclase or activate phospholipase C, thereby causing increased myometrial contractions.

Therefore the net action of prostanoids is highly dependent upon multiple factors. It is entirely possible that prostanoids contribute to myometrial relaxation at one stage of pregnancy and to myometrial contractions after the initiation of parturition ([Crankshaw and Dyal, 1994](#)).

CYCLIC GMP (cGMP) IN MYOMETRIUM AND MYOMETRIAL RELAXATION. The activation of guanylyl cyclase gives rise to increased intracellular levels of cGMP, which also promotes smooth muscle relaxation ([Word and colleagues, 1993](#)).

ATRIAL/BRAIN NATRIURETIC PEPTIDES. Two forms of atrial natriuretic peptide (ANP)/brain natriuretic peptide (BNP) receptors are present in the myometrium during human pregnancy ([Itoh and co-workers, 1994](#)). These receptors express guanylyl cyclase activity and mediate an increase in the cellular levels of cGMP. Specifically, the ANP⁶/BNP⁷ receptor molecule is a guanylyl cyclase. BNP is secreted by amnion in large amounts ([Itoh and associates, 1993](#)), and ANP is expressed in placenta ([Lim and Gude, 1995](#)).

NITRIC OXIDE SYNTHESIS AND cGMP. The soluble form of guanylyl cyclase is activated by nitric oxide, which because of its very hydrophobic nature, readily penetrates the plasma membrane to enter cells. Nitric oxide reacts with iron in the active site of the soluble guanylyl cyclase enzyme, stimulating it to produce cGMP. Nitric oxide acts to cause myometrial relaxation ([Izumi and colleagues, 1993](#)). Nitric oxide is synthesized in decidua, myometrial blood vessels, and nerves ([Yallampalli and colleagues, 1994a, 1994b](#)). Whether nitric oxide gains access to the myometrium and how the synthesis and action of nitric oxide is regulated as it pertains to a potential contribution to uterine quiescence is not understood.

ACCELERATED UTEROTONIN DEGRADATION AND PHASE 0 OF PARTURITION

In addition to pregnancy-induced compounds that stimulate myometrial cell refractoriness during phase 0, there are striking increases in the activities of enzymes that degrade or inactivate endogenously produced uterotonins. Some of these include prostaglandins—prostaglandin dehydrogenase (PGDH); endothelins—enkephalinase; oxytocin—oxytocinase; histamine—diamine oxidase; catecholamines—catechol-O-methyl transferase; angiotensin-II—angiotensinase(s); and, platelet-activating factor (PAF)—PAF⁸-acetylhydrolase. The activities of several of these enzymes are increased by progesterone action ([Bates and co-workers, 1979](#); [Casey and associates, 1980, 1991](#); [Germain and colleagues, 1994](#); [Yasuda and Johnston, 1992](#)).

A FAIL-SAFE SYSTEM TO ENSURE THE SUCCESS OF PHASE 2 OF PARTURITION

UTEROTONIN THEORIES OF THE INITIATION OF PARTURITION. In part because progesterone withdrawal does not precede the initiation of parturition in human pregnancy, many researchers began to investigate the possibility that an increase in the formation of a uterotonin is the most likely cause of the initiation of parturition. Once phase 0 is suspended and uterine phase 1 processes are implemented, a number of uterotonins may be important to the success of phase 2, active labor. Just as multiple processes may contribute to the maintenance of the myometrial unresponsiveness of phase 0 of parturition, other processes may contribute jointly to a system to ensure the success of labor. Many uterotonins known to cause myometrial contractions of smooth muscle in vitro have been proposed: oxytocin, prostaglandins, serotonin, histamine, platelet-activating factor (PAF⁸), angiotensin II, and many others. As opposed to the receptor-mediated G_s-adenylyl cyclase-linked systems of myometrium that may promote the accumulation of cAMP, other heptahelical receptors have been identified in human myometrium that more commonly activate G_i- or G_q-mediated processes that eventuate in increased myometrial cell [Ca²⁺]_i.

MYOMETRIAL HEPTAHHELICAL RECEPTORS AND PHASE 2 OF PARTURITION OXYTOCIN AND PHASE 2 OF PARTURITION. Oxytocin means quick birth; and, oxytocin was the first uterotonin to be implicated in the initiation of parturition. In 1906, Sir Henry Dale discovered uterotonic bioactivity in extracts of the posterior pituitary gland. By 1909, the uterotonic property of these extracts was confirmed, and by 1911, they were in use in clinical obstetrics. In 1950, Pierce and Du Vigneaud determined the structure of oxytocin, the uterotonic agent of the posterior pituitary.

Oxytocin does not appear to cause the initiation of parturition. Once phase 1 of parturition is in place, however, oxytocin may be one of several participants in ensuring the effectiveness of active labor. In experimental animals, oxytocin acts by way of a heptahelical receptor which likely activates phospholipase ([Ku and colleagues, 1995](#)). Oxytocin appears to be a very important hormone of phase 3 of parturition.

BIOLOGY AND CHEMISTRY. Oxytocin is a nanopeptide synthesized in the magnocellular neurons of the supraoptic and paraventricular neurons. The oxytocin prohormone is transported together with the carrier protein **neurophysin**, along the axons to the neural lobe of the posterior pituitary gland in membrane-bound vesicles for storage and later release. Oxytocin prohormone is converted enzymatically to oxytocin during transport ([Gainer and colleagues, 1988](#); [Leake, 1990](#)).

IS OXYTOCIN INVOLVED IN THE INITIATION OF HUMAN PARTURITION? There is a long history of the safe and successful induction of labor by oxytocin administration to near-term pregnant women. It was straightforward, therefore, to hypothesize that oxytocin was involved, physiologically, in the spontaneous initiation of parturition. Several lines of evidence were supportive of this premise. The effectiveness of oxytocin in inducing labor at term, the great potency of this uterotonin, and its natural occurrence in humans were sufficient reasons for suspecting that oxytocin might be involved in the initiation of parturition. More recent discoveries provide additional support for this theory:

1. There is a striking increase in the number of oxytocin receptors in myometrial and decidual tissues near the end of gestation.
2. Oxytocin acts upon endometrial (decidual) tissue to promote the release of prostaglandins.
3. Oxytocin is synthesized directly in decidual and extraembryonic fetal tissues or in the placenta ([Chibbar and associates, 1993](#); [Zingg and colleagues, 1995](#)).

The synthesis of oxytocin in the "uterus," however, is apparently confined to the endometrium and has not been demonstrated in the myometrium. This is an important distinction that is not emphasized in reports or reviews on the tissue site(s) of origin of oxytocin.

There is evidence of increased fetal oxytocin secretion during human labor. Oxytocin levels are higher in umbilical arterial than venous plasma and higher after spontaneous labor than before parturition begins. There is no evidence, however, that oxytocin can escape placental degradation and enter the maternal circulation ([Leake, 1990](#)).

All of the evidence, examined critically, does not favor a role for oxytocin in the initiation of parturition. The levels of oxytocin in maternal blood do not increase before or during labor, at least not until the second stage of labor. While there is a striking increase in the concentration of oxytocin receptors in myometrium late in pregnancy, this occurs for some time before labor begins. Moreover, oxytocin does not act as an antiprogesterin. There is no evidence that oxytocin is involved in the transition to phase 1 of parturition, specifically, it does not induce gap junction formation between myometrial cells, nor does it induce the synthesis of oxytocin receptors. Indeed, the infusion of oxytocin, even in relatively large amounts, is relatively ineffective in inducing labor in most human pregnancies except those near term.

OXYTOCIN AS THE PUERPERAL HORMONE OF PARTURITION. There is a large body of evidence in support of an important role for oxytocin during the second stage of labor and during the puerperium, phase 3 of parturition. There are increased maternal plasma levels of oxytocin during the second stage of labor (the end of phase 2 of parturition), in the early postpartum period, and during breast feeding (phase 3 of parturition) ([Nissen and co-workers, 1995](#)). This timing of increased oxytocin release is indicative of a role for oxytocin at the end of labor and during the puerperium.

Immediately after delivery of the fetus, placenta, and fetal membranes (completion of uterine phase 2), firm and persistent contraction and retraction of the uterus are essential for the prevention of postpartum uterine hemorrhage. Oxytocin likely causes persistent contraction of the uterus. Certainly, the levels of oxytocin in maternal plasma are increased at this time, and the increase in myometrial oxytocin receptors before the onset of labor favors this process.

UTERINE INVOLUTION. Oxytocin infusion in women promotes increased levels of mRNAs in myometrium of genes that encode proteins essential for uterine involution. These include interstitial collagenase, monocyte chemoattractant protein-1, interleukin-8 (IL-8), and urokinase plasminogen activator receptor (MacDonald and Casey, unpublished observations). Therefore, oxytocin action at the end of labor and during phase 3 of parturition may be involved in uterine involution.

OXYTOCIN AND MILK LET-DOWN. The oxytocin receptor population of the myoepithelial cells of the ducts of mammary tissue are increased in a fashion similar to that in the myometrial smooth muscle cells late in pregnancy. During the puerperium, oxytocin acts on these breast duct cells to effect milk let-down, a component of phase 3 of parturition.

PROSTAGLANDINS AND PHASE 2 OF PARTURITION. Many investigators have accepted and fostered the view that prostaglandins, particularly PGF_{2a} and PGE_2 , are involved in the initiation of parturition at term. Several lines of evidence are supportive of this theory. First, the levels of prostaglandins (or their metabolites) in amniotic fluid, maternal plasma, and maternal urine are increased during labor (Keirse, 1979). Second, the treatment of pregnant women with prostaglandins, by any of several routes of administration, causes abortion or labor at all stages of gestation (Novy and Liggins, 1980). Third, it is commonly believed, although not rigorously established (Keirse, 1990), that the administration of PGH_2 synthase inhibitors to pregnant women will delay the time of onset of induced abortion or spontaneous labor and sometimes arrest preterm labor (Besinger and Neibyl, 1990). Fourth, prostaglandin treatment of myometrial smooth muscle tissues in vitro sometimes causes contraction, dependent upon the prostanoid tested and the physiological status of the tissue treated.

EVIDENCE AGAINST PROSTAGLANDIN INVOLVEMENT. The findings of more recent studies have cast doubt on the preeminent role of autacoids in the initiation of parturition, either at term or preterm. As in the case of oxytocin, however, prostaglandins produced directly in myometrial tissue may contribute to the effectiveness of myometrial contractions of phase 2 (active labor) once parturition is initiated.

PROSTAGLANDINS IN AMNIONIC FLUID BEFORE LABOR. Prostaglandins, primarily PGE_2 (but also PGF_{2a}), are detected in amniotic fluid at all stages of gestation. Before labor begins, prostanoids in amniotic fluid originate by excretion in fetal urine and possibly skin, lungs, and umbilical cord (Casey and co-workers, 1983). As the fetus grows, the levels of prostaglandins in amniotic fluid increase gradually. There is, however, no increase in the levels of prostaglandins that can be related to or interpreted as a preparturition-related increase. In fact, the total amount of prostaglandins in amniotic fluid at term before labor begins (about 1 ug) is miniscule. Because the half-life of prostaglandins in amniotic fluid is very long (6 to 12 hours), the rate of entry of prostaglandins into amniotic fluid therefore is small.

PROSTAGLANDIN LEVELS IN AMNIONIC FLUID DURING LABOR. The relationship between increased levels of prostaglandins in amniotic fluid and the initiation of parturition stood largely unquestioned for almost 30 years. It is now known, however, that the data in support of this relationship were misleading because prostaglandins that enter amniotic fluid at parturition are produced after labor begins (MacDonald and Casey, 1993, 1996).

THE FOREBAG OF THE AMNIONIC SAC. To understand the experimental pitfalls in the evaluation of prostaglandins (and other mediators of inflammation) in amniotic fluid at parturition, the anatomical changes involving the fetal membranes during cervical dilatation must be envisioned. The lowermost pole of the fetal membranes is structurally modified in the formation of the forebag of the amniotic sac. Before labor, the fetal membranes are contiguous with and attached to the uterine decidua parietalis, which in the lower uterine segment of the uterus is thin and poorly developed. The slightest movement of the underlying uterine muscle during contractions causes the fetal membranes to be pulled away from and then to slip back and forth over the decidua. As the lower pole of the amniotic sac is pulled away from the wall of the uterus, fragments of decidua parietalis are torn away but remain attached rather firmly to the outer surface of the chorion laeve (Fig. 11-18).

This normal phenomenon of early labor is complementary to successful cervical dilatation. Membranes that slide readily over the lower uterine segment and partly through the cervix are much more efficacious dilators. Provided the membranes are intact, the lower pole of the membranes, the forebag, becomes the leading wedge that facilitates cervical dilatation during early labor. This is the case prior to the time when the fetal presenting part has descended far enough into the maternal pelvis to assume this role (Figs. 11-8, Figs. 11-9 and 11-10). Because the forebag is formed by the process of cervical effacement and dilatation, it comes into existence only after labor has begun—or with abnormal cervical dilatation or incompetence.

As the cervix is opened, the forebag presents through the cervix in the upper vagina, like the tip of a fluid-filled balloon under pressure being pushed through the enlarging diameter of a hollow cylinder. The surface area of the exposed forebag increases as cervical dilatation progresses during phase 2 of parturition. The innermost tissue of the forebag is the avascular amnion, which is bathed by the amniotic fluid on its epithelial surface. The outer surface of the amnion is adherent to the avascular chorion laeve. The traumatized, devascularized decidual tissue fragments that are torn away from the uterus form an irregular lining on the outer surface of the forebag, which presents in the vagina (Fig. 11-18).

Thereafter, the forebag tissues are bathed continuously by the vaginal fluid, which in all women (pregnant and nonpregnant) contains a large number and variety of microorganisms, bacterial toxins in large amounts, and prostaglandins and cytokines (Cox and associates, 1993b). Because of (1) trauma to decidual tissues in the formation of the forebag, (2) devascularization of the decidual fragments that are pulled away from the uterus, and (3) the action of the constituents of the vaginal fluids on these tissues, an inflammatory response in the decidual fragments of the forebag is obliged and readily demonstrable. The levels of pro-IL-1 β mRNA in forebag decidua are much greater than those in decidua parietalis from the chorion laeve of the amniotic sac of the upper compartment during labor (MacDonald and associates, 1991). The forebag tissues secrete prostaglandin F_{2a} and cytokines IL-1 β and IL-6 directly into the vagina. The quantity of the inflammatory mediators produced in forebag is large, but highly variable, dependent on the volume of decidual tissue that remains attached to the forebag (Cox and associates, 1993b). The prostaglandins synthesized in forebag tissues enter both the vagina and the forebag amniotic fluid (Fig. 11-19).

Recent findings of Rath and colleagues (1998) and Winkler and Rath (1999) are supportive of the possibility that inflammatory mediators facilitate cervical dilatation. Products of extracellular matrix degradation, such as hyaluronic acid, induce the expression of IL-1 and tumor necrosis factor- α (TNF- α). In response to these cytokines, other prostaglandins and IL-6 and IL-8⁹ induce further degradation of the extracellular matrix. It can be envisioned that these processes may effect the relatively rapid changes in the cervix that are characteristic of the parturitional process.

PROSTAGLANDINS IN AMNIONIC FLUID BEFORE AND DURING LABOR AT TERM. To obviate anatomical sampling errors, amniotic fluid samples must be collected during labor either from the forebag compartment by direct needle aspiration or from the upper compartment either by transuterine amniocentesis at cesarean delivery conducted during labor. MacDonald and Casey (1993, 1996) used these techniques, and the levels of PGE_2 , PGF_{2a} , and PGFM in these amniotic fluids were determined. The data for amniotic fluids of both compartments and the levels of these autacoids as a function of cervical dilatation are shown in Figures 11-20 and 11-21. The concentrations of PGF_{2a} , PGFM, and PGE_2 in the upper compartment of amniotic fluid early in labor (2.5 cm or less cervical dilatation) were no greater than those in amniotic fluid before labor began. The levels of prostaglandins in amniotic fluids obtained from the forebag during labor (collections commencing at 3 cm) were much greater than those in amniotic fluid before labor. Moreover, the levels and total content of PGF_{2a} in amniotic fluid of the forebag increased as cervical dilatation progressed.

Most importantly, the levels of prostaglandins in forebag amniotic fluid were much greater than those in the upper compartment at all stages of labor progress examined. The levels of prostaglandins in amniotic fluid of the upper compartment at 3 to 5 cm were significantly greater than those in amniotic fluid before labor began. Thereafter (5.5 to 7 cm), there was no further increase in the prostaglandin concentration in amniotic fluids of the upper compartment. As discussed in Chapter 19, cervical dilatation of 3 to 5 cm commonly is an important milestone in the progress of labor. At about this stage of labor progress, the presenting part of the fetus commonly has been engaged in the maternal pelvis, separating the amniotic fluid anatomically and functionally into two compartments. Before complete separation of the two compartments, constituents of the forebag amniotic fluid can mix with those in the upper compartment; but after complete separation of the amniotic fluid, the transfer of prostaglandins from the forebag to the upper compartment is attenuated or precluded.

The findings of this study also are indicative that the decidua parietalis lining the forebag is the principal site of formation of prostaglandins that enter forebag amniotic fluid. Specifically, PGF_{2a} and its stable metabolite, PGFM, are present in the forebag amniotic fluid in much greater quantities than PGE_2 . The decidua produces both PGF_{2a} and PGE_2 , but amnion and chorion laeve produce primarily PGE_2 and very little PGF_{2a} .

Thus, there are multiple lines of evidence that an increase in the levels of prostaglandins in amniotic fluid is not indicative of a role for these agents in the initiation of parturition.

1. There is no parturition-related increase in the levels of prostaglandins in amniotic fluid before labor begins.
2. The total amount of prostaglandins in amniotic fluid and the rate of entry of these autacoids into amniotic fluid before and during labor is miniscule compared with the amount required to induce labor.
3. The levels of prostaglandins in amniotic fluids obtained at the same stage of labor progress vary enormously (by 100-fold or more) among normal pregnancies (Fig. 11-22).
4. The concentrations of prostaglandins in the forebag compartment are correlated with the extent of cervical dilatation.
5. Prostaglandins are secreted at a brisk rate from the forebag into the vagina during labor.

While indeed these processes involved in parturition at term are similar to those of an inflammatory reaction, it is very unlikely that inflammatory processes initiate parturition. Rather, it is clear that the normal processes of labor beget inflammation, which includes increased prostaglandin synthesis.

INHIBITION OF PROSTAGLANDIN SYNTHESIS AND LABOR/INHIBITION OF PROSTAGLANDIN SYNTHESIS AND DELAYED ABORTION-INDUCTION TIME. Pretreatment of women with indomethacin, a prostaglandin synthase inhibitor, causes a delay in the abortion-induction time after intra-amniotic instillation of hypertonic solutions during the midtrimester of pregnancy. This observation also has been cited as evidence for the involvement of prostaglandins in the initiation of parturition. A meaningful interpretation of these findings of delayed abortion-induction time by prostaglandin synthase inhibitors is, realistically, not possible because of the extremely large number of variables involved in such studies. Obviously, the entry of a hypertonic solution into the amniotic fluid is not a physiological feature of spontaneous parturition. Moreover, the maintenance of pregnancy at 12 to 16 weeks' gestation is not identical with that during the third trimester. For example, the administration of antiprogesterins will effect abortion during early pregnancy, but the efficacy of these agents in promoting abortion or labor declines as pregnancy progresses. Near term, RU-486 treatment will not cause the onset of labor in human pregnancy. In addition, the effect of indomethacin and hypertonic solutions on the fetus may be important determinants of the outcome of such pregnancies.

INHIBITION OF PROSTAGLANDIN SYNTHESIS AND DELAYED PARTURITION AT TERM. There are few data to support the contention that the inhibition of prostaglandin synthesis delays the onset of parturition in human pregnancies at term. There are no properly conducted control studies to permit a definitive judgment concerning this possible relationship.

INHIBITION OF PROSTAGLANDIN SYNTHESIS AND PRETERM LABOR. Rigorous testing of the proposition that inhibitors of prostaglandin synthesis will prevent or arrest preterm labor has also not been conducted (Keirse, 1990). Fear of adverse effects on the fetus has prevented most investigators from conducting such studies. In monkeys, Sadowsky and colleagues (2000) showed that indomethacin blocked IL-1 β -induced PGF_{2a} amniotic fluid levels.

PROSTAGLANDINS AND PHASE 2 OF PARTURITION: SUMMARY. The evidence in favor of a role for prostaglandins in the initiation of parturition is fragile. It is quite possible, perhaps probable, that prostaglandins and other uterotonins, such as oxytocin, are involved in the success of phase 2 of parturition after phase 0 is suspended and phase 1 processes are implemented. It is reasonable to surmise that a fail-safe system is operative to promote phase 2 of parturition, just as there probably is a fail-safe system that ensures the success of phase 0.

PLATELET-ACTIVATING FACTOR AND PHASE 2 OF PARTURITION. The platelet-activating factor (PAF⁸) receptor also is a member of the heptahelical family of transmembrane receptors and acts to increase myometrial cell [Ca²⁺]_i and promote uterine contractions. The levels of PAF in amniotic fluid are increased during labor (Billah and colleagues, 1983; Nishihara and associates, 1984); and PAF treatment of myometrial tissue promotes contraction (Zhu and colleagues, 1992). It is likely that PAF, like prostaglandins, cytokines, and endothelin-1, is produced in leukocytes as a result of the inflammatory process that is obliged when cervical dilation brings about exposure of the traumatized forebag tissues to the vaginal fluids.

The transport of PAF⁸ from amniotic fluid to myometrium is uncertain but unlikely. PAF is inactivated enzymatically by PAF-acetylhydrolase; this enzyme is present in high specific activity in macrophages (Prescott and associates, 1990), which are present in large numbers in decidua. Thus, the myometrium may be protected from PAF action by PAF-acetylhydrolase in a manner similar to that for uterotonins: oxytocin and oxytocinase, endothelin-1 and enkephalinase, and prostaglandins and prostaglandin dehydrogenase.

ENDOTHELIN-1 AND PHASE 2 OF PARTURITION. The endothelins are very powerful inducers of myometrial smooth muscle contraction and endothelin receptors are demonstrable in myometrial tissue (Word and colleagues, 1990). The endothelin A receptor, preferentially expressed in smooth muscle cells, including the myometrium, acts to effect an increase in [Ca²⁺]_i, apparently by linkage to both G_q- and G₁₂-subunits of the G-proteins. Endothelin-1 is produced in myometrium, but the exact cellular site of synthesis is not clearly established and the potential contribution of myometrial endothelin-1 to phase 2 of parturition is not defined.

Endothelin-1 is also synthesized in amnion. Like other uterotonins synthesized in amnion, it is unlikely that endothelin-1 can be transported from reflected amnion (or amniotic fluid), without degradation, to the myometrium (Eis and colleagues, 1992). One obstacle to endothelin-1 transport across the fetal membranes is the enzyme enkephalinase (membrane metalloendopeptidase), which is present in chorion laeve in high specific activity (Germain and associates, 1994). Enkephalinase catalyzes the degradation of endothelin-1 as well as several other small, bioactive peptides (e.g., the enkephalins, substance P, and atrial and brain natriuretic peptides).

MAST CELLS PRODUCTS AND PHASE 2 OF PARTURITION. The concentration of mast cells in the myometrium is very high and is increased further during pregnancy. The secretory products of mast cells (histamine and serotonin) act in vitro as uterotonins. Moreover, serotonin acts uniquely in myometrial cells to induce the expression of interstitial collagenase, membrane metalloproteinase-1, a major participant in postpartum uterine involution (Jeffrey and associates, 1991). Consequently, the products of mast cells, histamine and serotonin, also may promote the contractions of phase 2 of parturition.

ANGIOTENSIN II AND PHASE 2 OF PARTURITION. There are two heptahelical G-protein-linked angiotensin II receptors (AT1 and AT2) expressed in the uterus. In nonpregnant women, the AT2 receptor is predominant, but in myometrium of pregnant women, it is the AT1 receptor that is preferentially expressed (Cox and associates, 1993a). Most commonly, angiotensin II binding to the plasma membrane receptor on smooth muscle cells evokes contraction. During pregnancy, vascular smooth muscle, which expresses the AT2 receptor, is refractory to the pressor effects of angiotensin II (Chap. 8, p. 183). In myometrium near term, however, angiotensin II may be another component of the uterotoin system of phase 2 of parturition, acting to promote increased myometrial cell [Ca²⁺]_i.

CRH¹⁰, hCG, PTH-rP¹¹, AND PHASE 2 OF PARTURITION. There may be a late pregnancy modification in the CRH¹², LH/hCG, and/or PTH-rP¹³ receptor-G-protein phenotype in myometrium that favors a switch from cAMP formation to increased myometrial cell [Ca²⁺]_i. Oxytocin acts to attenuate CRH-stimulated accumulation of cAMP in myometrial tissue, and CRH augments the contraction-inducing potency of a given dose of oxytocin in human myometrial strips (Quarero and colleagues, 1991, 1992). CRH also acts to increase myometrial contractile force in response to PGF_{2a} (Benedetto and associates, 1994). This was reviewed recently by Lockwood (1999).

HEPTAHELICAL RECEPTORS AND PHASE 2 OF PARTURITION: SUMMARY. Whereas multiple processes likely contribute to the success of phase 0 of parturition, it also is likely that multiple (possibly redundant) processes contribute to the success of phase 2 (active labor) once phase 0 is suspended and phase 1 of parturition is implemented. A variety of myometrial heptahelical receptors may promote uterine quiescence; but there is another group that should inhibit cAMP formation and/or activate phospholipase C. Perhaps the heptahelical receptor-G-protein-effector phenotype of the myometrial cells at various stages of pregnancy and under the influence of external signals contributes to the contractile response of the myometrium, that is, relaxation or contraction.

CONTRIBUTION OF INTRAUTERINE TISSUES TO PARTURITION

The potential role of amnion, chorion laeve, and decidua parietalis has been studied to define the participation, if any, of each tissue in promoting the initiation of parturition; but presently, an alternative role for these tissues appears to be more likely. The fetal membranes and decidua are part of an important tissue shell around the fetus that serves as a physical, immunological, and metabolic shield that protects against the untimely initiation of parturition.

AMNION. The amnion provides virtually all of the tensile strength (resistance to tearing and rupture) of the fetal membranes (Chap. 5, p. 103). The avascular human amnion is highly resistant to penetration by leukocytes, microorganisms, and neoplastic cells from the maternal compartment and constitutes a selective filter to prevent fetal squames as well as particulate-bound lung and skin secretions from reaching the maternal compartment. In this manner, maternal tissues are protected from constituents in the amniotic fluid that could adversely affect decidual or myometrial function or even maternal well-being, such as amniotic fluid embolism, which is discussed in Chapter 25 (p. 660).

A number of bioactive peptides and polypeptides, which are effective smooth muscle relaxants, are synthesized in amnion: PTH-rP¹⁴, CRH¹⁵, and brain natriuretic peptide. Specific receptors for these agents are present in myometrial tissue during pregnancy. A mechanism has not been established, however, whereby these vasoactive peptides can be transported from amnion to the myometrium without degradation. It is more likely that these agents act on contiguous tissues, such as the chorionic vessels of the placenta, or after inspiration or swallowing into the fetal lungs or gastrointestinal tract.

CHORION LAEVE AND PARTURITION. It is appreciably more difficult to work with isolated chorion laeve and its cytotrophoblastic cells than with isolated amnion and its epithelial cells or with decidua and isolated decidual cells. It is very difficult to separate chorion laeve tissue completely from tightly adherent fragments of decidua parietalis, and vice versa. After these technical problems are overcome, the chorion is similar to the amnion by serving primarily as a protective

tissue—providing immunological acceptance—in the prevention of untimely parturition. In addition, the chorion laeve is enriched in enzymes that inactivate uterotonins such as prostaglandin dehydrogenase, oxytocinase, and enkephalinase ([Germain and associates, 1994](#)).

DECIDUA PARIETALIS AND PARTURITION. A metabolic contribution of decidua parietalis to the initiation of parturition has been an appealing possibility for a number of reasons, both anatomical and functional. The generation of uterotonins in decidua that act in a paracrine manner on contiguous myometrium is an interesting option. There are also several lines of evidence that decidual activation is an accompaniment of human parturition ([Casey and MacDonald, 1988a, 1988b, 1990; MacDonald and colleagues, 1991](#)). The central question, however, is whether decidual activation precedes or follows the onset of labor. The process of decidual activation appears to be localized to the exposed decidual fragments lining the forebag. Trauma, hypoxia, and exposure of forebag decidua to endotoxin lipopolysaccharide, microorganisms, and IL-1 β in the vaginal fluids provokes an inflammatory reaction, which is an inevitable and consistent sequela of labor.

PRETERM LABOR

In a survey conducted by the Institute of Medicine of chairpersons of departments of obstetrics and gynecology in the United States and Canada, preterm birth was selected as the single most important clinical health problem encountered in the practice of obstetrics-gynecology ([Townsend, 1992](#)). As discussed in [Chapter 27](#), preterm birth is one of the major health hazards of humans, being the greatest cause (other than congenital anomalies) of neonatal morbidity and mortality.

Preterm birth is not singularly the consequence of preterm labor. There are three major etiological factors that contribute to delivery before 34 weeks:

1. Preterm, premature rupture of the fetal membranes.
2. Spontaneous preterm labor in pregnancies with intact fetal membranes.
3. Complications of pregnancy that severely jeopardize fetal and sometimes maternal health and mandate delivery, usually because of a deteriorating intrauterine environment for the fetus ([Goldenberg and colleagues, 2000](#)).

PRETERM PREMATURE RUPTURE OF THE MEMBRANES. This term is used to denote spontaneous rupture of the fetal membranes before the onset of labor, whether at term or preterm. In some institutions, including Parkland Hospital, as many or more preterm deliveries are preceded by preterm premature rupture of the membranes as by spontaneous preterm labor ([Chap. 27, p. 704](#)). The pathogenesis of premature rupture of the membranes is obscure; and unfortunately, new insights into the prevention of this serious pregnancy complication have not emerged.

MANDATED PRETERM DELIVERY INDEPENDENT OF LABOR: COMPROMISED FETAL, MATERNAL HEALTH. All too often, pregnancy complications oblige a clinical decision to effect preterm delivery rather than continue pregnancy in a deteriorating intrauterine environment for the fetus. A host of pregnancy disorders may mandate such a choice. Most commonly, these complications of pregnancy threaten fetal health so that a continued intrauterine existence will likely result in fetal death. Many examples may be cited, but the most common are maternal hypertension, severe diabetes mellitus, failure of fetal growth, and abruptio placenta. Each of these conditions is considered separately in great detail in other chapters.

PRETERM DELIVERY: SPONTANEOUS PRETERM LABOR. Pregnancies with intact fetal membranes and spontaneous preterm labor (for clinical as well as research purposes) must be distinguished from those in which there has been preterm premature rupture of the membranes.

Pregnancies complicated by spontaneous preterm labor, however, do not constitute a homogeneous group of pregnancies characterized singularly by the early initiation of parturition. Among the more common associated findings are preterm cervical dilatation; anatomical incompetence of the cervix; shortening of the cervix; uterine (fundal) abnormalities; fetal anomalies; multifetal pregnancies; severe maternal illness, including extrauterine infection such as appendicitis, peritonitis, pyelonephritis, and pneumonia; maternal thermal injury (body burns); autoimmune diseases; pregnancy-induced hypertension; and maternal systemic disorders. Setting aside uterine abnormalities, a common denominator among the fetal or maternal conditions that would provide a clue to the cause of the preterm onset of parturition has not been identified. If such a factor were found, many physiological processes of human parturition at term and preterm might become more understandable.

DOES INTRAUTERINE INFECTION CAUSE PRETERM LABOR?

During the past few years, the most popular theory for one cause of preterm labor has been intrauterine infection. Many investigators suggest that preterm labor with intact fetal membranes is sometimes the result of ascending spread of bacteria from the vagina or cervical canal. It has been estimated that upwards of one third of preterm labor with intact membranes may be caused by intrauterine infection.

BACKGROUND. Among many obstetricians, there has been great suspicion that "silent" infection is a common accompaniment and cause of preterm labor. The term "silent" is used to describe a condition in which intrauterine infection exists but there is little or no clinical evidence of infection in the pregnant woman, and sometimes microorganisms cannot be cultured from the amniotic fluid ([Iams and co-workers, 1987](#)). The critical question, however, is whether infection—or an inflammatory process—precedes or follows the onset of labor (phase 2 of parturition). A distinction must be made between intrauterine infection as a cause of preterm labor and the development of inflammation in exposed tissues of the amniotic sac as a sequela of labor, at term and preterm.

THE IMPORTANCE OF THE PROBLEM. As [MacDonald and Casey \(1996\)](#) have cautioned, it is vitally important to establish or refute the validity of the theory that infection is a cause of the initiation of preterm parturition. If such an etiology were established, it also is crucial to determine the incidence of infection-induced preterm labor. If infection were a cause of preterm labor, this cause should be preventable. If, however, the evidence in favor of infection as a cause of preterm labor is artificial, and the actual incidence of preterm labor caused by infection is very small, the widespread use of antibiotic treatment regimens to prevent preterm birth would be largely useless and unacceptable.

The evidence that infection causes preterm labor could be misinterpreted if based solely of the finding of mediators of the inflammatory response, including microorganisms and bacterial toxins, in amniotic fluids collected after labor is in progress. The inflammatory reaction that gave rise to these findings may not have begun until after labor started; the inflammatory response identified from studies of amniotic fluid could be the normal consequence of labor. Inflammation in the fragments of decidual tissue attached to the forebag of the amniotic sac is obliged during preterm labor as it is during spontaneous parturition at term (see p. 285). Mediators of the inflammatory response produced therein sometimes accumulate in the amniotic fluid during spontaneous labor both at term and preterm.

PROPOSED PATHOGENESIS OF INFECTION-INDUCED PRETERM LABOR

ANATOMICAL CONSIDERATIONS. The patency of the reproductive tract of women, although essential for the achievement of pregnancy and delivery of the fetus, is theoretically problematic during phase 0 of parturition. The lower pole of the fetal membrane-decidual junction embraces the orifice of the cervical canal, which anatomically is patent to the vagina. There is, of course, functional obliteration of the cervical canal during pregnancy by a mucus plug, and significant antimicrobial properties have been identified in the cervical mucus. Nonetheless, this anatomical arrangement could provide a passageway for the spread of microorganisms to intrauterine tissues. There are large numbers of microorganisms of a wide variety in the vaginal fluid of all women. Theoretically, microorganisms in the endocervical canal or vagina may, by ascending spread, colonize tissues at the lower pole of the fetal membranes and contiguous decidua.

Why is it, therefore, that all human pregnancies are not complicated by infection? It seems reasonable to surmise that the antimicrobial properties of the cervical glands and mucus are appreciable. In addition, the fetal membranes and amniotic fluid also must be highly capable of resisting invasion by most microorganisms. These factors, together with the antimicrobial properties of the resident leukocytes in the decidua, must be substantial in preventing ascending infection.

It has been suggested that selected microorganisms are more likely to be the pathogens that bring about preterm labor. But an association between specific microorganisms in the vaginal fluid or endocervix and an increased risk for preterm labor has not been established. A potential exception to this generalization, bacterial vaginosis, is considered separately ([Chap. 27, p. 699](#)).

BACKGROUND. It has been known for more than 50 years that the administration of bacterial endotoxin (lipopolysaccharide, or LPS) to pregnant animals causes abortion or preterm delivery, which is accompanied by decidual hemorrhage and necrosis ([Zahl and Bjerknes, 1943](#)). It was not until many years later, however, that the biomolecular particulars of the inflammatory response were defined in detail. These latter findings provided an attractive potential explanation whereby intrauterine infection might cause preterm labor. The inflammatory response elicited by bacterial toxins is mediated, in large measure, by specific receptors on mononuclear phagocytes. These cells release arachidonic acid, and PGE₂, in response to LPS. The primary cytokine, IL-1 β , also is produced rapidly after LPS stimulation

(Dinarello, 1986). IL-1 β in turn acts to promote a series of responses that includes increased synthesis of other cytokines such as TNF- α , IL-6, IL-8¹⁶, the proliferation, activation, and migration of leukocytes, modifications in extracellular matrix proteins, mitogenic and cytotoxic effects, fever, and the acute phase response (El-Bastawissi and colleagues, 2000). IL-1 β also acts to promote prostaglandin formation in many tissues, including myometrium, decidua, and amnion (Romero and colleagues, 1989; Semer and associates, 1991).

INFECTION-INDUCED PRETERM LABOR: HYPOTHESIS. Based on these insights into the inflammatory response, it was straightforward to construct a theory for the pathogenesis of infection-induced preterm labor. Namely, microorganisms, originating in the vagina or cervix, after ascending spread, colonize tissues (decidua and possibly the fetal membranes) and/or invade the amniotic sac. LPS (or other toxins) elaborated by these bacteria induce the formation of cytokines in mononuclear phagocytes of decidua or in monocytes recruited into the amniotic fluid. The cytokines, especially IL-1 β , provoke prostaglandin release and thereby preterm labor (El-Bastawissi, 2000; MacDonald, 1988; Romero, 1998, and all their co-workers).

PRETERM LABOR: AMNIONIC FLUID CONSTITUENTS. Many groups of investigators have evaluated amniotic fluids collected during preterm labor to identify and quantify mediators of inflammation. These have included microorganisms and bacterial products such as endotoxin and short-chain fatty acids; leukocyte number and type as well as leukocyte enzymes; prostaglandins; IL-1 β , IL-1 α , TNF- α , IL-6, IL-8¹⁷, and other cytokines; and endothelin-1. Generally, the preterm labor pregnancies studied were less than 34 weeks' gestation with intact fetal membranes.

MICROORGANISMS IN AMNIONIC FLUID DURING PRETERM LABOR. It is important to consider the potential mechanisms(s) whereby microorganisms may gain entrance into the amniotic fluid. The capacity for penetration of tissues (including the fetal membranes) by microorganisms varies appreciably among bacteria and among tissues. The likelihood of bacterial penetration of the amniotic sac may be dependent upon:

1. Exposure of these tissues to the microorganisms (cervical dilatation).
2. Metabolic integrity of the tissues (especially decidua parietalis).
3. The vaginal flora of a given woman.
4. Numbers of specific microorganisms.
5. Integrity of the fetal membranes.
6. The pH of the vaginal fluid.
7. Cooperative actions among microorganisms.

Most likely, the invasion of the amniotic sac by microorganisms occurs after labor begins, and the forebag tissues are exposed. Another factor in determining the likelihood of microbial invasion is the duration of exposure of the tissues in the vagina, that is, the duration of cervical dilatation.

Some microorganisms, for example, *Fusobacterium* species, are detected in amniotic fluid much more commonly than others. This finding was interpreted by some as presumptive evidence that specific microorganisms are more commonly involved as pathogens in the induction of preterm labor. Another interpretation, however, is that given direct access to the membranes (after cervical dilatation), selected microorganisms (such as fusobacteria) that are more capable of burrowing through these exposed tissues will do so. Fusobacteria are not commonly found in the vagina; nonetheless, they are the microorganisms most commonly isolated from amniotic fluid during preterm labor (Hill, 1993). Fusobacteria are found in the vaginal fluid of only 9 percent of women but in 28 percent of positive amniotic fluid cultures from preterm labor pregnancies with intact membranes (Chaim and Mazor, 1992).

Altshuler and Hyde (1988) found that fusobacteria burrow through amnion tissue rapidly and sometimes are present in amnion tissue in large numbers as if penetrating between the amnion epithelial cells. They also identified large numbers of fusobacteria in the Wharton jelly of the umbilical cord with intra-amniotic infections, suggesting a peculiar propensity for these microorganisms to penetrate amnion tissue, which also covers the umbilical cord. Fusobacteria produce a variety of toxins, some of which are extraordinarily potent in stimulating cytokine formation in mononuclear phagocytes. We interpret these data, and Hyde and Altshuler concur (personal communication), to mean that fusobacteria and possibly other microorganisms penetrate the fetal membranes **after** the tissues are exposed to these microorganisms in the cervical/vaginal fluid. This provides a reasonable explanation for the low incidence of fusobacteria in vaginal fluids but a much higher incidence in positive cultures of amniotic fluids.

MICROORGANISMS IN AMNIONIC FLUID DURING PRETERM AND TERM LABOR. The incidence of positive cultures of amniotic fluid collected during **preterm labor** varies among studies from 10 to 40 percent, the average being about 13 percent (Romero and associates, 1988). In a study conducted by Gomez and co-workers (1995), the incidence of culture-positive amniotic fluids collected by amniocentesis during spontaneous **term labor** was 19 percent, which is similar to or greater than the incidence of culture-positive amniotic fluids during preterm labor identified by the same investigators. If the incidence of bacterial culture-positive amniotic fluids obtained during spontaneous labor at term was greater or equal to the incidence of positive cultures in amniotic fluids during preterm labor, the theory of infection-induced preterm labor must be reevaluated. Gomez and associates (1995) rationalized these findings by pointing to the sometimes larger number of microorganisms in amniotic fluid during preterm labor. This explanation is tenuous, however, because many cases of preterm labor have been in labor for a much longer time before amniotic fluid was collected, and therefore more time was available for microbial replication in the amniotic fluid in situ.

LEUKOCYTES IN AMNIONIC FLUID. Macrophages are present in amniotic fluid in very small numbers before the onset of labor. Indeed, leukocytes do not readily penetrate normal fetal membranes either in vivo or in vitro. With inflammation of the exposed decidua of the tissues that form the forebag during preterm labor, however, maternal leukocytes are recruited into the amniotic fluid (presumably in response to chemoattractants). The same phenomenon is noted at term. Leukocyte activation is accelerated with inflammation, and activated leukocytes are able to penetrate the fetal membranes.

INTERLEUKIN-1 β IN AMNIONIC FLUID. It is convenient, in both the physiological context and in accordance with current nomenclature, to consider IL-1 β as a primary cytokine. IL-1 β is produced rapidly in response to infectious and immunological challenges and IL-1 β acts in many cells to promote the synthesis of many other cytokines and other mediators of inflammation.

IL-1 β is not detected in amniotic fluid of pregnancies with intact membranes before labor begins. The first extensive studies of amniotic fluid IL-1 β during labor were conducted with samples collected during preterm labor. The results of these studies, from all laboratories reporting, have been virtually identical. Namely, IL-1 β is present in amniotic fluid in approximately one third of preterm labor pregnancies (Romero and associates, 1987). The finding of IL-1 β in amniotic fluid in these earlier studies was believed to constitute corroborative evidence of infection-induced preterm labor. It was hoped that confirmation for one cause of preterm labor had been obtained, supporting what many obstetricians had suspected for decades, that silent infection is a relatively common cause of preterm labor.

At the time of this interpretation, however, it was not realized that IL-1 β was found with about equal frequency in amniotic fluid samples obtained from pregnancies during spontaneous labor at term. In about one third of pregnancies during spontaneous labor at term, there is readily measurable IL-1 β in concentrations of about 100 to 5000 pg/mL (Romero and colleagues, 1990). Importantly, these amniotic fluids were collected by transabdominal or transuterine amniocentesis.

The finding of IL-1 β in approximately equal proportions of amniotic fluids collected during spontaneous preterm and term labor also necessitated a reevaluation of the original hypothesis. Is the accumulation of a given agent in amniotic fluid indicative of a role for that compound in the initiation of parturition? Or does a particular agent accumulate in amniotic fluid as a natural consequence of the changes obliged during labor? Parturition research often has been, and frequently continues to be, stilled by this dilemma. In part, this is because the initiation of parturition and the onset of labor have been taken as one and the same event.

ORIGIN OF IL-1 β IN AMNIONIC FLUID. As in the case of prostaglandins, IL-1 β is produced in cells of the forebag decidua after labor-induced cervical dilatation exposes this tissue in the vagina. The distribution of IL-1 β from forebag decidua into the vagina and amniotic fluid, however, is not comparable with the entry of prostaglandins produced in the forebag into these two spaces. First, IL-1 β is a protein (M_r about 17,000). The transfer of IL-1 β from decidua across the fetal membranes of the forebag into amniotic fluid appears to be severely limited. The rate of IL-1 β secretion from forebag decidual tissue is great, but IL-1 β is not detected in forebag amniotic fluid in two thirds of pregnancies during labor at term (Cox and colleagues, 1993b). Indeed, Kent and colleagues (1994) found that the transfer of radiolabeled IL-1 β across the fetal membranes in vitro was negligible. The IL-1 β in amniotic fluid does not arise from amnion tissue, fetal urine, or fetal lung secretions. Most likely, IL-1 β in amniotic fluid is secreted by mononuclear phagocytes or neutrophils activated and recruited into the amniotic fluid after labor begins. Therefore, IL-1 β in amniotic fluid likely is generated in situ from cells newly recruited into this space.

CHEMOATTRACTANTS. There are very few leukocytes in the amniotic fluid of normal pregnancies before the onset of labor, but monocytes and neutrophils do enter amniotic fluid during labor in some pregnancies. There is a highly significant correlation between the presence of leukocytes and the concentration of IL-1 β in amniotic fluid ([Cox and colleagues, 1993b](#); Dr. Judith Head, personal communication). The amount of IL-1 β in amniotic fluid may be determined by the number of leukocytes recruited, the activation status of these cells, or the effect of constituents of amniotic fluid on the rate of secretion of IL-1 β by these leukocytes. The chemoattractants IL-8¹⁸ (neutrophils) and monocyte chemoattractant protein-1 (monocytes/macrophages) are produced in amnion, and the synthesis of these chemoattractants in amnion cells is increased in response to LPS and IL-1 treatment. These chemoattractants may act to recruit leukocytes into the amniotic fluid from maternal decidual and fetal chorionic vessels.

OTHER CYTOKINES IN AMNIONIC FLUID. A number of investigators also have cited the finding of very high levels of IL-6 or IL-8¹⁹ (and many other cytokines) in amniotic fluid as evidence of an intrauterine infection-based cause of preterm labor. More recently, [Athayde and associates \(2000\)](#) found that the proinflammatory IL-16 is a marker for microbial invasion of amniotic fluid. However, at least IL-6 and IL-8, unlike IL-1 β , are present in amniotic fluid of normal pregnancies throughout most of gestation. These cytokines, again unlike IL-1 β , are produced by amnion cells, and the production of IL-8 by amnion epithelial cells and IL-6 and IL-8 by amnion mesenchymal cells is increased strikingly by IL-1 β (Casey and MacDonald, unpublished observations). It is not surprising, therefore, that the levels of IL-6 and IL-8 are increased in amniotic fluids in which IL-1 β is present. Indeed, a very high correlation is found between the concentrations of IL-1 β and IL-6 in amniotic fluids during labor at term and preterm ([Cox and associates, 1997](#)). Thus, increased levels of IL-6, and other cytokines, are to be expected whenever IL-1 β formation is increased. IL-1 β acts as a primary cytokine to promote the synthesis of other cytokines ([MacDonald and Casey, 1996](#)).

PRETERM LABOR AND HIGH LEVELS OF CYTOKINES IN AMNIONIC FLUID. In a small fraction of preterm labor pregnancies, the levels of cytokines in amniotic fluid are increased massively, that is, the levels are much greater than the highest levels in amniotic fluids collected during labor at term. Indeed, the levels of IL-1 β in some preterm labor amniotic fluids may be 10 to 100 times the maximum values observed in IL-1 β -positive fluids at term. These findings also have been cited as evidence of intrauterine infection as a cause of preterm labor.

To analyze this particular issue, it is important to recognize that there is a fundamental difference in the obstetrical management of labor in pregnancies at term compared with the management of preterm labor. In the former, efforts are directed toward effecting delivery in a safe and expedient manner. In the latter, management is commonly directed toward delaying delivery. In consequence, it is rare for labor to extend beyond 18 hours in term pregnancies. It is common, however, for the cervix to be dilated for more than 18 hours, sometimes for days during preterm labor. The very high levels of cytokines in amniotic fluid of preterm labor pregnancies are found primarily in those collected after very prolonged labor and dilatation of the cervix. The suggestion was made earlier that these prolonged preterm labor pregnancies also may be those in which the number of microorganisms is great.

PROSTAGLANDINS IN AMNIONIC FLUID DURING PRETERM LABOR. The infection-based theory of preterm labor has been anchored to the proposition that the proximate event in the onset of preterm labor is the accelerated production of prostaglandins. The levels of PGE₂ and PGF_{2a} in amniotic fluid during preterm labor are, however, not strikingly elevated ([Fig. 11-23](#)).

Upon assessment of prostaglandins in amniotic fluid during preterm labor, many observers have been surprised to find that the levels usually are very low ([Gomez and associates, 1995](#)). Indeed, several groups of investigators have commented specifically on the surprisingly low levels of prostaglandins in amniotic fluid during preterm labor. The mean levels of prostaglandins in amniotic fluid during preterm labor, at comparable stages of labor progress, are similar to those in amniotic fluids of the upper compartment during labor at term ([Fig. 11-23](#)). In many cases of preterm labor, however, the levels of prostaglandins in amniotic fluids are no greater than those in amniotic fluids before labor began. The levels of prostaglandins in amniotic fluid during preterm labor also vary enormously among pregnancies at similar stages of labor progress ([Fig. 11-24](#)).

These findings are to be expected if the forebag tissues are the source of prostaglandins in amniotic fluid during preterm labor, as there is only a single amniotic fluid compartment in such pregnancies because the preterm fetal presenting part does not obstruct the maternal pelvis and separate amniotic fluid compartments are not formed.

It is clear that the prostaglandins that sometimes accumulate in amniotic fluid during labor, both at term and preterm, are produced as part of the inflammatory process in the forebag tissues that normally accompanies labor. The enormous variation in the levels of prostaglandins in amniotic fluids among pregnancies at similar stages of labor progress (at term and preterm) is likely explained by variations in the amount of decidual tissue fragments attached to the forebag.

INFLAMMATORY MEDIATORS IN AMNIONIC FLUID: INTERPRETATION. Many of the bioactive agents that accumulate in amniotic fluid of some pregnancies during labor (both at term and preterm) are typical of the inflammatory mediators produced in other tissue sites with inflammation. The only unique feature of this response in intrauterine tissues is that several of the agents produced could serve as uterotonins: PGE₂, PGF_{2a}, PAF⁸, and endothelin-1 ([Casey and co-workers, 1993a](#); [Casey and MacDonald, 1993b](#)). Nonetheless, these agents, produced in the forebag tissues exposed in the vagina, are formed after (not before) labor begins, and are largely unavailable to the myometrium because of sequestration in the amniotic fluid of the isolated forebag.

Inflammatory mediators (PGs and inflammatory cytokines) may be important in the process of cervical dilation and cervical extracellular matrix degradation ([Rath and colleagues, 1998](#); [Winkler and Rath, 1999](#)).

FIGURE 11-1. Metabolic regulation of myometrial smooth muscle contraction and relaxation. An increase in intracellular, cytoplasmic, free Ca²⁺ activates myosin light chain kinase, which catalyzes the phosphorylation of the 20-kd light chain of myosin. Phosphorylated myosin interacts with actin and thereby activates ATPase; with the hydrolysis of ATP, force is generated and the muscle shortens. Relaxation is promoted by sequestration of Ca²⁺ in the sarcoplasmic reticulum, dephosphorylation of phosphorylated myosin by the action of phosphatase, and possibly by phosphorylation (inactivation) of myosin light chain kinase by a cAMP-dependent protein kinase.

FIGURE 11-2. Sequence of development of the segments and rings in the uterus in pregnant women at term and in labor. Note comparison between the uterus of a nonpregnant woman, the uterus at term, and the uterus during labor. The passive lower segment of the uterine body is derived from the isthmus; the physiological retraction ring develops at the junction of the upper and lower uterine segments. The pathological retraction ring develops from the physiological ring. (Anat. Int. Os = anatomical internal os; E.O. = external os; Hist. Int. Os = histological internal os; Ph.R.R. = physiological retraction ring.)

12. Mechanisms of Normal Labor

At the onset of labor, the position of the fetus, with respect to the birth canal, is critical to the route of delivery. For example, if at the time of labor the fetus is transverse to the birth canal, either cesarean delivery or podalic version to a longitudinal lie are the only options for delivery of a viable infant. It is thus of paramount importance to know the fetal position within the uterine cavity at the onset of labor.

LIE, PRESENTATION, ATTITUDE, AND POSITION

By convention, fetal orientation is described with respect to fetal lie, presentation, attitude, and position. These can be established clinically by abdominal palpation, vaginal examination, and auscultation, or by technical means using sonography or x-ray. Clinical assessment is less accurate, or even sometimes impossible to perform and interpret in obese women.

FETAL LIE

The lie is the relation of the long axis of the fetus to that of the mother, and is either longitudinal or transverse. Occasionally, the fetal and the maternal axes may cross at a 45-degree angle, forming an oblique lie, which is unstable and always becomes longitudinal or transverse during the course of labor. Longitudinal lies are present in over 99 percent of labors at term. Predisposing factors for transverse lies include multiparity, placenta previa, hydramnios, and uterine anomalies ([Gemer and Segal, 1994](#)).

FETAL PRESENTATION

The presenting part is that portion of the body of the fetus that is either foremost within the birth canal or in closest proximity to it. The presenting part can be felt through the cervix on vaginal examination. The presenting part determines the presentation. Accordingly, in longitudinal lies, the pre-senting part is either the fetal head or breech, creating cephalic and breech presentations, respectively. When the fetus lies with the long axis transversely, the shoulder is the presenting part. Thus, a shoulder presentation is felt through the cervix on vaginal examination.

CEPHALIC PRESENTATION. These are classified according to the relation of the head to the body of the fetus ([Fig. 12-1](#)). Ordinarily the head is flexed sharply so that the chin is in contact with the thorax. In this circumstance, the occipital fontanel is the presenting part, and such a presentation is usually referred to as a vertex or occiput presentation. Actually, the vertex lies just in front of the occipital fontanel, and the occiput just behind the fontanel, as illustrated in [Figure 7-7](#) (p. 136). Much less commonly, the fetal neck may be sharply extended so that the occiput and back come in contact and the face is foremost in the birth canal— *face presentation*. The fetal head may assume a position between these extremes, partially flexed in some cases, with the anterior (large) fontanel, or bregma, presenting (*sinciput presentation*), or partially extended in other cases, with the brow presenting (*brow presentation*). These latter two presentations are usually transient. As labor progresses, sinciput and brow presentations are almost always converted into vertex or face presentations by flexion or extension, respectively.

BREECH PRESENTATION. When the fetus presents as a breech, there are three general configurations. When the thighs are flexed and the legs extended over the anterior surfaces of the body, this is termed a *frank breech presentation* ([Fig. 12-2](#)). If the thighs are flexed on the abdomen and the legs upon the thighs, this is a *complete breech presentation* ([Fig. 12-3](#)). If one or both feet, or one or both knees, are lowermost, then there is an *incomplete, or footling, breech presentation* ([Fig. 12-4](#)).

FETAL ATTITUDE OR POSTURE

In the later months of pregnancy the fetus assumes a characteristic posture described as attitude or habitus ([Fig. 12-1](#)). As a rule, the fetus forms an ovoid mass that corresponds roughly to the shape of the uterine cavity. The fetus becomes folded or bent upon itself in such a manner that the back becomes markedly convex; the head is sharply flexed so that the chin is almost in contact with the chest; the thighs are flexed over the abdomen; the legs are bent at the knees; and the arches of the feet rest upon the anterior surfaces of the legs. In all cephalic presentations, the arms are usually crossed over the thorax or become parallel to the sides, and the umbilical cord lies in the space between them and the lower extremities. This characteristic posture results from the mode of growth of the fetus and its accommodation to the uterine cavity.

Abnormal exceptions to this attitude occur as the fetal head becomes progressively more extended from the vertex to the face presentation ([Fig. 12-1D](#)). This results in a progressive change in fetal attitude from a convex (flexed) to a concave (extended) contour of the vertebral column.

FETAL POSITION

Position refers to the relation of an arbitrarily chosen portion of the fetal presenting part to the right or left side of the maternal birth canal. Accordingly, with each presentation there may be two positions, right or left. The fetal occiput, chin (mentum), and sacrum are the determining points in vertex, face, and breech presentations, respectively ([Figs. 12-5 12-6 12-7 12-8](#)).

VARIETIES OF PRESENTATION AND POSITION

For still more accurate orientation, the relation of a given portion of the presenting part to the anterior, transverse, or posterior portion of the maternal pelvis is considered. Because there are two positions, it follows that there must be three varieties for each position (either right or left), and six varieties for each presentation (three right and three left) ([Figs. 12-5 12-6 12-7 12-8](#)). Because the presenting part may be in either the left or right position, there are left and right occipital, left and right mental, and left and right sacral presentations, abbreviated as LO and RO, LM and RM, and LS and RS, respectively. Because the presenting part in each of the two positions may be directed anteriorly (A), transversely (T), or posteriorly (P), there are six varieties of each of these three presentations ([Figs. 12-5 12-6 12-7 12-8](#)). Thus, in an occiput presentation, the presentation, position, and variety may be abbreviated in clockwise fashion as:

In shoulder presentations, the acromion (scapula) is the portion of the fetus arbitrarily chosen for orientation with the maternal pelvis. One example of the terminology sometimes employed for the purpose is illustrated in [Figure 12-9](#). The acromion or back of the fetus may be directed either posteriorly or anteriorly and superiorly or inferiorly ([Chap. 19, p. 455](#)). Because it is impossible to differentiate exactly the several varieties of shoulder presentation by clinical examination, and because such differentiation serves no practical purpose, it is customary to refer to all transverse lies simply as shoulder presentations. Another term used is transverse lie, with back up or back down.

FREQUENCY OF THE VARIOUS PRESENTATIONS AND POSITIONS

At or near term the incidence of the various presentations is approximately as follows: vertex, 96 percent; breech, 3.5 percent; face, 0.3 percent; and shoulder, 0.4 percent. About two thirds of all vertex presentations are in the left occiput position, and a third in the right.

Although the incidence of breech presentation is only a little over 3 percent at term (see [Table 19-1](#)), it is much greater earlier in pregnancy. [Scheer and Nubar \(1976\)](#), using ultrasonography, found the incidence of breech presentation to be 14 percent between 29 and 32 weeks' gestation. Subsequently, the breech converted

spontaneously to vertex in increasingly higher percentages as term approached.

There are several explanations of why the term fetus usually presents by the vertex. The most logical is because the uterus is piriform shaped. Although the fetal head at term is slightly larger than the breech, the entire podalic pole of the fetus—that is, the breech and its flexed extremities—is bulkier and more movable than the cephalic pole. The cephalic pole is comprised of the fetal head only.

Until about 32 weeks, the amniotic cavity is large compared with the fetal mass, and there is no crowding of the fetus by the uterine walls. At approximately this time, however, the ratio of amniotic fluid volume to fetal mass becomes altered by relative diminution of amniotic fluid and by increasing fetal size. As a result, the uterine walls are apposed more closely to the fetal parts. The fetal lie then is more nearly dependent upon the piriform shape of the uterus. The fetus, if presenting by the breech, often changes polarity in order to make use of the roomier fundus for its bulkier and more movable podalic pole. The high incidence of breech presentation in hydrocephalic fetuses is in accord with this theory, because in this circumstance the cephalic pole of the fetus is larger than the podalic pole.

The cause of breech presentation may be some circumstance that prevents the normal version from taking place, for example, a septum that protrudes into the uterine cavity ([Chap. 35, p. 914](#)). A peculiarity of fetal attitude, particularly extension of the vertebral column as seen in frank breeches, may also prevent the fetus from turning. If the placenta implants in the lower uterine segment, normal intrauterine anatomy is distorted. Also, any condition contributing to an abnormality of fetal muscle tone or movement may predispose to persistent breech presentations.

DIAGNOSIS OF FETAL PRESENTATION AND POSITION

Several methods can be used to diagnose fetal presentation and position. These include abdominal palpation, vaginal examination, combined examination, auscultation, and in certain doubtful cases, imaging studies such as ultrasonography, computerized tomographic scans (CT), or magnetic resonance imaging (MRI) studies.

ABDOMINAL PALPATION—LEOPOLD MANEUVERS

Abdominal examination should be conducted systematically employing the four maneuvers described by [Leopold and Spurlin in 1894](#). The mother should be supine and comfortably positioned with her abdomen bared. During the first three maneuvers, the examiner stands at the side of the bed that is most convenient and faces the patient; the examiner reverses this position and faces her feet for the last maneuver ([Fig. 12-10](#)). These maneuvers may be difficult if not impossible to perform and interpret if the patient is obese or if the placenta is anteriorly implanted.

FIRST MANEUVER. After outlining the contour of the uterus and ascertaining how nearly the fundus approaches the xiphoid cartilage, the examiner gently palpates the fundus with the tips of the fingers of both hands in order to define which fetal pole is present in the fundus. The breech gives the sensation of a large, nodular body, whereas the head feels hard and round and is more freely movable and ballotable.

SECOND MANEUVER. After determination of the pole that lies in the fundus, the palms are placed on either side of the abdomen, and gentle but deep pressure is exerted. On one side, a hard, resistant structure is felt, the back; and on the other, numerous small, irregular and mobile parts are felt, the fetal extremities. In women with a thin abdominal wall, the fetal extremities can often be differentiated, but in heavier women, only these irregular nodulations may be felt. In the presence of obesity or considerable amniotic fluid, the back is felt more easily by exerting deep pressure with one hand while counter-palpating with the other. By next noting whether the back is directed anteriorly, transversely, or posteriorly, a more accurate picture of the orientation of the fetus is obtained.

THIRD MANEUVER. Using the thumb and fingers of one hand, the lower portion of the maternal abdomen is grasped just above the symphysis pubis. If the presenting part is not engaged, a movable body will be felt, usually the head. The differentiation between head and breech is made as in the first maneuver. If the presenting part is not engaged, all that remains to be defined is the attitude of the head. If by careful palpation it can be shown that the cephalic prominence is on the same side as the small parts, the head must be flexed, and therefore the vertex is the presenting part. When the cephalic prominence of the fetus is on the same side as the back, the head must be extended. If the presenting part is deeply engaged, however, the findings from this maneuver are simply indicative that the lower fetal pole is fixed in the pelvis; the details are then defined by the last (fourth) maneuver.

FOURTH MANEUVER. The examiner faces the mother's feet and, with the tips of the first three fingers of each hand, exerts deep pressure in the direction of the axis of the pelvic inlet. If the head presents, one hand is arrested sooner than the other by a rounded body, the cephalic prominence, while the other hand descends more deeply into the pelvis. In vertex presentations, the prominence is on the same side as the small parts; and in face presentations, on the same side as the back. The ease with which the prominence is felt is indicative of the extent to which descent has occurred. In many instances, when the head has descended into the pelvis, the anterior shoulder may be differentiated readily by the third maneuver. In breech presentations, the information obtained from this maneuver is less precise.

Abdominal palpation can be performed throughout the latter months of pregnancy and during and between the contractions of labor. The findings provide information about the presentation and position of the fetus and the extent to which the presenting part has descended into the pelvis. For example, so long as the cephalic prominence is readily palpable, the vertex has not descended to the level of the ischial spines. The degree of cephalopelvic disproportion, moreover, can be gauged by evaluating the extent to which the anterior portion of the fetal head overrides the symphysis pubis. With experience, it is possible to estimate the size of the fetus, and even to map out the presentation of the second fetus in a twin gestation. According to [Lydon-Rochelle and colleagues \(1993\)](#), experienced clinicians accurately identify fetal malpresentation using Leopold maneuvers with a high sensitivity (88 percent), specificity (94 percent), positive predictive value (74 percent), and negative predictive value (97 percent).

VAGINAL EXAMINATION

Before labor, the diagnosis of fetal presentation and position by vaginal examination is often inconclusive, because the presenting part must be palpated through a closed cervix and lower uterine segment. With the onset of labor and after cervical dilatation, important information may be obtained. In vertex presentations, the position and variety are recognized by differentiation of the various sutures and fontanels. Face presentations are identified by the differentiation of the portions of the face. Breech presentations are identified by palpation of the sacrum and maternal ischial tuberosities.

In attempting to determine presentation and position by vaginal examination, it is advisable to pursue a definite routine, comprised of four maneuvers ([Figs. 12-11](#) and [12-12](#)):

1. After the woman is prepared appropriately, as described in [Chapter 13 \(p. 311\)](#), two fingers of either gloved hand are introduced into the vagina and carried up to the presenting part. The differentiation of vertex, face, and breech is then accomplished readily.
2. If the vertex is presenting, the fingers are introduced into the posterior aspect of the vagina. The fingers are then swept forward over the fetal head toward the maternal symphysis ([Fig. 12-11](#)). During this movement, the fingers necessarily cross the fetal sagittal suture. When it is felt, its course is outlined, with small and large fontanels at the opposite ends.
3. The positions of the two fontanels then are ascertained. The fingers are passed to the most anterior extension of the sagittal suture, and the fontanel encountered there is examined carefully and identified; then by a circular motion, the fingers are passed around the side of the head until the other fontanel is felt and differentiated ([Fig. 12-12](#)).
4. The station, or extent to which the presenting part has descended into the pelvis, can also be established at this time ([Chap. 3, p. 53](#)).

Using these maneuvers, the various sutures and fontanels ([Chap. 7, p. 135](#)) are located readily, and the possibility of error is lessened considerably. In face and breech presentations, errors are minimized, because the various parts are distinguished more readily.

AUSCULTATION

While auscultation alone does not provide reliable information concerning fetal presentation and position, auscultatory findings sometimes reinforce results obtained by palpation. Ordinarily, fetal heart sounds are transmitted through the convex portion of the fetus that lies in intimate contact with the uterine wall. Therefore, fetal heart sounds are heard best through the fetal back in vertex and breech presentations, and through the fetal thorax in face presentations. The region of the abdomen in which fetal heart sounds are heard most clearly varies according to the presentation and the extent to which the presenting part has descended. In cephalic

presentations, fetal heart sounds are best heard midway between the maternal umbilicus and the anterior superior spine of her ilium. In breech presentations, fetal heart tones are usually heard at or slightly above the umbilicus. In occipitoanterior positions, heart sounds usually are heard best a short distance from the midline; in the transverse varieties, they are heard more laterally; and in the posterior varieties, they are best heard well back in the flank.

SONOGRAPHY

Improvements in ultrasonic techniques have provided another diagnostic aid of particular value in doubtful cases. In obese women or in women whose abdominal walls are rigid, a sonographic examination may provide information to solve many diagnostic problems and lead to early recognition of a breech or shoulder presentation that might otherwise have escaped detection until late in labor. Employing ultrasonography, the fetal head and body can be located without the potential hazards of radiation. In some clinical situations, the information obtained radiographically far exceeds the minimal risk from a single x-ray exposure ([Chap. 41, p. 1112](#)).

LABOR WITH OCCIPUT PRESENTATIONS

The fetus is in the occiput or vertex presentation in approximately 95 percent of all labors. Presentation is most commonly ascertained by abdominal palpation and confirmed by vaginal examination sometime before or at the onset of labor. In the majority of cases, the vertex enters the pelvis with the sagittal suture in the transverse pelvic diameter ([Caldwell and associates, 1934](#)). The fetus enters the pelvis in the **left occiput transverse (LOT)** position in 40 percent of labors, compared with 20 percent in the **right occiput transverse (ROT)** position ([Caldwell and associates, 1934](#)). In **occiput anterior positions (LOA¹ or ROA)**, the head either enters the pelvis with the occiput rotated 45 degrees anteriorly from the transverse position, or subsequently does so. The mechanism of labor usually is very similar to that in occiput transverse positions.

In about 20 percent of labors, the fetus enters the pelvis in an **occiput posterior (OP)** position. The right occiput posterior (**ROP²**) is slightly more common than the left (LOP) ([Caldwell and associates, 1934](#)). It appears likely from evidence obtained by radiographic studies that posterior positions are more often associated with a narrow forepelvis. They are also more commonly seen in association with anterior placentation ([Gardberg and Tuppurainen, 1994a](#)).

OCCIPUT ANTERIOR PRESENTATION

Because of the irregular shape of the pelvic canal and the relatively large dimensions of the mature fetal head, it is evident that not all diameters of the head can necessarily pass through all diameters of the pelvis. It follows that a process of adaptation or accommodation of suitable portions of the head to the various segments of the pelvis is required for vaginal delivery. These positional changes in the presenting part constitute the mechanisms of labor. The **cardinal movements of labor** are engagement, descent, flexion, internal rotation, extension, external rotation, and expulsion ([Fig. 12-13](#)).

For purposes of instruction, the various movements often are described as though they occurred separately and independently. In reality, the mechanism of labor consists of a combination of movements that are ongoing simultaneously. For example, as part of the process of engagement, there is both flexion and descent of the head. It is impossible for the movements to be completed unless the presenting part descends simultaneously. Concomitantly, uterine contractions effect important modifications in fetal attitude, or habitus, especially after the head has descended into the pelvis. These changes consist principally of a straightening of the fetus, with loss of dorsal convexity and closer application of the extremities to the body. As a result, the fetal ovoid is transformed into a cylinder, with the smallest possible cross section normally passing through the birth canal.

ENGAGEMENT. As discussed in [Chapter 3 \(p. 58\)](#), the mechanism by which the biparietal diameter, the greatest transverse diameter of the fetal head in occiput presentations, passes through the pelvic inlet is designated engagement. This phenomenon may take place during the last few weeks of pregnancy, or it may not occur until after the commencement of labor. In many multiparous and some nulliparous women, the fetal head is freely movable above the pelvic inlet at the on-set of labor. In this circumstance, the head is some-times referred to as "floating." A normal-sized head usually does not engage with its sagittal suture directed anteroposteriorly. Instead, the fetal head usually enters the pelvic inlet either in the transverse diameter or in one of the oblique diameters ([Caldwell and colleagues, 1934](#)).

ASYNCLITISM. Although the fetal head tends to accommodate to the transverse axis of the pelvic inlet, the sagittal suture, while remaining parallel to that axis, may not lie exactly midway between the symphysis and sacral promontory. The sagittal suture frequently is deflected either posteriorly toward the promontory or anteriorly toward the symphysis ([Fig. 12-14](#)). Such lateral deflection of the head to a more anterior or posterior position in the pelvis is called **asynclitism**. If the sagittal suture approaches the sacral promontory, more of the anterior parietal bone presents itself to the examining fingers, and the condition is called *anterior asynclitism*. If, however, the sagittal suture lies close to the symphysis, more of the posterior parietal bone will present, and the condition is called *posterior asynclitism*. At the extreme of posterior asynclitism, also called *Litzmann obliquity*, the posterior ear may be easily palpated.

Moderate degrees of asynclitism are the rule in normal labor, but if severe, the asynclitism may lead to cephalopelvic disproportion even with an otherwise normal-sized pelvis. Successive changes from posterior to anterior asynclitism facilitate descent by allowing the fetal head to take advantage of the roomiest areas of the pelvic cavity.

DESCENT. This is the first requisite for birth of the infant. In nulliparas, engagement may take place before the onset of labor, and further descent may not follow until the onset of the second stage. In multiparous women, descent usually begins with engagement. Descent is brought about by one or more of four forces:

1. Pressure of the amniotic fluid.
2. Direct pressure of the fundus upon the breech with contractions.
3. Bearing down efforts with the abdominal muscles.
4. Extension and straightening of the fetal body.

FLEXION. As soon as the descending head meets resistance, whether from the cervix, walls of the pelvis, or pelvic floor, flexion of the head normally results. In this movement, the chin is brought into more intimate contact with the fetal thorax, and the appreciably shorter suboccipitobregmatic diameter is substituted for the longer occipitofrontal diameter ([Figs. 12-15 and 12-16](#)).

INTERNAL ROTATION. This is a turning of the head in such a manner that the occiput gradually moves from its original position anteriorly toward the symphysis pubis or, less commonly, posteriorly toward the hollow of the sacrum ([Figs. 12-17 12-18 12-19](#)). Internal rotation is essential for the completion of labor, except when the fetus is unusually small. While it always is associated with descent, it usually is not accomplished until the head has reached the level of the spines and therefore is engaged.

[Calkins \(1939\)](#) studied more than 5000 women in labor to ascertain the time of internal rotation. He concluded that in approximately two thirds, internal rotation is completed by the time the head reaches the pelvic floor; in about a fourth, internal rotation is completed very shortly after the head reaches the pelvic floor; and in about 5 percent, anterior rotation does not take place. When rotation fails to occur until the head reaches the pelvic floor, it takes place during the next one or two contractions in multiparas; and in nulliparas, it occurs during the next three to five. He also found that rotation before the head reaches the pelvic floor is more frequent in multiparas than in nulliparas.

EXTENSION. When, after internal rotation, the sharply flexed head reaches the vulva, it undergoes extension which is essential to birth. This brings the base of the occiput into direct contact with the inferior margin of the symphysis pubis ([Fig. 12-18](#)). Because the vulvar outlet is directed upward and forward, extension must occur before the head can pass through it. If the sharply flexed head, on reaching the pelvic floor, did not extend but was driven farther downward, it would impinge upon the posterior portion of the perineum and would eventually be forced through the tissues of the perineum. When the head presses upon the pelvic gutter, however, two forces come into play. The first, exerted by the uterus, acts more posteriorly, and the second, supplied by the resistant pelvic floor and the symphysis, acts more anteriorly. The resultant vector is in the direction of the vulvar opening, thereby causing extension.

With progressive distention of the perineum and vaginal opening, an increasingly larger portion of the occiput gradually appears. The head is born by further extension as the occiput, bregma, forehead, nose, mouth, and finally the chin pass successively over the anterior margin of the perineum ([Fig. 12-19](#)). Immediately after its birth, the head drops downward so that the chin lies over the maternal anal region.

EXTERNAL ROTATION. The delivered head next undergoes restitution. If the occiput was originally directed toward the left, it rotates toward the left ischial tuberosity; if it was originally directed toward the right, the occiput rotates to the right. Restitution of the head to the oblique position is followed by completion of external rotation to the transverse position, a movement that corresponds to rotation of the fetal body, serving to bring its bisacromial diameter into relation with the anteroposterior diameter of the pelvic outlet. Thus, one shoulder is anterior behind the symphysis and the other is posterior. This movement is apparently brought about by the same pelvic factors that produced internal rotation of the head.

EXPULSION. Almost immediately after external rotation, the anterior shoulder appears under the symphysis pubis, and the perineum soon becomes distended by the posterior shoulder. After delivery of the shoulders, the rest of the body is quickly extruded.

OCCIPUT POSTERIOR POSITION

In the great majority of labors in the occiput posterior positions, the mechanism of labor is identical to that observed in the transverse and anterior varieties, except that the occiput has to rotate to the symphysis pubis through 135 degrees, instead of 90 and 45 degrees, respectively ([Fig. 12-19](#)).

With effective contractions, adequate flexion of the head, and a fetus of average size, the great majority of posteriorly positioned occiputs rotate promptly as soon as they reach the pelvic floor, and labor is not lengthened appreciably. In perhaps 5 to 10 percent of cases, however, these favorable circumstances do not occur ([Gardberg and Tuppurainen, 1994b](#)). For example, with poor contractions, faulty flexion of the head, or both, rotation may be incomplete or may not take place at all, especially if the fetus is large. Epidural analgesia, which diminishes abdominal muscular pushing as well as relaxing the muscles of the pelvic floor, also predisposes to incomplete rotation ([Chap. 15, p. 376](#)). If rotation is incomplete, transverse arrest results. If rotation toward the symphysis does not take place, the occiput may rotate to the direct occiput posterior position, a condition known as *persistent occiput posterior*. Both persistent occiput posterior and transverse arrest represent deviations from the normal mechanisms of labor and are considered further in [Chapter 19](#).

Utilizing sonography in 408 women in labor at term, [Gardberg and colleagues \(1998\)](#) found that 68 percent of persistent occiput posterior positions resulted from malrotation during labor from an occipitoanterior position. Only approximately a third of persistent cases were in a posterior position at the onset of labor. In a review of 210 vaginal occiput posterior deliveries, [Riethmuller and colleagues \(1999\)](#) report that the overall prognosis for this presentation was good.

CHANGES IN SHAPE OF THE FETAL HEAD

CAPUT SUCCEDANEUM

In vertex presentations, the fetal head undergoes important characteristic changes in shape as the result of the pressures to which it is subjected during labor. In prolonged labors before complete cervical dilatation, the portion of the fetal scalp immediately over the cervical os becomes edematous, forming a swelling known as the *caput succedaneum* ([Fig. 12-20](#)). It usually attains a thickness of only a few millimeters, but in prolonged labors it may be sufficiently extensive to prevent the differentiation of the various sutures and fontanelles. More commonly the caput is formed when the head is in the lower portion of the birth canal and frequently only after the resistance of a rigid vaginal outlet is encountered. Because it occurs over the most dependent area of the head, in [LOT³](#) position it is found over the upper and posterior portion of the right parietal bone, and in ROT positions over the corresponding area of the left parietal bone. It follows that after labor the original position may often be ascertained by noting the location of the caput succedaneum.

MOLDING

Molding describes the change in fetal head shape from external compressive forces. Some molding occurs before labor, possibly related to Braxton Hicks contractions. Although taught in previous editions, most studies indicate that there is seldom overlapping of the parietal bones. Instead, a "locking" mechanism at the coronal and lambdoidal connections prevents such overlapping ([Carlan and colleagues, 1991](#)). Molding is associated with a shortened suboccipitobregmatic diameter and a lengthening of the mentovertebral diameter. These changes are of greatest importance in contracted pelvises or asynclitic presentations. In these circumstances, the degree to which the head is capable of molding may make the difference between spontaneous vaginal delivery versus an operative delivery. Some older literature cited severe head molding as a cause for possible cerebral trauma. Because of the multitude of associated factors, for example, prolonged labor with fetal sepsis and acidosis, it is impossible to quantify the effects of molding with any alleged fetal or neonatal neurological sequelae.

13. Conduct of Normal Labor and Delivery

The ideal conduct of labor and delivery requires two potentially opposing accommodations on the part of obstetrical providers: first, that birthing be recognized as a normal physiological process that most women experience without complications, and second, that intrapartum complications can arise very quickly and unexpectedly. Thus, providers must simultaneously make the woman and her supporters feel comfortable, yet ensure safety for the mother and infant should complications suddenly develop. The [American Academy of Pediatrics and the American College of Obstetricians and Gynecologists \(1997\)](#) have collaborated in the development of *Guidelines for Perinatal Care*. These provide detailed information on the appropriate content of intrapartum care to include both personnel and facility requirements. Shown in [Table 13-1](#) are the recommended nurse-to-patient ratios recommended for labor and delivery. Shown in [Table 13-2](#) are the recommended room dimensions for these functions.

ADMISSION PROCEDURES

Pregnant women should be urged to report early in labor rather than to procrastinate until delivery is imminent for fear that they might be experiencing false labor. Early admittance to the labor and delivery unit is important; especially so if during antepartum care the woman, her fetus, or both have been identified as being at risk.

IDENTIFICATION OF LABOR. One of the most critical diagnoses in obstetrics is the accurate diagnosis of labor. If labor is falsely diagnosed, inappropriate interventions to augment labor may be made. Conversely, if labor is not diagnosed, the fetus-infant may be damaged by unexpected complications occurring in sites remote from medical personnel and adequate medical facilities. Although the differential diagnosis between false and true labor is difficult at times, it usually can be made on the basis of the contractions.

Contractions of True Labor

- Contractions occur at regular intervals
- Intervals gradually shorten
- Intensity gradually increases
- Discomfort is in the back and abdomen
- Cervix dilates
- Discomfort is not stopped by sedation

Contractions of False Labor

- Contractions occur at irregular intervals
- Intervals remain long
- Intensity remains unchanged
- Discomfort is chiefly in lower abdomen
- Cervix does not dilate
- Discomfort is usually relieved by sedation

In those instances when a diagnosis of labor cannot be established with certainty, it is often wise to observe the woman over a longer period of time. The general condition of mother and fetus should be ascertained accurately by history and physical examination, including blood pressure, temperature, and pulse. The frequency, duration, and intensity of the uterine contractions should be documented, and the time established when they first become uncomfortable. The degree of discomfort that the mother displays is noted. The heart rate, presentation, and size of the fetus should be determined and documented on admission. **The fetal heart rate should be checked, especially at the end of a contraction and immediately thereafter, to identify pathological slowing of the heart rate** ([Chap. 14, p. 354](#)). Inquiries are made about the status of the fetal membranes and whether there has been any vaginal bleeding. The questions of whether fluid has leaked from the vagina and, if so, how much and when the leakage first commenced are also addressed.

FEDERAL REQUIREMENTS FOR INTER-HOSPITAL TRANSFER OF LABORING WOMEN. All Medicare-participating hospitals with emergency services must provide an appropriate medical screening examination for any pregnant woman experiencing contractions who comes to the emergency department for evaluation. The definition of an emergency condition makes specific reference to a pregnant woman who is having contractions. Labor is defined as "...the process of childbirth beginning with the latent phase of labor continuing through delivery of the placenta. A woman experiencing contractions is in true labor unless a physician certifies that after a reasonable time of observation the woman is in false labor." A woman in true labor is considered "unstable" for inter-hospital transfer purposes until the child and placenta are delivered. An unstable woman may, however, be transferred at the direction of the patient or when a physician signs a written certification that benefits of treatment at another facility outweigh the risks of transfer. Physicians and hospitals violating these federal requirements are subject to civil penalties of up to \$50,000, as well as termination from the Medicare program.

ELECTRONIC ADMISSION TESTING. Some investigators recommend that a nonstress test (NST) or contraction stress test (CST) be performed on all patients admitted to the labor and delivery unit, the so-called "fetal admission test" ([Ingemarsson and associates, 1986](#)). Such fetal surveillance is in reality an assessment of fetal heart rate accelerations or lack of the same with fetal movement ([NST¹](#)); or an assessment of fetal heart rate before, during, and following a uterine contraction if the patient is in labor ([CST²](#)) ([Freeman and colleagues, 1991](#)). Fetal heart rate variability and variable decelerations also are used in these evaluations. It has been suggested that such tests of fetal well-being, alone or in combination with fetal acoustic stimulation, will identify unsuspected cases of fetal jeopardy ([Ingemarsson and associates, 1988](#); [Sarno and co-workers, 1990](#)). Certainly, if the woman is to be discharged from the labor unit undelivered, this practice is reasonable to ensure, as nearly as possible, that fetal compromise is not identified at this time. At Parkland Hospital, external electronic monitoring is performed for at least one hour before discharging women with false labor.

VAGINAL EXAMINATION. Most often, *unless there has been bleeding in excess of bloody show*, a vaginal examination under aseptic conditions is performed. Careful attention to the following items is essential in order to obtain the greatest amount of information and to minimize bacterial contamination from multiple examinations.

1. *Amnionic fluid.* If there is a question of membrane rupture, a sterile speculum is carefully inserted, and fluid is sought in the posterior vaginal fornix. Any fluid is observed for vernix or meconium; if the source of the fluid remains in doubt, it is collected on a swab for further study, as described later.
2. *Cervix.* Softness, degree of effacement (length), extent of dilatation, and location of the cervix with respect to the presenting part and vagina are ascertained, as will be described. The presence of membranes with or without amnionic fluid below the presenting part often can be felt by careful palpation. The fetal membranes often can be visualized if they are intact and the cervix is dilated somewhat.
3. *Presenting part.* The nature of the presenting part should be positively determined and, ideally, its position as well, as described in [Chapter 12](#).
4. *Station.* The degree of descent of the presenting part into the birth canal is identified, as will be described. If the fetal head is high in the pelvis (above the level of the ischial spines), the effect of firm fundal pressure on descent of the fetal head is tested.
5. *Pelvic architecture.* The diagonal conjugate, ischial spines, pelvic sidewalls, and sacrum are reevaluated for adequacy ([Chap. 3, p. 51](#)).

CERVICAL EFFACEMENT. The degree of cervical effacement is usually expressed in terms of the length of the cervical canal compared to that of an uneffaced cervix ([Chap. 11, p. 256](#)). When the length of the cervix is reduced by one half, it is 50 percent effaced; when the cervix becomes as thin as the adjacent lower uterine segment, it is completely, or 100 percent, effaced.

CERVICAL DILATATION. This is ascertained by estimating the average diameter of the cervical opening. The examining finger is swept from the margin of the cervix on one side to the opposite side, and the diameter traversed is expressed in centimeters. The cervix is said to be dilated fully when the diameter measures 10 cm, because the presenting part of a term-size infant usually can pass through a cervix this widely dilated.

POSITION OF THE CERVIX. The relationship of the cervical os to the fetal head is categorized as posterior, midposition, or anterior. A posterior position is suggestive of preterm labor.

STATION. The level of the presenting fetal part in the birth canal is described in relationship to the ischial spines, which are halfway between the pelvic inlet and the pelvic outlet. When the lowermost portion of the presenting fetal part is at the level of the ischial spines, it is designated as being at zero (0) station. In the past, the long axis of the birth canal above the ischial spines was arbitrarily divided into thirds. In 1988, the American College of Obstetricians and Gynecologists began using a classification of station that divides the pelvis above and below the spines into fifths. These divisions represent centimeters above and below the spines. Thus, as the presenting fetal part descends from the inlet toward the ischial spines, the designation is -5, -4, -3, -2, -1, then 0 station. Below the ischial spines, the presenting fetal part passes +1, +2, +3, +4, and +5 stations to delivery. Station +5 cm corresponds to the fetal head being visible at the introitus. An approximate correlation of the two methods of describing station is: +2 cm = +1/3 and +4 cm = +2/3 ([American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 1997](#)).

If the leading part of the fetal head is at 0 station or below, most often engagement of the head has occurred; that is, the biparietal plane of the fetal head has passed through the pelvic inlet. **If the head is unusually molded, or if there is an extensive caput formation, or both, engagement might not have taken place even though the head appears to be at 0 station.**

DETECTION OF RUPTURED MEMBRANES. The pregnant woman should be instructed during the antepartum period to be aware of leakage of fluid from the vagina and to report such an occurrence promptly. Rupture of the membranes is significant for three reasons. First, if the presenting part is not fixed in the pelvis, the possibility of prolapse of the umbilical cord and cord compression is greatly increased. Second, labor is likely to occur soon if the pregnancy is at or near term. Third, if delivery is delayed for 24 hours or more after membrane rupture, there is increasing likelihood of serious intrauterine infection.

A conclusive diagnosis of rupture of the membranes is made when amniotic fluid is seen pooling in the posterior fornix or clear fluid is passing from the cervical canal ([American College of Obstetricians and Gynecologists, 2000](#)). Although several diagnostic tests for the detection of ruptured membranes have been recommended, none is completely reliable. If the diagnosis remains uncertain, another method involves testing the pH of the vaginal fluid; the pH of vaginal secretions normally ranges between 4.5 and 5.5, whereas that of amniotic fluid is usually 7.0 to 7.5. The use of the indicator **nitrazine** for the diagnosis of ruptured membranes, first suggested by [Baptisti \(1938\)](#), is a simple and fairly reliable method. Test papers are impregnated with the dye, and the color of the reaction is interpreted by comparison with a standard color chart. The pH of the vaginal secretion is estimated by inserting a sterile cotton-tipped applicator deeply into the vagina, and then touching it to a strip of the nitrazine paper and comparing the color of the paper with the chart supplied with the paper. A pH above 6.5 is consistent with ruptured membranes. False-positive tests occur with blood, semen, or bacterial vaginosis and false-negative tests with minimal fluid ([American College of Obstetricians and Gynecologists, 2000](#)).

Other tests have been used as markers for rupture of the membranes. Arborization or ferning of vaginal fluid suggests amniotic rather than cervical fluid. Detection of alpha-fetoprotein in the vaginal vault has been used to identify amniotic fluid ([Yamada and colleagues, 1998](#)). Unequivocal identification comes from injection of various dyes, including Evans blue, methylene blue, indigo carmine, or fluorescein, into the amniotic sac via abdominal amniocentesis.

VITAL SIGNS AND REVIEW OF PREGNANCY RECORD. The maternal blood pressure, temperature, pulse, and respiratory rate are checked for any abnormality, and these are recorded. The pregnancy record is promptly reviewed to identify complications. Any problems identified during the antepartum period, as well as any that were anticipated, should be displayed prominently in the pregnancy record.

PREPARATION OF VULVA AND PERINEUM. The woman is positioned to allow inspection and cleansing of the vulva and perineum. Scrubbing is directed from above, downward, and away from the introitus. Attention should be paid to careful cleansing of the vulvar folds. As the scrub sponge passes over the anal region, it is discarded. If hair on the lower half of the vulva or perineum is felt to interfere at the time of delivery, it can be clipped with scissors or a mini-shave prep can be performed. Routine shaving of the perineum is not performed at Parkland Hospital.

VAGINAL EXAMINATIONS. Ideally, after the vulvar and perineal regions have been properly prepared, and the examiner has donned sterile gloves, the thumb and forefinger of one hand are used to separate the labia widely to expose the vaginal opening and prevent the examining fingers from coming in contact with the inner surfaces of the labia. The index and second fingers of the other hand are then introduced into the vagina ([Fig. 13-1](#)). A precise routine of evaluation, as described earlier should be followed. It is important to avoid the anal region and not to withdraw the fingers from the vagina until the examination is completed. The number of vaginal examinations during labor does correlate with infectious morbidity, especially in cases of early membrane rupture.

ENEMA. Early in labor, a cleansing enema often is given to minimize subsequent contamination by feces, which otherwise may be a problem during the second stage of labor and delivery. A ready-to-use enema solution of sodium phosphate in a disposable container (Fleet enema) has proven satisfactory. Enemas are not routinely used at Parkland Hospital.

LABORATORY. When the woman is admitted in labor, most often the hematocrit, or hemoglobin concentration, should be rechecked. The hematocrit can be measured easily and quickly. Blood may be collected in a plain tube from which a heparinized capillary tube is filled immediately. By employing a small microhematocrit centrifuge in the labor-delivery unit, the value can be obtained in 3 minutes. A labeled tube of blood is allowed to clot and is kept on hand for blood type and screen, if needed, and another is used for routine serology. In some units, a voided urine specimen, as free as possible of debris, is examined for protein and glucose. We obtain a urine specimen for protein analysis only in hypertensive women. Patients who have had no prenatal care should be considered to be at risk for syphilis, hepatitis B, and human immunodeficiency virus ([American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 1997](#)). In unregistered patients, these laboratory studies as well as a blood type, Rh, and antibody screen for atypical antibodies should be performed. Some states, for example Texas, now require routine testing for syphilis, hepatitis B, and human immunodeficiency virus in all women admitted to labor and delivery units.

MANAGEMENT OF FIRST STAGE OF LABOR

As soon as possible after admittance, the remainder of the general physical examination is completed. The physician can best reach a conclusion about the normalcy of the pregnancy when all examinations, including record and laboratory review, are completed. A rational plan for monitoring labor then can be established based on the needs of the fetus and the mother. If no abnormality is identified or suspected, the mother should be reassured. Although the average duration of the first stage of labor in nulliparous women is about 7 hours and in parous women about 4 hours, there are marked individual variations. Any precise statement as to the duration of labor, therefore, is unwise ([Chap. 18, p. 427](#)).

MONITORING FETAL WELL-BEING DURING LABOR

It is mandatory for optimal pregnancy outcome that a well-defined program be established that provides careful surveillance of the well-being of both mother and fetus during labor. All observations must be appropriately recorded. The frequency, intensity, and duration of uterine contractions, and the response of the fetal heart rate to the contractions, are of considerable concern. These features can be promptly evaluated in logical sequence.

FETAL HEART RATE. The fetal heart rate may be identified with a suitable stethoscope or any of a variety of Doppler ultrasonic devices. Changes in the fetal heart rate that most likely are ominous almost always are detectable immediately after a uterine contraction. Therefore, it is imperative that the fetal heart be monitored by auscultation immediately after a contraction. To avoid confusing maternal and fetal heart rates, the maternal pulse should be counted as the fetal heart rate is counted. Otherwise, maternal tachycardia may be misinterpreted as a normal fetal heart rate.

Fetal jeopardy, compromise, or distress—that is, loss of fetal well-being—is suspected if the fetal heart rate immediately after a contraction is repeatedly below 110 bpm. Fetal jeopardy very likely exists if the rate is heard to be less than 100 per minute, even though there is recovery to a rate in the 110 to 160 bpm range before

the next contraction. When decelerations of this magnitude are found after a contraction, further labor, if allowed, is best monitored electronically, as described in [Chapter 14](#).

The [American Academy of Pediatrics and American College of Obstetricians and Gynecologists \(1997\)](#) recommend that during the first stage of labor, in the absence of any abnormalities, the fetal heart should be checked immediately after a contraction at least every 30 minutes and then every 15 minutes during the second stage. If continuous electronic monitoring is used, the tracing is evaluated at least every 30 minutes during the first stage and at least every 15 minutes during second-stage labor. For women with pregnancies at risk, auscultation is performed at least every 15 minutes during the first stage of labor and every 5 minutes during the second stage. Continuous electronic monitoring may be used with evaluation of the tracing every 15 minutes during the first stage of labor, and every 5 minutes during the second stage.

UTERINE CONTRACTIONS. With the palm of the hand lightly on the uterus, the examiner determines the time of onset of the contraction. The intensity of the contraction is gauged from the degree of firmness the uterus achieves. At the acme of effective contractions, the finger or thumb cannot readily indent the uterus. Next, the time that the contraction disappears is noted. This sequence is repeated in order to evaluate the frequency, duration, and intensity of uterine contractions. It is best to quantify the contractions as regards the degree of firmness or resistance to indentation.

MATERNAL MONITORING AND MANAGEMENT DURING LABOR

MATERNAL VITAL SIGNS. Maternal temperature, pulse, and blood pressure are evaluated at least every 4 hours ([Table 13-3](#)). If fetal membranes have been ruptured for many hours before the onset of labor, or if there is a borderline temperature elevation, the temperature is checked hourly. Moreover, with prolonged membrane rupture—defined as greater than 18 hours—antimicrobial administration for prevention of group B streptococcal infections is recommended ([American College of Obstetricians and Gynecologists, 1996](#)). This is discussed in [Chapter 56 \(p. 1471\)](#).

SUBSEQUENT VAGINAL EXAMINATIONS. During the first stage of labor, the need for subsequent vaginal examinations to identify the status of the cervix and the station and position of the presenting part will vary considerably ([Table 13-3](#)). When the membranes rupture, an examination should be repeated expeditiously if the fetal head was not definitely engaged at the previous vaginal examination. The fetal heart rate should be checked immediately and during the next uterine contraction in order to detect an occult umbilical cord compression. At Parkland Hospital, periodic pelvic examinations are often performed at 2- to 3-hour intervals to evaluate the progress of labor ([Chap. 18, p. 446](#)).

ORAL INTAKE. Food should be withheld during active labor and delivery. Gastric emptying time is remarkably prolonged once labor is established and analgesics are administered. As a consequence, ingested food and most medications remain in the stomach and are not absorbed; instead, they may be vomited and aspirated ([Chap. 15, p. 366](#)). There is a trend toward giving liquids in moderation to laboring women ([Table 13-3](#)). [Guyton and Gibbs \(1994\)](#) cite studies in which 150 mL of fluids were given orally 2 hours before elective surgery. The incidence of aspiration was not affected. It is unclear whether these studies can be applied to women in labor, who are at risk for urgent cesarean delivery at all times.

INTRAVENOUS FLUIDS. Although it has become customary in many hospitals to establish an intravenous infusion system routinely early in labor, there is seldom any real need for such in the normally pregnant woman at least until analgesia is administered. An intravenous infusion system is advantageous during the immediate puerperium in order to administer oxytocin prophylactically, and at times therapeutically when uterine atony persists. Moreover, with longer labors, the administration of glucose, sodium, and water to the otherwise fasting woman at the rate of 60 to 120 mL/hr is efficacious to prevent dehydration and acidosis ([Table 13-3](#)).

MATERNAL POSITION DURING LABOR. The normal laboring woman need not be confined to bed early in labor. A comfortable chair may be beneficial psychologically and perhaps physiologically. In bed, the laboring woman should be allowed to assume the position she finds most comfortable, which will be lateral recumbency most of the time. She must not be restricted to lying supine. [Bloom and colleagues \(1998\)](#) conducted a randomized trial of walking during labor in over 1000 women with low-risk pregnancies. They found that walking neither enhanced nor impaired active labor and that it was not harmful.

ANALGESIA. As noted in [Table 13-3](#), most often, analgesia is initiated on the basis of maternal discomfort. The kinds of analgesia, amounts, and frequency of administration should be based on the need to allay pain on the one hand and the likelihood of delivering a depressed infant on the other ([Chap. 15, p. 363](#)).

The timing, method of administration, and size of initial and subsequent doses of systemically acting analgesic agents are based to a considerable degree on the anticipated interval of time until delivery. A repeat vaginal examination is often appropriate before administering more analgesia. With the onset of symptoms characteristic of the second stage of labor, that is, an urge to bear down or "push," the status of the cervix and the presenting part should be reevaluated.

AMNIOTOMY. If the membranes are intact, there is a great temptation even during normal labor to perform amniotomy. The presumed benefits are more rapid labor, earlier detection of instances of meconium staining of amniotic fluid, and the opportunity to apply an electrode to the fetus and insert a pressure catheter into the uterine cavity. The advantages and disadvantages of amniotomy are discussed in [Chapter 18 \(p. 446\)](#). If amniotomy is performed, an aseptic technique should be used. Importantly, the fetal head must be well applied to the cervix and not be dislodged from the pelvis during the procedure; such an action invites prolapse of the umbilical cord.

URINARY BLADDER FUNCTION. Bladder distention should be avoided, because it can lead to obstructed labor and to subsequent bladder hypotonia and infection. During each abdominal examination, the suprapubic region should be visualized and palpated in order to detect a filling bladder. If the bladder is readily seen or palpated above the symphysis, the woman should be encouraged to void. At times she can ambulate with assistance to a toilet and successfully void, even though she could not void on a bedpan. If the bladder is distended and she cannot void, intermittent catheterization is indicated.

MANAGEMENT OF SECOND-STAGE LABOR

With full dilatation of the cervix, which signifies the onset of the second stage of labor, the woman typically begins to bear down, and with descent of the presenting part she develops the urge to defecate. Uterine contractions and the accompanying expulsive forces may last 1 1/2 minutes and recur at times after a myometrial resting phase of no more than a minute.

DURATION

The median duration of the second stage is 50 minutes in nulliparas and 20 minutes in multiparas, but it can be highly variable. In a woman of higher parity with a relaxed vagina and perineum, two or three expulsive efforts after the cervix is fully dilated may suffice to complete the delivery of the infant. Conversely, in a woman with a contracted pelvis or a large fetus, or with impaired expulsive efforts from conduction analgesia or intense sedation, the second stage may become abnormally long ([Chap. 18, p. 430](#)).

FETAL HEART RATE. For the low-risk fetus, the heart rate should be auscultated during the second stage of labor at least every 15 minutes, whereas in those at high risk, 5-minute intervals are recommended ([American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 1997](#)). Slowing of the fetal heart rate induced by head compression is common during a contraction and the accompanying maternal expulsive efforts. If recovery of the fetal heart rate is prompt after the contraction and expulsive efforts cease, labor is allowed to continue. Not all instances of fetal heart rate slowing during second-stage labor are the consequence of head compression. The vigorous force generated within the uterus by its contraction and by maternal expulsive efforts may reduce placental perfusion appreciably. Descent of the fetus through the birth canal and the consequent reduction in uterine volume may trigger some degree of premature separation of the placenta, with further compromise of fetal well-being. Descent is more likely to tighten a loop or loops of umbilical cord around the fetus, especially the neck, sufficiently to obstruct umbilical blood flow. Prolonged, uninterrupted maternal expulsive efforts can be dangerous to the fetus in these circumstances. Maternal tachycardia, which is common during the second stage, must not be mistaken for a normal fetal heart rate.

MATERNAL EXPULSIVE EFFORTS. In most cases, bearing down is reflex and spontaneous during second-stage labor, but occasionally the woman does not employ her expulsive forces to good advantage and coaching is desirable. Her legs should be half-flexed so that she can push with them against the mattress. Instructions should be to take a deep breath as soon as the next uterine contraction begins, and with her breath held, to exert downward pressure exactly as though she were straining at stool. She should not be encouraged to "push" beyond the time of completion of each uterine contraction. Instead, she and her fetus should be allowed to rest and recover from the combined effects of the uterine contraction, breath holding, and considerable physical effort. [Gardosi and associates \(1989\)](#) have recommended a squatting or semi-squatting position using a specialized pillow. They claim that this shortens second-stage labor by increasing expulsive forces and by increasing the diameter of the pelvic outlet. [Eason and colleagues \(2000\)](#) performed an extensive review of positions and their effect on the incidence of perineal trauma. They found that the supported upright position had no advantages over the recumbent one.

Usually, bearing down efforts result in increasing bulging of the perineum—that is, further descent of the fetal head. The woman should be informed of such progress, for encouragement is very important. During this period of active bearing down, the fetal heart rate auscultated immediately after the contraction is likely to be slow, but should recover to normal range before the next expulsive effort.

As the head descends through the pelvis, feces is frequently expelled by the woman. As the head descends still farther, the perineum begins to bulge and the overlying skin becomes tense and glistening. Now the scalp of the fetus may be visible through the vulvar opening ([Fig. 13-2](#)). At this time, or before in instances where little perineal resistance to expulsion is anticipated, the woman and her fetus are prepared for delivery.

PREPARATION FOR DELIVERY. Delivery can be accomplished with the mother in a variety of positions. The most widely used and often the most satisfactory one is the dorsal lithotomy position in order to increase the diameter of the pelvic outlet. In many birthing rooms this is accomplished with the woman lying flat on the bed. For better exposure, leg holders or stirrups are used. In placing the legs in leg holders, care should be taken not to separate the legs too widely or place one leg higher than the other, as this will exert pulling forces on the perineum that might easily result in the extension of a spontaneous tear or an episiotomy into a fourth-degree tear. The popliteal region should rest comfortably in the proximal portion and the heel in the distal portion of the leg-holder. The leg should not be forced to conform to the preexisting setting. The legs are not strapped into the stirrups, thereby allowing quick flexion of the thighs back onto the abdomen should shoulder dystocia be encountered. Cramps in the legs may develop during the second stage in part because of pressure by the fetal head on nerves in the pelvis. Such cramps may be relieved by changing the position of the leg or by brief massage, but leg cramps should never be ignored.

Preparation for delivery entails vulvar and perineal cleansing. If desired, sterile drapes may be placed in such a way that only the immediate area about the vulva is exposed ([Fig. 13-3](#)). In the past, the major reason for care in scrubbing, gowning, and gloving was to protect the laboring woman from the introduction of infectious agents. Although these considerations remain valid, concern today also must be extended to the health-care providers, because of the threat of exposure to human immunodeficiency virus. Recommendations for protection of those who care for women during labor and delivery are summarized in [Chapter 57 \(p. 1498\)](#).

SPONTANEOUS DELIVERY

DELIVERY OF THE HEAD

With each contraction, the perineum bulges increasingly and the vulvovaginal opening becomes more dilated by the fetal head ([Fig. 13-4](#)), gradually forming an ovoid and finally an almost circular opening. With the cessation of each contraction, the opening becomes smaller as the head recedes. As the head becomes increasingly visible, the vaginal outlet and vulva are stretched further until they ultimately encircle the largest diameter of the fetal head ([Fig. 13-5](#)). This encirclement of the largest head diameter by the vulvar ring is known as crowning.

Unless an episiotomy has been made, as described later in the chapter, the perineum by now is extremely thin and, especially in the case of the nulliparous woman, may undergo spontaneous laceration. At the same time, the anus becomes greatly stretched and protuberant, and the anterior wall of the rectum may be easily seen through it. Over many years there has been considerable controversy concerning whether an episiotomy should be cut. We advocate individualization and do not routinely cut an episiotomy. It is now clear that an episiotomy will increase the risk of a tear into the external anal sphincter and/or the rectum. Conversely, anterior tears involving the urethra and labia are much more common in women in whom an episiotomy is not cut. This is discussed in detail on page 325.

RITGEN MANEUVER. By the time the head distends the vulva and perineum (during a contraction) enough to open the vaginal introitus to a diameter of 5 cm or more, a towel-draped, gloved hand may be used to exert forward pressure on the chin of the fetus through the perineum just in front of the coccyx. At the same time, the other hand exerts pressure superiorly against the occiput ([Fig. 13-6](#)). Although this maneuver is simpler than that originally described by [Ritgen \(1855\)](#), it is customarily designated the Ritgen maneuver, or the modified Ritgen maneuver. It allows control of the delivery of the head. It also favors extension, so that the head is delivered with its smallest diameters passing through the introitus and over the perineum ([Fig. 13-7](#)). The head is delivered slowly with the base of the occiput rotating around the lower margin of the symphysis pubis as a fulcrum, while the bregma (anterior fontanel), brow, and face pass successively over the perineum ([Fig. 13-8](#)).

DELIVERY OF SHOULDERS

After its birth, the head falls posteriorly, bringing the face almost into contact with the anus. As described in [Chapter 12](#), the occiput promptly turns toward one of the maternal thighs so that the head assumes a transverse position ([Fig. 13-9](#)). The movement of restitution (external rotation) indicates that the bisacromial diameter (transverse diameter of the thorax) has rotated into the anteroposterior diameter of the pelvis.

Most often, the shoulders appear at the vulva just after external rotation and are born spontaneously. Occasionally, a delay occurs and immediate extraction may appear advisable. In this event, the sides of the head are grasped with the two hands and gentle downward traction applied until the anterior shoulder appears under the pubic arch ([Fig. 13-10](#)). Some practitioners prefer to deliver the anterior shoulder prior to suctioning the nasopharynx or checking for a nuchal cord to try to avoid shoulder dystocia. Next, by an upward movement, the posterior shoulder is delivered ([Fig. 13-10](#)).

The rest of the body almost always follows the shoulders without difficulty; but in case of prolonged delay, its birth may be hastened by moderate traction on the head and moderate pressure on the uterine fundus. Hooking the fingers in the axillae should be avoided because this may injure the nerves of the upper extremity, producing a transient or possibly even a permanent paralysis. Traction, furthermore, should be exerted only in the direction of the long axis of the infant, for if applied obliquely it causes bending of the neck and excessive stretching of the brachial plexus.

Immediately after delivery of the infant, there is usually a gush of amniotic fluid, often tinged with blood but not grossly bloody.

CLEARING THE NASOPHARYNX. To minimize the likelihood of aspiration of amniotic fluid, debris, and blood that might occur once the thorax is delivered and the infant can inspire, the face is quickly wiped and the nares and mouth are aspirated, as demonstrated in [Figure 13-9](#).

NUCHAL CORD. Following delivery of the anterior shoulder, the finger should be passed to the neck of the fetus to ascertain whether it is encircled by one or more coils of the umbilical cord ([Fig. 13-11](#)). Nuchal cords occur in about 25 percent of cases and ordinarily do no harm. If a coil of umbilical cord is felt, it should be drawn down between the fingers and, if loose enough, slipped over the infant's head. If it is applied too tightly to the neck to be slipped over the head, it should be cut between two clamps and the infant promptly delivered.

CLAMPING THE CORD

The umbilical cord is cut between two clamps placed 4 or 5 cm from the fetal abdomen, and later an umbilical cord clamp is applied 2 or 3 cm from the fetal abdomen. A plastic clamp (Hollister, Double Grip Umbilical Clamp) that is safe, efficient, easy to sterilize, and fairly inexpensive is shown in [Figure 13-12](#).

TIMING OF CORD CLAMPING. If, after delivery, the infant is placed at or below the level of the vaginal introitus for 3 minutes and the fetoplacental circulation is not immediately occluded by clamping the cord, an average of 80 mL of blood may be shifted from the placenta to the infant ([Yao and Lind, 1974](#)). One benefit to be derived from placental transfusion is that the hemoglobin in 80 mL of placental blood that shifts to the fetus eventually provides about 50 mg of iron, which reduces the frequency of iron-deficiency anemia later in infancy. In the presence of accelerated destruction of erythrocytes, as occurs with maternal alloimmunization, the bilirubin formed from the added erythrocytes contributes further to the danger of hyperbilirubinemia ([Chap. 39, p. 1061](#)). Although the theoretical risk of circulatory overloading from gross hypervolemia is formidable, especially in preterm and growth-retarded infants, addition of placental blood to the otherwise normal infant's circulation ordinarily does not cause difficulty.

Our policy is to clamp the cord after first thoroughly clearing the airway, all of which usually takes about 30 seconds. The infant is not elevated above the introitus at vaginal delivery or much above the maternal abdominal wall at the time of cesarean delivery.

MANAGEMENT OF THE THIRD STAGE

Immediately after delivery of the infant, the height of the uterine fundus and its consistency are ascertained. As long as the uterus remains firm and there is no unusual bleeding, watchful waiting until the placenta is separated is the usual practice. No massage is practiced; the hand is simply rested on the fundus frequently, to make certain that the organ does not become atonic and filled with blood behind a separated placenta.

SIGNS OF PLACENTAL SEPARATION

Because attempts to express the placenta prior to its separation are futile and possibly dangerous, it is most important that the following signs of placental separation be recognized:

1. The uterus becomes globular and, as a rule, firmer. This sign is the earliest to appear.
2. There is often a sudden gush of blood.
3. The uterus rises in the abdomen because the placenta, having separated, passes down into the lower uterine segment and vagina, where its bulk pushes the uterus upward.
4. The umbilical cord protrudes farther out of the vagina, indicating that the placenta has descended.

These signs sometimes appear within about 1 minute after delivery of the infant and usually within 5 minutes. When the placenta has separated, it should be ascertained that the uterus is firmly contracted. The mother may be asked to bear down, and the intra-abdominal pressure so produced may be adequate to expel the placenta. If these efforts fail, or if spontaneous expulsion is not possible because of anesthesia, and after ensuring that the uterus is contracted firmly, pressure is exerted with the hand on the fundus to propel the detached placenta into the vagina, as depicted and described in [Figure 13-13](#). This approach has been termed physiological management, as later to be contrasted with "active management" of the third stage ([Thilaganathan and colleagues, 1993](#)).

DELIVERY OF THE PLACENTA

Placental expression should never be forced before placental separation lest the uterus be turned inside out. **Traction on the umbilical cord must not be used to pull the placenta out of the uterus.** *Inversion* of the uterus is one of the grave complications associated with delivery ([Chap. 25, p. 642](#)). As pressure is applied to the body of the uterus ([Fig. 13-13](#)), the umbilical cord is kept slightly taut. The uterus is lifted cephalad with the abdominal hand. This maneuver is repeated until the placenta reaches the introitus ([Prendiville and associates, 1988b](#)). As the placenta passes through the introitus, pressure on the uterus is stopped. The placenta is then gently lifted away from the introitus ([Fig. 13-14](#)). Care is taken to prevent the membranes from being torn off and left behind. If the membranes start to tear, they are grasped with a clamp and removed by gentle traction ([Fig. 13-15](#)). The maternal surface of the placenta should be examined carefully to ensure that no placental fragments are left in the uterus.

MANUAL REMOVAL OF PLACENTA. Occasionally, the placenta will not separate promptly. This is especially common in cases of preterm delivery ([Dombrowski and colleagues, 1995](#)). If at any time there is brisk bleeding and the placenta cannot be delivered by these techniques, manual removal of the placenta is indicated, using the safeguards described in [Chapter 25](#) (p. 638 and [Fig. 25-17](#)). It is unclear as to the length of time that should elapse in the absence of bleeding before the placenta is manually removed. Manual removal of the placenta is rightfully practiced much sooner and more often than in the past. In fact, some obstetricians practice routine manual removal of any placenta that has not separated spontaneously by the time they have completed delivery of the infant and care of the cord in women with conduction analgesia. Proof of the benefits of this practice, however, has not been established, and most obstetricians await spontaneous placental separation unless bleeding is excessive.

ACTIVE MANAGEMENT OF THE THIRD STAGE

[Thilaganathan and associates \(1993\)](#) compared a regimen of active management with syntometrine (5 units of oxytocin with 0.5 mg of ergometrine) and controlled cord traction with one of physiological management wherein the cord was not clamped and the placenta was delivered by maternal efforts. Among 103 low-risk term deliveries, active management resulted in a reduction in the length of the third stage of labor, but no reduction in blood loss compared with physiological management. [Mitchell and Elbourne \(1993\)](#) found that syntometrine administered intramuscularly concurrent with delivery of the anterior shoulder was more effective than oxytocin (5 units intramuscularly) alone in the prevention of postpartum hemorrhage. Duration of the third stage of labor and need for manual removal of the placenta were similar. Side effects of nausea, vomiting, and blood pressure elevations with ergometrine prevented any recommendation for its routine usage.

"FOURTH STAGE" OF LABOR

The placenta, membranes, and umbilical cord should be examined for completeness and for anomalies, as described in [Chapters 31](#) and [32](#). The hour immediately following delivery is critical and it has been designated by some as the "fourth stage of labor." Even though oxytocics are administered, postpartum hemorrhage as the result of uterine atony is more likely at this time. The uterus is frequently evaluated during this time. The perineum likewise is inspected frequently to detect excessive bleeding. The [American Academy of Pediatrics and the American College of Obstetricians and Gynecologists \(1997\)](#) recommend that maternal blood pressure and pulse should be recorded immediately after delivery and every 15 minutes for the first hour.

OXYTOCIC AGENTS

After the uterus has been emptied and the placenta has been delivered, the primary mechanism by which hemostasis is achieved at the placental site is vasoconstriction produced by a well-contracted myometrium. Oxytocin (Pitocin, Syntocinon), ergonovine maleate (Ergotrate), and methylergonovine maleate (Methergine) are employed in various ways in the conduct of the third stage of labor, principally to reduce blood loss by stimulating myometrial contractions ([Phillips and Kinch, 1994](#); [Prendiville and associates, 1988a](#)).

OXYTOCIN

The synthetic form of the octapeptide oxytocin is commercially available in the United States as Syntocinon and Pitocin; 1 mg of oxytocin is equal to about 500 USP units. Each mL of injectable oxytocin contains 10 USP units, which is not effective by mouth. The half-life of intravenously infused oxytocin is approximately 3 minutes.

Before delivery, the spontaneously laboring uterus is very likely to be exquisitely sensitive to oxytocin. With an inappropriate dose of oxytocin, the pregnant uterus may contract so violently as to kill the fetus, rupture itself, or both ([Chap. 20, p. 476](#)). After delivery of the fetus, these dangers no longer exist. Nonetheless, at this time, there are other potentially grave dangers from inappropriate use of oxytocin.

CARDIOVASCULAR EFFECTS. Deleterious effects may on occasion follow the intravenous injection of a bolus of oxytocin. [Hendricks and Brenner \(1970\)](#) demonstrated with the rapid intravenous injection of 5 units (0.5 mL) of oxytocin that the uterus contracted tetanically for several minutes and maternal blood pressure decreased simultaneously. In one dramatic instance of hypotension from uterine bleeding following delivery of twins, they noted that a bolus injection of 5 units of oxytocin intravenously was promptly followed by a further decrease in blood pressure from 70/42 to 44/26 mm Hg ([Fig. 13-16](#)). After rapid administration of 500 mL of saline, the blood pressure increased and the mother again became responsive.

[Secher and co-workers \(1978\)](#) consistently observed that, even in healthy women, an intravenous bolus of 10 units of oxytocin caused a transient but marked fall in arterial blood pressure that was followed by an abrupt increase in cardiac output. They too concluded that these hemodynamic changes could be dangerous to women already hypovolemic from hemorrhage, or who had cardiac disease that limited cardiac output. The same danger is present for women with right-to-left cardiac shunts, as the decrease in systemic resistance would further increase the shunt. **Oxytocin should not be given intravenously as a large bolus**, but rather as a much more dilute solution by continuous intravenous infusion, or be injected intramuscularly in a dose of 10 USP units. In cases of postpartum hemorrhage, direct injection into the uterus, either transvaginally or transabdominally, if following a vaginal birth, or directly if at cesarean delivery, has also proven effective. The use of nipple stimulation in the third stage of labor has also been shown to increase uterine pressures and to decrease the duration of the third stage of labor as well as blood loss ([Irons and associates, 1994](#)). Indeed, results were similar to those achieved using the combination of oxytocin (5 units) and ergometrine (0.5 mg).

ANTI-DIURESIS. Although rare today, water intoxication causing maternal convulsions may result from the considerable antidiuretic action of oxytocin ([Abdul-Karim and Assali, 1961](#)). In women who are undergoing diuresis in response to the administration of water, the continuous intravenous infusion of 20 mU of oxytocin per minute usually produces a demonstrable decrease in urine flow. When the rate of infusion is raised to 40 mU/min, urinary flow is strikingly reduced. With doses of this magnitude, it is possible to produce water intoxication if the oxytocin is administered in a large volume of electrolyte-free aqueous dextrose solution ([Eggers and Fliegner, 1979](#); [Whalley and Pritchard, 1963](#)). [Schwartz and Jones \(1978\)](#) described convulsions in both the mother and her newborn following the administration of 6.5 liters of 5 percent dextrose solution and 36 units of oxytocin predelivery. The concentration of sodium in cord plasma was 114 mEq/L.

In general, if oxytocin is to be administered in high doses for a considerable period of time, its concentration should be increased rather than increasing the rate of flow of a more dilute solution (see [Chap. 20](#)). Consideration should also be given to use of either normal saline or lactated Ringer solution in these circumstances.

ERGONOVINE AND METHYLERGONOVINE

Ergonovine is an alkaloid obtained from ergot, a fungus that grows on rye and some other grains, or it is synthesized in part from lysergic acid. Methylergonovine and ergonovine (also ergometrine or ergostetrine) are very similar alkaloids made from lysergic acid. The alkaloids are dispensed as the maleate (Ergotrate and Methergine) either in solution for parenteral use or in tablets for oral use.

EFFECTS. There is no convincing evidence of any appreciable difference in the actions of ergonovine and methylergonovine. Whether given intravenously, intramuscularly, or orally, ergonovine and methylergonovine are powerful stimulants of myometrial contraction, exerting an effect that may persist for hours. The sensitivity of the pregnant uterus to ergonovine and methylergonovine is very great. In pregnant women, an intravenous dose of as little as 0.1 mg, or an oral dose of only 0.25 mg, results in a tetanic uterine contraction that occurs almost immediately after intravenous injection of the drug and within a few minutes after intramuscular or oral administration. Moreover, the response is sustained with little tendency toward relaxation. The tetanic effect of ergonovine and methylergonovine is effective for the prevention and control of postpartum hemorrhage, but is very dangerous for the fetus and the mother prior to delivery.

The parenteral administration of these alkaloids, especially by the intravenous route, sometimes initiates transient but severe hypertension. Such a reaction is most likely when conduction analgesia is used for delivery and in women who are prone to develop hypertension. [Browning \(1974\)](#) described four instances of serious postdelivery side effects attributable to 0.5 mg of ergonovine administered intramuscularly. Two women promptly became severely hypertensive, the third became hypertensive and convulsed, and the fourth suffered a cardiac arrest. We have also seen an instance of such profound vasoconstriction from these compounds when given intravenously that all peripheral pulses were lost, and sodium nitroprusside was required to restore the peripheral circulation. Unfortunately, the mother sustained cerebral hypoxic ischemic injury. Because of the frequency of hypertension among our obstetrical population, we do not use these alkaloids routinely.

PROSTAGLANDINS

Prostaglandin compounds are not used routinely for management of the third stage of labor. Their use is restricted to the management of postpartum hemorrhage due to uterine atony, which is discussed in [Chapter 25 \(p. 637\)](#).

OXYTOCICS AFTER DELIVERY

Oxytocin, ergonovine, and methylergonovine are all employed widely in the conduct of the normal third stage of labor, but the timing of their administration differs in various institutions. Oxytocin, and especially ergonovine, given before delivery of the placenta will decrease blood loss somewhat ([Prendiville and associates, 1988a](#)). There is, however, a significant danger associated with this practice. The use of oxytocin, and especially ergonovine or methylergonovine, before delivery of the placenta may entrap an undiagnosed, undelivered second twin. This may prove injurious, if not fatal, to the entrapped fetus. In most cases following uncomplicated vaginal delivery, the third stage of labor can be conducted with reasonably small blood loss without using these agents before delivery of the placenta ([Mitchell and Elbourne, 1993](#); [Thilaganathan and associates, 1993](#)).

If an intravenous infusion is in place, our standard practice has been to add 20 units (2 mL) of oxytocin per liter of infusate. This solution is administered after delivery of the placenta at a rate of 10 mL/min (200 mU/min) for a few minutes until the uterus remains firmly contracted and bleeding is controlled. The infusion rate then is reduced to 1 to 2 mL/min until the mother is ready for transfer from the recovery suite to the postpartum unit. At this time, the infusion is usually discontinued.

LACERATIONS OF THE BIRTH CANAL

Lacerations of the vagina and perineum are classified as first, second, third, or fourth degree. First-degree lacerations involve the fourchette, perineal skin, and vaginal mucous membrane but not the underlying fascia and muscle. Second-degree lacerations involve, in addition to skin and mucous membrane, the fascia and muscles of the perineal body but not the anal sphincter ([Fig. 13-17](#)). These tears usually extend upward on one or both sides of the vagina, forming an irregular triangular injury. Third-degree lacerations extend through the skin, mucous membrane, and perineal body, and involve the anal sphincter. A fourth-degree laceration extends through the rectal mucosa to expose the lumen of the rectum. Tears in the region of the urethra that may bleed profusely are also likely to occur with this type of laceration.

Because the repair of perineal tears is virtually the same as that of episiotomy incisions, albeit often less satisfactory because of irregular lines of tissue cleavage, the technique of repairing lacerations is discussed in the following section.

EPISIOTOMY AND REPAIR

In a strict sense, episiotomy is incision of the pudenda. Perineotomy is incision of the perineum. In common parlance, however, episiotomy is often used synonymously with perineotomy, a practice that will be followed here. The incision may be made in the midline (median or midline episiotomy), or it may begin in the midline but be directed laterally and downward away from the rectum (mediolateral episiotomy).

PURPOSES OF EPISIOTOMY

While still a common obstetrical procedure, the use of episiotomy has decreased remarkably over the past 20 years. Through the 1970s, it was common practice to cut an episiotomy for almost all women having their first delivery. This practice became controversial, and with the concept of evidence-based outcomes, a number of large studies have been carried out to address these controversies. The reasons for its popularity included substitution of a straight, neat surgical incision for the ragged laceration that otherwise might result. It is easier to repair, but the long-held beliefs that postoperative pain is less and healing improved with an episiotomy compared with a tear appeared not to be true ([Larsson and colleagues, 1991](#)).

Another commonly cited but unproven benefit of routine episiotomy was that it prevented pelvic relaxation, that is, cystocele, rectocele, and urinary incontinence. A number of observational studies and randomized trials showed that routine episiotomy is associated with an increased incidence of anal sphincter and rectal tears ([Angioli, 2000](#); [Argentine Collaborative Group, 1993](#); [Eason, 2000](#); [Henriksen, 1992](#); [Thorp, 1987](#); [Wilcox, 1989](#), and all their colleagues).

[Caroli and Belizan \(2000\)](#) reviewed the Cochrane Pregnancy and Childbirth Group trials registry. There were six randomized trials of nearly 5000 deliveries in which routine (73 percent rate) versus restrictive (28 percent rate) use of episiotomy was evaluated. There was less posterior perineal trauma, need for repair, and healing complications in the restrictive-use group. Alternatively, there was less anterior perineal trauma in the routine-use group. Along with these findings came the realization that while episiotomy did not protect the perineal body, it contributed to anal sphincter incontinence by increasing the risk of third- and fourth-degree tears. [Signorello and associates \(2000\)](#) reported that fecal and flatus incontinence were increased four- to sixfold in women with an episiotomy compared with a group delivered over an intact perineum. Even compared with spontaneous perineal lacerations, episiotomy tripled the risk of fecal incontinence and doubled it for flatus incontinence. Non-extension of the episiotomy did not lower this risk. Finally, even with recognition and repair of a third-degree extension, 30 to 40 percent of women have long-term anal incontinence ([Gjessing and co-workers, 1998](#); [Poen and colleagues, 1998](#)).

It seems reasonable to conclude that episiotomy should not be performed routinely ([Eason and Feldman, 2000](#)). The procedure should be applied selectively for appropriate indications, some of which include fetal indications such as shoulder dystocia and breech delivery; forceps or vacuum extractor operations; occiput posterior positions; and in instances where it is obvious that failure to perform an episiotomy will result in perineal rupture. **The final rule is that there is no substitute for surgical judgment and common sense.**

The important variables if an episiotomy is to be used include when the incision is performed, the type of incision, and techniques for repair.

TIMING OF EPISIOTOMY

If episiotomy is performed unnecessarily early, bleeding from the incision may be considerable during the interim between the episiotomy and the delivery. If episiotomy is performed too late, lacerations will not be prevented. It is common practice to perform episiotomy when the head is visible during a contraction to a

diameter of 3 to 4 cm (see [Fig. 13-4](#)). When used in conjunction with forceps delivery, most practitioners perform an episiotomy after application of the blades ([Chap. 21, p. 493](#)).

MIDLINE VERSUS MEDIOLATERAL EPISIOTOMY

The advantages and disadvantages of the two types of episiotomies are summarized in [Table 13-4](#). Except for the important issue of third- and fourth-degree extensions, midline episiotomy is superior. With proper selection of cases, it is possible to secure the advantages of midline episiotomy and at the same time reduce to a minimum this one disadvantage. In addition to a midline episiotomy, [Combs and associates \(1990\)](#) reported the following factors to be associated with an increased risk for third- and fourth-degree lacerations: nulliparity, second-stage arrest of labor, persistent occiput posterior position, mid- or low-forceps instead of a vacuum extractor, use of local anesthetics, and Asian race.

It is reasonable to use a mediolateral episiotomy when a third- or fourth-degree extension is likely, but to employ the midline incision otherwise. This policy was substantiated by [Anthony and colleagues \(1994\)](#), who presented data from the Dutch National Obstetric Database of over 43,000 deliveries. Indeed, many practitioners in the United States use midline episiotomy exclusively. Even with careful selection, however, the total number of third- and fourth-degree lacerations sustained with this policy is probably greater than with routine mediolateral episiotomy.

[Venkatesh and colleagues \(1989\)](#) reported a 5-percent incidence of third- and fourth-degree perineal tears in 20,500 vaginal deliveries. About 10 percent of these 1040 primary repairs had a wound disruption and 67 of the 101 required surgical correction. [Goldaber and associates \(1993\)](#) found that 21 of 390 (5.4 percent) women with fourth-degree lacerations experienced significant morbidity. There were 7 (1.8 percent) dehiscences, 11 (2.8 percent) infections with dehiscences, and 3 (0.8 percent) infections alone. Although administration of perioperative antibiotics (cefazolin sodium, 2 g intravenously) reduced this morbidity, it was not totally eliminated.

TIMING OF THE REPAIR OF EPISIOTOMY

The most common practice is to defer episiotomy repair until the placenta has been delivered. This policy permits undivided attention to the signs of placental separation and delivery. Early delivery of the placenta is believed to decrease blood loss from the implantation site because it prevents the development of extensive retroplacental bleeding. A further advantage is that episiotomy repair is not interrupted or disrupted by the obvious necessity of delivering the placenta, especially if manual removal must be performed.

TECHNIQUE

There are many ways to close an episiotomy incision, but *hemostasis and anatomical restoration without excessive suturing are essential* for success with any method. A technique that commonly is employed is shown in [Figure 13-18](#). The suture material ordinarily used is 3-0 chromic catgut, but [Grant \(1989\)](#) recommends suture composed of derivatives of polyglycolic acid. A decrease in postsurgical pain is cited as the major advantage of the newer materials despite the occasional need to remove some of the suture from the site of repair. It is important to distinguish that the repairs described by Grant involved predominantly mediolateral episiotomies and an entirely different closure, including transdermal sutures, than is usually employed for midline episiotomies, especially as done in the United States.

FOURTH-DEGREE LACERATION. The technique of repairing a fourth-degree laceration is shown in [Figure 13-19](#). Various techniques have been recommended; but in all instances, it is essential to approximate the torn edges of the rectal mucosa with muscularis sutures placed approximately 0.5 cm apart. This muscular layer then is covered with a layer of fascia. Finally, the cut ends of the anal sphincter are isolated, approximated, and sutured together with three or four interrupted stitches. The remainder of the repair is the same as for an episiotomy. Stool softeners should be prescribed for a week, and enemas should be avoided. Prophylactic antimicrobials should be considered, as described by [Goldaber and colleagues \(1993\)](#).

Unfortunately, normal function is not always assured even with correct and complete surgical repair. Some women may experience continuing fecal incontinence due to injury to the innervation of the pelvic floor musculature ([Roberts and co-workers, 1990](#)).

PAIN AFTER EPISIOTOMY

Application of ice packs tends to reduce swelling and allay discomfort. Aerosol sprays containing a local anesthetic are helpful at times. Analgesics such as codeine give considerable relief. **Because pain may be a signal of a large vulvar, paravaginal, or ischioanal hematoma or perineal cellulitis, it is essential to examine these sites carefully if pain is severe or persistent.** Management of these complications is discussed in [Chapter 25](#).

TABLE 13-3. Recommendations for Conduct of Normal First- and Second-Stage Labor in Women without Any Anesthetic, Medical, or Obstetrical Risk Factors

1. Maternal vital signs are checked at least every 4 hours.
2. Periodic vaginal examinations using sterile, water-soluble lubricants; avoid povidone-iodine and hexachlorophene antiseptics.
3. Sips of clear liquids, occasional ice chips, and lip moisturizers are permitted. Intravenous hydration is indicated when labor is lengthy.
4. The mother should have the option to stay out of bed during the early stages of labor.
5. Pain relief should depend on the needs and desires of the woman.

From the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 1997, with permission.

Repair of median episiotomy. **A.** Chromic 2-0 or 3-0 suture is used as a continuous suture to close the vaginal mucosa and submucosa. **B.** After closing the vaginal incision and reapproximating the cut margins of the hymenal ring, the suture is tied and cut. Next, three or four interrupted sutures of 2-0 or 3-0 chromic are placed in the fascia and muscle of the incised perineum. **C.** A continuous suture is carried downward to unite the superficial fascia. **D.** Completion of repair. The continuous suture is carried upward as a subcuticular stitch. (An alternative method of closure of skin and subcutaneous fascia is illustrated in E.) **E.** Completion of repair of median episiotomy. A few interrupted sutures of 3-0 chromic are placed through the skin and subcutaneous fascia and loosely tied. This closure avoids burying two layers of suture in the more superficial layers of the perineum.

14. Intrapartum Assessment

As safe methods were developed to intervene operatively during labor, various methods of intrapartum surveillance have been designed. Periodic auscultation with a fetoscope led to development of continuous electronic fetal heart rate monitoring, which is a marvelous invention introduced into obstetrical practice during the late 1960s. No longer was the perception of fetal distress limited to heart sounds; the continuous graph paper portrayal of the fetal heart rate was potentially diagnostic in assessing pathophysiological events affecting the fetus. There were great expectations that:

1. Electronic fetal heart rate monitoring provided accurate information.
2. The information was of value in diagnosing fetal distress.
3. It would be possible to intervene to prevent fetal death or morbidity.
4. Continuous electronic fetal heart rate monitoring was superior to intermittent methods.

When first introduced, electronic fetal heart rate monitoring was used primarily in complicated pregnancies, but gradually it came to be used in most pregnancies. By 1978 it was estimated that nearly two thirds of American women were being monitored electronically during labor ([Banta and Thacker, 1979](#)). In 1998, nearly 3.3 million American women, comprising 84 percent of all live births, underwent electronic fetal monitoring ([Ventura and colleagues, 2000](#)). Indeed, fetal monitoring was the most prevalent obstetrical procedure in the United States.

INTRAPARTUM FETAL ASSESSMENT

INTERNAL ELECTRONIC FETAL HEART RATE MONITORING

The fetal heart rate may be measured by attaching a bipolar spiral electrode directly to the fetus ([Fig. 14-1](#)). The wire electrode penetrates the fetal scalp and the second pole is the metal wing on the electrode. Vaginal body fluids create a saline electrical bridge that completes the circuit and permits measurement of the voltage differences between the two poles. The electrical fetal cardiac signal—P wave, QRS complex, and T wave—is amplified and fed into a cardiometer for heart rate calculation. The peak R-wave voltage is the portion of the fetal electrocardiogram most reliably detected. The two wires of the bipolar electrode are attached to a reference electrode on the maternal thigh to eliminate electrical interference. Shown in [Figure 14-2](#) is an example of the method of fetal heart rate processing employed when a scalp electrode is used. Time (t) in milliseconds between fetal R waves is fed into a cardiometer, where a new fetal heart rate is set with the arrival of each new R wave. As shown in [Figure 14-2](#), a premature atrial contraction is computed as a heart rate acceleration because the interval (t_2) is shorter than the preceding one (t_1). The phenomena of continuous R wave to R wave fetal heart rate computation is known as *beat-to-beat variability*. The physiological event being counted, however, is not a mechanical event corresponding to a heartbeat but rather an electrical event.

Electrical cardiac complexes detected by the electrode include those generated by the mother. Although the maternal electrocardiogram (ECG) signal is approximately five times stronger than the fetal [ECG¹](#), its amplitude is diminished when it is recorded through the fetal scalp electrode. In a live fetus, this low maternal ECG signal is detected but masked by the fetal ECG. If the fetus is dead, the weaker maternal signal will be amplified by the automatic gain control circuitry in the fetal monitor and displayed as "fetal" heart rate ([Freeman and co-authors, 1991](#)). Shown in [Figure 14-3](#) are simultaneous recordings of maternal chest wall ECG signals and fetal scalp electrode ECG signals. This fetus is experiencing premature atrial contractions, which cause the cardiometer to rapidly and erratically seek new heart rates, resulting in the rate "spiking" shown in the standard fetal monitor tracing. Importantly, when the fetus is dead, the maternal R waves are still detected by the scalp electrode and are counted by the cardio-tachometer as the next best signal ([Fig. 14-4](#)).

EXTERNAL (INDIRECT) ELECTRONIC FETAL HEART RATE MONITORING

The necessity for membrane rupture and uterine invasion may be avoided by use of external detectors to monitor fetal heart action and uterine activity. External monitoring does not provide the precision of fetal heart measurement or the quantification of uterine pressure afforded by internal monitoring.

The fetal heart rate is detected through the maternal abdominal wall using the *ultrasound Doppler principle* ([Fig. 14-5](#)). Ultrasonic waves undergo a shift in frequency as they are reflected from moving fetal heart valves and from pulsatile blood ejected during systole. The unit consists of a transducer that emits ultrasound and a sensor to detect a shift in frequency of the reflected sound. The transducer is placed on the maternal abdomen at a site where fetal heart action is best detected. A coupling gel must be applied because air conducts ultrasound poorly. The device is held in position by a belt. Care should be taken that maternal aortic pulsations are not confused with fetal cardiac motion.

Ultrasound Doppler signals are edited electronically before fetal heart rate data are printed onto the bedside monitor tracing paper. Reflected ultrasound signals from moving fetal heart valves are put through a microprocessor that compares incoming signals with the most recent previous signal. This process, called *auto-correlation*, is based on the premise that the fetal heart rate has regularity whereas "noise" is random and without regularity. Several fetal heart motions must be deemed electronically acceptable by the microprocessor before the fetal heart rate is printed. Such electronic editing has greatly improved the tracing quality of externally recorded fetal heart rate.

FETAL HEART RATE PATTERNS

It is now generally accepted that interpretation of fetal heart rate patterns can be problematic because of the lack of agreement on definitions and nomenclature ([Parer and Quilligan, 1996](#)). The National Institute of Child Health and Human Development (NICHD) Fetal Monitoring Workshop (1997) brought together investigators with expertise in the field to propose standardized, unambiguous definitions for interpretation of fetal heart rate patterns during labor. The definitions proposed as a result of this workshop will be used in this chapter. It is important to recognize that interpretation of electronic fetal heart rate data is based upon the visual pattern of the heart rate as portrayed on chart recorder graph paper. Thus, the choice of vertical and horizontal scaling greatly affects the appearance of the fetal heart rate. Scaling factors recommended by the workshop are 30 bpm per vertical cm (range, 30 to 240 bpm) and 3 cm/min chart recorder paper speed. Fetal heart rate variation is falsely displayed at the slower 1 cm/min paper speed when compared with the smoother baseline recorded at 3 cm/min ([Fig. 14-6](#)). Thus, pattern recognition can be considerably distorted depending on the scaling factors used.

BASELINE FETAL HEART ACTIVITY. Baseline fetal heart activity refers to the modal characteristics that prevail apart from periodic accelerations or decelerations associated with uterine contractions. Descriptive characteristics of baseline fetal heart activity include *rate*, *beat-to-beat variability*, *fetal arrhythmia*, and distinct patterns such as *sinusoidal* or *saltatory* fetal heart rates.

RATE. With increasing fetal maturation, the heart rate decreases. This continues postnatally such that the average rate is 90 bpm by age 8 ([Behrman, 1992](#)). [Pillai and James \(1990\)](#) longitudinally studied fetal heart rate characteristics in 43 normal pregnancies. The base-line fetal heart rate decreased an average of 24 bpm between 16 weeks and term, or approximately 1 bpm/week. At 16 weeks the average baseline rate was about 160 bpm, which decreased to 150 at 40 weeks. It is postulated that this normal gradual slowing of the fetal heart rate corresponds to maturation of parasympathetic (vagal) heart control ([Renou and co-workers, 1969](#)).

The baseline fetal heart rate is the approximate mean rate rounded to increments of 5 bpm during a 10-minute tracing segment. In any 10-minute window the minimum interpretable baseline duration must be at least 2 min-utes. If the baseline fetal heart rate is less than 110 bpm, it is termed **bradycardia**; if the baseline rate is greater than 160 bpm, it is termed **tachycardia**. The average fetal heart rate is considered to be the result of tonic balance between *accelerator* and *decelerator* influences on pacemaker cells. In this concept, the sympathetic system is the accelerator influence, and the parasympathetic system is the decelerator factor mediated via vagal slowing of heart rate ([Dawes, 1985](#)). Heart rate is also under the control of arterial chemoreceptors such that both hypoxia and hypercapnia can modulate rate. More severe and prolonged hypoxia, with a rising blood lactate level and severe metabolic acidemia, induces a prolonged fall of heart rate due to direct effects on the myocardium.

BRADYCARDIA. During the third trimester, the normal mean baseline fetal heart rate has generally been accepted to be between 120 and 160 bpm. The lower normal limit is disputed internationally with some investigators recommending 110 bpm ([Manassiev, 1996](#)). Pragmatically, a rate between 100 and 119 bpm, in the absence of other changes, is usually not considered to represent fetal compromise. Such low but potentially normal baseline heart rates have also been attributed to head compression from occiput posterior or trans-verse positions, particularly during second-stage labor ([Young and Weinstein, 1976](#)). Such mild bradycardias were

observed in 2 percent of monitored pregnancies and averaged about 50 minutes in duration. Moderate bradycardias are defined as 80 to 100 bpm, and severe bradycardias are less than 80 bpm, for 3 minutes or longer ([Freeman and co-authors, 1991](#)).

Other causes of fetal bradycardia include congenital heart block and serious fetal compromise. [Figure 14-7](#) shows bradycardia in a fetus dying from placental abruption. Maternal hypothermia under general anesthesia for repair of a cerebral aneurysm or during maternal cardiopulmonary bypass for open-heart surgery can also cause fetal bradycardia ([Chap. 44, p. 1187](#)). Sustained fetal bradycardia in the setting of severe pyelonephritis and maternal hypothermia has also been reported ([Hankins and co-workers, 1997](#)). These infants are apparently not harmed by several hours of such bradycardia.

TACHYCARDIA. This is considered by most as *mild* if the baseline rate is between 161 and 180 bpm and *severe* if 181 or more. The most common explanation for fetal tachycardia is maternal fever from amnionitis, although fever from any source can increase baseline fetal heart rate. Such infections have also been observed to induce fetal tachycardia before overt maternal fever is diagnosed ([Gilstrap and associates, 1987](#)). Fetal tachycardia caused by maternal infection is typically not associated with fetal compromise unless there are associated periodic heart rate changes or fetal sepsis.

Other causes of fetal tachycardia include fetal compromise, cardiac arrhythmias, and maternal administration of parasympathetic (atropine) or sympathomimetic (terbutaline) drugs. The key feature to distinguish fetal compromise in association with tachycardia seems to be concomitant heart rate decelerations. Prompt relief of the compromising event, such as correction of maternal hypotension caused by epidural analgesia, can result in fetal recovery.

BEAT-TO-BEAT VARIABILITY. Baseline variability is an important index of cardiovascular function and appears to be regulated largely by the autonomic nervous system ([Kozuma and colleagues, 1997](#)). That is, sympathetic and parasympathetic control via the sinoatrial node mediates moment-to-moment or beat-to-beat oscillation of the baseline heart rate. Such irregularity of the heart rate is defined as baseline variability. Variability is further divided into *short term* and *long term*.

Short-term variability reflects the instantaneous change in fetal heart rate from one beat (or R wave) to the next. This variability is a measure of the time interval between cardiac systoles ([Fig. 14-8](#)). *It can most reliably be determined to be normally present only when electrocardiac cycles are measured directly with a scalp electrode.*

Long-term variability is used to describe the oscillatory changes that occur during the course of 1 minute and result in the waviness of the baseline ([Fig. 14-9](#)). The normal frequency of such waves is three to five cycles per minute ([Freeman and co-authors, 1991](#)).

It should be recognized that precise quantitative analysis of both short- and long-term variability presents a number of frustrating problems due to technical and scaling factors. For example, [Parer and co-workers \(1985\)](#) evaluated 22 mathematical formulas designed to quantify heart rate variability and most were unsatisfactory. Consequently, most clinical interpretation is based on visual analysis with subjective judgment of the smoothness or flatness of the baseline. The [NICHD² Fetal Monitoring Workshop \(1997\)](#) did not recommend differentiating short-term variability and long-term variability because in actual practice they are visually determined as a unit.

The Workshop did, however, define baseline variability as those baseline fluctuations of two cycles per minute or greater. They recommended the criteria shown in [Figure 14-10](#) for quantification of variability. Normal beat-to-beat variability was accepted to be 6 to 25 bpm.

Several physiological and pathological processes can affect or interfere with beat-to-beat variability. [Dawes and co-workers \(1981\)](#) described increased variability during **fetal breathing**. In healthy infants, short-term variability is attributable to respiratory sinus arrhythmia ([Divon and co-workers, 1986](#)). **Fetal body movements** also affect variability. [Granat and co-investigators \(1979\)](#) observed that fetuses exhibited 40- to 80-minute cycles of movements thought to correspond to fetal wakefulness. [Van Geijn and co-workers \(1980\)](#) analyzed electroencephalographic data in healthy term infants and observed 30- to 70-minute sleep cycles corresponding to fetal physical inactivity. [Pillai and James \(1990\)](#) reported increased baseline variability with **advancing gestation**. Up to 30 weeks, baseline characteristics were similar during both fetal rest and activity. After 30 weeks, fetal inactivity was associated with diminished baseline variability and, conversely, variability was increased during fetal activity. Fetal gender does not affect heart rate variability ([Ogueh and Steer, 1998](#)).

It is important to recognize that the baseline fetal heart rate becomes more physiologically fixed (less variable) as the rate increases. Conversely, there is more instability or variability of the baseline at lower heart rates. This phenomenon presumably reflects less cardiovascular physiological wandering as beat-to-beat intervals shorten due to increasing heart rate.

Diminished beat-to-beat variability can be an ominous sign indicating a seriously compromised fetus. [Paul and co-workers \(1975\)](#) reported that loss of variability in combination with decelerations was associated with fetal acidemia. They analyzed variability in the 20 minutes preceding delivery in 194 pregnancies. Decreased variability was defined as 5 or fewer bpm excursion of the baseline ([Fig. 14-10](#)), whereas acceptable variability exceeded this range. Fetal scalp pH was measured 1119 times in these pregnancies, and mean values were progressively more acidemic when decreased variability was added to progressively intense heart rate decelerations. For example, mean fetal scalp pH was about 7.10 when severe decelerations were combined with 5 bpm or less variability, compared with a pH about 7.20 when greater variability was associated with similarly severe decelerations.

Severe **maternal acidemia** can also cause decreased fetal beat-to-beat variability, as shown in [Figure 14-11](#) in a mother with diabetic ketoacidosis. The precise pathological mechanisms by which fetal hypoxemia results in diminished beat-to-beat variability are not totally understood.

Although loss of variability and its ominous significance are concepts familiar to most obstetricians, mild degrees of fetal hypoxemia have been reported to *increase* variability, at least at the outset of the hypoxic episode ([Murotsuki and co-authors, 1997](#)). According to [Dawes \(1985\)](#), it seems probable that the loss of variability is a result of metabolic acidemia that causes depression of the fetal brainstem or the heart itself. Thus, diminished beat-to-beat variability, when a reflection of compromised fetal condition, likely reflects acidemia rather than hypoxia.

A common cause of diminished beat-to-beat variability is analgesic drugs given during labor. A large variety of central nervous system depressant drugs can cause transient diminished beat-to-beat variability. Included are narcotics, barbiturates, phenothiazines, tranquilizers, and general anesthetics. Diminished variability occurs regularly within 5 to 10 minutes following intravenous meperidine administration, and the effects may last up to 60 minutes or longer depending on the dosage given ([Petrie, 1993](#)). Butorphanol given intravenously diminishes fetal heart rate reactivity ([Schucker and colleagues, 1996](#)). Reduced variability was observed by [Viscomi and co-workers \(1990\)](#) but not [Hoffman and associates \(1996\)](#) when fentanyl was administered epidurally for labor analgesia.

Magnesium sulfate, widely used in the United States for tocolysis as well as management of hypertensive women, has been arguably associated with diminished beat-to-beat variability. [Hallak and colleagues \(1999\)](#) randomized 34 normal, nonlaboring women to standard magnesium sulfate infusion versus isotonic saline. Magnesium sulfate was associated with statistically decreased variability only in the third hour of the infusion. However, the average decrease in variability was deemed clinically insignificant because the mean variability was 2.7 bpm in the third hour of magnesium infusion compared with 2.8 bpm at baseline. Magnesium sulfate also blunted the frequency of accelerations.

It is generally believed that reduced baseline heart rate variability is the single most reliable sign of fetal compromise. For example, [Smith and co-workers \(1988\)](#) performed a computerized analysis of beat-to-beat variability in growth-restricted fetuses *before* labor. They observed that diminished variability (4.2 bpm or less) that was maintained for 1 hour is diagnostic of developing acidemia and imminent fetal death. By contrast, [Samueloff and associates \(1994\)](#) evaluated variability as a predictor of fetal outcome during labor in 2200 consecutive deliveries. They concluded that variability by itself cannot be used as the only indicator of fetal well-being. Conversely, they also concluded that good variability should not be interpreted as necessarily reassuring.

In summary, beat-to-beat variability is affected by a variety of pathological and physiological mechanisms. Variability has considerably different meaning depending on the clinical setting. The development of decreased variability in the absence of decelerations is unlikely to be due to fetal hypoxia ([Davidson and co-workers, 1992](#)).

CARDIAC ARRHYTHMIA. When fetal cardiac arrhythmias are first suspected using electronic monitoring, findings can include baseline bradycardia, tachycardia, or most commonly in our experience, **abrupt baseline spiking** ([Fig. 14-12](#)). Intermittent baseline bradycardia is frequently due to congenital heart block. Documentation of an arrhythmia can only be accomplished, practically speaking, when scalp electrodes are used. Most fetal monitors can be adapted to output the scalp electrode signals into an electrocardiographic recorder. Because, only a single lead is obtained, this severely restricts interpretation of analysis of rhythm and rate disturbances.

[Southall and co-authors \(1980\)](#) studied antepartum fetal cardiac rate and rhythm disturbances in 934 normal pregnancies between 30 and 40 weeks. Arrhythmias and episodes of bradycardia less than 100 bpm, or tachycardia greater than 180 bpm, were encountered in 3 percent. Most supraventricular arrhythmias are of little

significance during labor unless there is coexistent heart failure as evidenced by fetal hydrops. Many supraventricular arrhythmias disappear in the immediate neonatal period, although some are associated with structural cardiac defects. [Simpson and Sharland \(1998\)](#) retrospectively reviewed 127 consecutive fetuses with tachycardia. Echocardiography showed supraventricular tachycardia in 105 fetuses and atrial flutter in 22. Maternally administered drugs, to include digoxin, verapamil, and flecainide, were used to control the fetal arrhythmias. Almost all nonhydropic fetuses survived the neonatal period compared with only 73 percent in those with hydrops. [Copel and co-authors \(2000\)](#) used echocardiography to evaluate 614 fetuses referred for auscultated irregular heart rate without hydrops. Only 10 fetuses (2 percent) were found to have significant arrhythmias and all but one infant survived.

Other than ectopic systoles, which are as common in fetuses as in adults, ventricular arrhythmias are unusual in utero. As discussed in [Chapter 52 \(p. 1389\)](#), conduction defects, most commonly complete atrioventricular (AV) block, are usually found in association with connective-tissue diseases.

Although most fetal arrhythmias are of little consequence during labor when there is no evidence for fetal hydrops, such arrhythmias impair interpretation of intrapartum heart rate tracings. Ultrasonic survey of fetal anatomy as well as echocardiography may be useful. Some clinicians use fetal scalp sampling as an adjunct. Generally, in the absence of fetal hydrops, neonatal outcome is not measurably improved by pregnancy intervention. At Parkland Hospital, intrapartum fetal cardiac arrhythmias, especially in the presence of clear amniotic fluid, are managed conservatively. [Deans and Steer \(1994\)](#) have extensively reviewed interpretation of the fetal electrocardiogram during labor.

SINUSOIDAL HEART RATES. A true sinusoidal pattern such as that shown in panel 5 of [Figure 14-10](#) may be observed with serious fetal anemia, whether from *D*-isoimmunization, ruptured vasa previa, fetomaternal hemorrhage, or twin-to-twin transfusion. Insignificant sinusoidal patterns have been reported following administration of meperidine, morphine, alphaprodine, and butorphanol ([Angel, 1984](#); [Egley, 1991](#); [Epstein, 1982](#), and their associates). The pattern has also been described with amnionitis, fetal distress, and umbilical cord occlusion ([Murphy and associates, 1991](#)). [Young and co-workers \(1980a\)](#) and [Johnson and colleagues \(1981\)](#) concluded that intrapartum sinusoidal fetal heart patterns were not generally associated with fetal compromise.

[Modanlou and Freeman \(1982\)](#), based on their extensive review, proposed adoption of a strict definition:

1. Stable baseline heart rate of 120 to 160 bpm with regular oscillations.
2. Amplitude of 5 to 15 bpm (rarely greater).
3. Frequency of 2 to 5 cycles/min long-term variability.
4. Fixed or flat short-term variability.
5. Oscillation of the sinusoidal waveform above or below a baseline.
6. Absence of accelerations.

Although these criteria were selected to define a sinusoidal pattern that is most likely ominous, they observed that the pattern associated with alphaprodine is indistinguishable. Other investigators have proposed a classification of sinusoidal heart rate patterns into mild (amplitude 5 to 15 bpm), intermediate (16 to 24 bpm), and major (25 or more bpm) to quantify fetal risk ([Murphy and colleagues, 1991](#); [Neesham and co-workers, 1993](#)).

Some investigators have defined intrapartum sine-wave-like baseline variation with periods of acceleration as *pseudosinusoidal*. [Murphy and co-workers \(1991\)](#) reported that pseudosinusoidal patterns were seen in 15 percent of monitored labors. Mild pseudosinusoidal patterns were associated with use of meperidine and epidural analgesia. Intermediate pseudosinusoidal patterns were linked to fetal sucking or transient episodes of fetal hypoxia caused by umbilical cord compression. In contrast, [Egley and colleagues \(1991\)](#) reported that 4 percent of fetuses demonstrated sinusoidal patterns transiently during normal labor. These authors observed patterns for up to 90 minutes in some cases and also in association with oxytocin and/or alphaprodine usage.

Shown in [Figure 14-13](#) is a sinusoidal pattern seen with maternal meperidine administration. An important characteristic of this pattern when due to narcotics is the 6 cycles/min sine frequency.

The pathophysiology of sinusoidal patterns is unclear, in part due to various definitions. There seems to be general agreement that *antepartum* sine wave baseline undulation portends severe fetal anemia; however, few *d*-isoimmunized fetuses develop this pattern ([Nicolaidis, 1989](#)). The sinusoidal pattern has been reported to develop or disappear after fetal transfusion ([Del Valle and associates, 1992](#); [Lowe and co-workers, 1984](#)). [Ikeda and colleagues \(1999\)](#) have proposed, based upon studies in fetal lambs, that the sinusoidal fetal heart rate pattern is related to waves of arterial blood pressure, reflecting oscillations in the baroreceptor/chemoreceptor feedback mechanism for control of the circulation.

PERIODIC FETAL HEART RATE. The periodic fetal heart rate refers to deviations from baseline that are related to uterine contractions. **Acceleration** refers to an increase in fetal heart rate above baseline and **deceleration** to a decrease below baseline rate. The most commonly used system in the United States is based on the *timing* of the deceleration in relation to contractions—thus, **early**, **late**, or **variable** in onset compared with the corresponding uterine contraction. The waveform of these decelerations is also significant for pattern recognition. In early and late decelerations, the slope of fetal heart rate change is gradual, resulting in a curvilinear and uniform or symmetrical waveform. With variable decelerations, the slope of fetal heart rate change is abrupt and erratic, giving the waveform a jagged appearance. It has been proposed that decelerations be defined as *recurrent* if they occur with 50 percent or more of contractions in any 20-minute period ([NICHD³ Fetal Monitoring Workshop, 1997](#)).

Another system now used less often for description of decelerations is based on the pathophysiological events considered most likely to cause the pattern. In this system, early decelerations are termed *head compression*, late decelerations are termed *uteroplacental insufficiency*, and variable decelerations become *cord compression patterns*. The nomenclature of type I (early), type II (late), and type III (variable) "dips" proposed by [Caldeyro-Barcia and co-workers \(1973\)](#) is not used in the United States.

ACCELERATIONS. An acceleration is a visually apparent abrupt increase (defined as onset of acceleration to a peak in < 30 seconds) in the fetal heart rate baseline ([NICHD⁴ Fetal Monitoring Workshop, 1997](#)). According to [Freeman and co-authors \(1991\)](#), accelerations occur most commonly antepartum, in early labor, and in association with variable decelerations. Proposed mechanisms for intrapartum accelerations include fetal movement, stimulation by uterine contractions, umbilical cord occlusion, and fetal stimulation during pelvic examination. Fetal scalp blood sampling and acoustic stimulation also incite fetal heart rate acceleration ([Clark and co-workers, 1982](#)). Finally, acceleration can occur during labor without any apparent stimulus. Indeed, accelerations are common in labor and nearly always associated with fetal movement. These accelerations are virtually always reassuring and almost always confirm that the fetus is not acidemic at that time.

Accelerations seem to have the same physiological explanations as beat-to-beat variability in that they represent intact neurohormonal cardiovascular control mechanisms linked to fetal behavioral states. [Krebs and co-workers \(1982a\)](#) analyzed electronic heart rate tracings in nearly 2000 fetuses and found sporadic accelerations during labor in 99.8 percent. The presence of fetal heart accelerations during the first and/or last 30 minutes was a favorable sign for fetal well-being. The absence of such accelerations during labor, however, is not necessarily an unfavorable sign unless coincidental with other nonreassuring changes. There is about a 50 percent chance of acidemia in the fetus who fails to respond to stimulation in the presence of an otherwise nonreassuring pattern ([Clark and colleagues, 1984](#); [Smith and colleagues, 1986](#)).

EARLY DECELERATION. Early deceleration of the fetal heart rate is a gradual decrease and return to baseline associated with a contraction ([Fig. 14-14](#)). *Early* deceleration of the fetal heart rate was first described by [Hon \(1958\)](#). He observed that there was a drop in heart rate with uterine contractions, and that this was related to cervical dilatation. He considered these physiological.

[Freeman and co-authors \(1991\)](#) defined early decelerations as those generally seen in active labor between 4 and 7 cm dilatation. In their definition, the degree of deceleration is generally proportional to the contraction strength and rarely falls below 100 to 110 bpm or 20 to 30 bpm below baseline. Such decelerations are uncommon during active labor and are not associated with baseline changes. Importantly, early decelerations are not associated with fetal hypoxia, acidemia, or low Apgar scores.

Head compression probably causes vagal nerve activation due to dural stimulation that mediates heart rate deceleration ([Paul and co-workers, 1964](#)). [Ball and Parer \(1992\)](#) concluded that fetal head compression is a likely cause not only for the deceleration shown in [Figure 14-14](#) but also for those shown in [Figure 14-15](#), which

typically occur during second-stage labor. Indeed, they observed that head compression is the likely cause of many variable decelerations classically attributed to cord compression.

LATE DECELERATION. The fetal heart rate response to uterine contractions can be an index of either uterine perfusion or placental function. A late deceleration is a smooth, gradual symmetrical decrease in fetal heart rate beginning at or after the peak of the contraction and returning to baseline only after the contraction has ended ([American College of Obstetrics and Gynecologists, 1995b](#)). In most cases the onset, nadir, and recovery of the deceleration occur after the beginning, peak, and ending of the contraction, respectively ([Fig. 14-16](#)). The magnitude of late decelerations is rarely more than 30 to 40 bpm below baseline and typically not more than 10 to 20 bpm in intensity. Late decelerations are usually not accompanied by accelerations.

[Myers and associates \(1973\)](#) studied monkeys in which they compromised uteroplacental perfusion by lowering maternal aortic blood pressure. The time interval, or lag period from the onset of a contraction to the onset of a late deceleration, was directly related to basal fetal oxygenation. They demonstrated that the length of the lag phase was predictive of the fetal P_{O_2} but not fetal pH. The lower the fetal P_{O_2} prior to contractions, the shorter the lag phase to onset of late decelerations. This lag period reflected the time necessary for the fetal P_{O_2} to fall below a critical level necessary to stimulate arterial chemoreceptors which mediated decelerations.

[Murata and co-workers \(1982\)](#) also showed that a late deceleration was the first fetal heart rate consequence of uteroplacental induced hypoxia. During the course of progressive hypoxia that led to death over 2 to 13 days, the monkey fetuses invariably exhibited late decelerations before the development of acidemia. Variability of the baseline heart rate disappeared as acidemia developed.

A large number of clinical circumstances can result in late decelerations. Generally, any process that causes maternal hypotension, excessive uterine activity, or placental dysfunction can induce late decelerations. The two most common causes are hypotension from epidural analgesia and uterine hyperactivity due to oxytocin stimulation. Maternal diseases such as hypertension, diabetes, and collagen-vascular disorders can cause chronic placental dysfunction. A rare cause is severe chronic maternal anemia without hypovolemia. Placental abruption can cause acute and severe late decelerations ([Fig. 14-17](#)).

VARIABLE DECELERATIONS. The most common deceleration patterns encountered during labor are variable decelerations attributed to umbilical cord occlusion. [Melchior and Bernard \(1985\)](#) identified variable decelerations in 40 percent of over 7000 monitor tracings when labor had progressed to 5 cm dilatation and in 83 percent by the end of the first stage. Variable deceleration of the fetal heart rate is defined as a visually apparent abrupt decrease in rate. The onset of deceleration commonly varies with successive contractions ([Fig. 14-18](#)). The duration is less than 2 minutes.

Very early in the development of electronic monitoring, [Hon \(1959\)](#) tested the effects of umbilical cord compression on fetal heart rate ([Fig. 14-19](#)). Similar complete occlusion of the umbilical cord in experimental animals produces abrupt, jagged-appearing deceleration of the fetal heart rate ([Fig. 14-20](#)). Concomitantly, fetal aortic pressure increases. [Itskovitz and co-workers \(1983\)](#) observed that variable decelerations in fetal lambs occurred only after umbilical blood flow was reduced by at least 50 percent.

Two types of variable decelerations are shown in [Figure 14-21](#). The deceleration denoted by A is very much like that seen with complete umbilical cord occlusion in experimental animals ([Fig. 14-20](#)). Deceleration B, however, has a different configuration because of the "shoulders" of acceleration before and after the deceleration component. [Lee and co-workers \(1975\)](#) proposed that the variation of variable decelerations was caused by differing degrees of partial cord occlusion. In this physiological scheme, occlusion of only the vein reduces fetal blood return, thereby triggering a baroreceptor-mediated acceleration. Subsequent complete occlusion results in fetal systemic hypertension due to obstruction of umbilical artery flow. This stimulates a baroreceptor-mediated deceleration. Presumably, the aftercoming shoulder of acceleration represents the same events occurring in reverse ([Fig. 14-22](#)).

[Ball and Parer \(1992\)](#) concluded that variable decelerations are vagally mediated and that the vagal response may be due to chemoreceptor or baroreceptor activity or both. Partial or complete cord occlusion (baroreceptor) produces afterload increase, hypertension, and decreases in fetal arterial oxygen content (chemoreceptor), both of which result in vagal activity leading to deceleration. In fetal monkeys the baroreceptor reflexes appear to be operative during the first 15 to 20 seconds of umbilical cord occlusion followed by decline in P_{O_2} at approximately 30 seconds, which then serves as a chemoreceptor stimulus ([Mueller-Heubach and Battelli, 1982](#)).

Thus, variable decelerations represent fetal heart rate reflexes that reflect either blood pressure changes due to interruption of umbilical flow or changes in oxygenation. It is likely that most fetuses have experienced brief but recurrent periods of hypoxia due to umbilical cord compression during gestation. The frequency and inevitability of cord occlusion has undoubtedly provided the fetus with these physiological mechanisms as a means of coping. The great dilemma for the obstetrician in managing variable fetal heart rate decelerations is determining when variable decelerations are pathological. The [American College of Obstetricians and Gynecologists \(1995b\)](#) has defined **significant** variable decelerations as those decreasing to less than 70 bpm and lasting more than 60 seconds.

Other fetal heart rate patterns have been associated with umbilical cord compression. **Saltatory** baseline heart rate ([Fig. 14-23](#)) was first described by [Hammacher and co-workers \(1968\)](#) and linked to umbilical cord complications during labor. The pattern is considered due to rapidly recurring couplets of acceleration and deceleration causing relatively large oscillations of the baseline fetal heart rate. We also observed a relationship between cord occlusion and the saltatory pattern ([Leveno and associates, 1984](#)). In the absence of other fetal heart rate findings, these do not signal fetal compromise.

PROLONGED DECELERATION. Shown in [Figure 14-24](#), these are defined as isolated decelerations lasting 2 minutes or longer, but less than 10 minutes from onset to return to baseline ([NICHD⁵ Fetal Monitoring Workshop, 1997](#)). Prolonged decelerations are difficult to interpret because they are seen in many different clinical situations. Some of the more common causes include cervical examination, uterine hyperactivity, cord entanglement, and maternal supine hypotension.

Epidural, spinal, or paracervical analgesia are frequent causes of prolonged deceleration of the fetal heart rate. For example, [Eberle and colleagues \(1998\)](#) reported that prolonged decelerations occurred in 4 percent of normal parturients given either epidural or intrathecal labor analgesia. Other causes of prolonged deceleration include maternal hypoperfusion or hypoxia due to any cause; placental abruption; umbilical cord knots or prolapse; maternal seizures including eclampsia and epilepsy; application of a fetal scalp electrode; impending birth; or even maternal Valsalva maneuver.

The placenta is very effective in resuscitating the fetus if the original insult does not recur immediately. Occasionally, such self-limited prolonged decelerations are followed by loss of beat-to-beat variability, baseline tachycardia, and even a period of late decelerations, all of which resolve as the fetus recovers. [Freeman co-authors \(1991\)](#) emphasize rightfully that the fetus may die during prolonged decelerations. Thus, management of prolonged decelerations can be extremely tenuous. Management of isolated prolonged decelerations is based on bedside clinical judgment, which will inevitably sometimes be imperfect given the unpredictability of these decelerations.

AMNIOINFUSION. [Gabbe and co-workers \(1976\)](#) showed in monkeys that removal of amniotic fluid produced variable decelerations and that replenishment of fluid with saline relieved the decelerations. [Miyazaki and Taylor \(1983\)](#) infused saline through the intrauterine pressure catheter in laboring women who had either variable decelerations or prolonged decelerations attributed to cord entrapment. They found that such therapy improved the heart rate pattern in half. [Miyazaki and Nevarez \(1985\)](#) subsequently randomized 96 pregnancies and found that nulliparous women in labor with cord compression patterns who were treated with amnioinfusion less often required cesarean delivery for fetal distress.

On the basis of these early reports, transvaginal amnioinfusion has been extended into three clinical areas:

1. Treatment of variable or prolonged decelerations.
2. Prophylactically in cases of known oligohydramnios, as with prolonged rupture of membranes.
3. In an attempt to dilute or wash out thick meconium ([Chap. 39, p. 1044](#)).

Many different amnioinfusion protocols have been reported, but most include a 500 to 800 mL bolus of warmed normal saline followed by a continuous infusion of approximately 3 mL per hour ([Owen and co-workers, 1990](#); [Pressman and Blakemore, 1996](#)). [Wenstrom and co-authors \(1995\)](#) surveyed use of amnioinfusion in American teaching hospitals. The procedure was used in 96 percent of the 186 centers surveyed, and it was estimated that 3 to 4 percent of all women delivered at these centers received such infusion. Potential complications of amnioinfusion are summarized in [Table 14-1](#).

TREATMENT OF ABNORMAL HEART RATE PATTERN. As previously mentioned, [Miyazaki and Nevarez \(1985\)](#) found that women in labor with cord compression patterns who were treated with amnioinfusion less often required cesarean delivery for fetal distress. [Spong and associates \(1996\)](#) reported that relief of variable fetal

heart rate decelerations was related to the amniotic fluid index (AFI) determined ultrasonically ([Chap. 31, p. 816](#)). For example, variable decelerations were relieved in 76 percent of women with AFI⁶ values 4 cm or less compared with 33 percent when the AFI was 8 cm or greater. In a randomized study, however, [Owen and colleagues \(1990\)](#) concluded that amnioinfusion was not beneficial in management of intrapartum variable decelerations.

PROPHYLACTIC AMNIOINFUSION FOR OLIGOHYDRAMNIOS. Amnioinfusion for oligohydrnios has been used prophylactically in an effort to avoid intrapartum fetal heart rate patterns from umbilical cord occlusion. [Nageotte and co-workers \(1991\)](#) found that such amnioinfusion resulted in significantly decreased frequency and severity of variable decelerations in labor. There was no improvement, however, in the cesarean delivery rate or condition of term infants. [Macri and co-workers \(1992\)](#) randomized prophylactic amnioinfusion in 170 term and postterm pregnancies complicated by both thick meconium and oligohydrnios. Amnioinfusion significantly reduced cesarean deliveries for fetal distress as well as meconium aspiration syndrome. In contrast, [Ogundipe and associates \(1994\)](#) randomly assigned 116 term pregnancies with an amniotic fluid index of less than 5 cm to receive prophylactic amnioinfusion or standard obstetrical care. There were no significant differences in overall cesarean delivery rates, deliveries for fetal distress, or umbilical gas studies.

AMNIOINFUSION FOR MECONIUM-STAINED AMNIONIC FLUID. [Pierce and associates \(2000\)](#) summarized the results of 13 prospective trials of intrapartum amnioinfusion in 1924 women with moderate to thick meconium-stained fluid. Infants born to women treated by amnioinfusion were significantly less likely to have meconium below the vocal cords and were less likely to develop meconium aspiration syndrome than infants not given amnioinfusion. The cesarean delivery rate was also lower in the amnioinfusion group. In contrast, at the University of Tennessee, amnioinfusion was found not feasible in half of women with moderate or thick meconium who were randomized to this treatment ([Usta and colleagues, 1995](#)). These investigators were also unable to demonstrate any improvement in neonatal outcomes. [Spong and associates \(1994\)](#) also concluded that, although prophylactic amnioinfusion did dilute meconium, it did not improve perinatal outcome.

SECOND-STAGE LABOR FETAL HEART RATE PATTERNS. Decelerations are virtually ubiquitous. [Melchior and Bernard \(1985\)](#) reported that only 1.4 percent of over 7000 deliveries *did not* have fetal heart rate decelerations during second-stage labor. Both cord compression and fetal head compression have been implicated to cause decelerations and baseline bradycardia during second-stage labor. The high incidence of such patterns minimized their potential significance during early development of electronic monitoring. For example, [Boehm \(1975\)](#) described profound, prolonged fetal heart rate deceleration in the 10 minutes preceding vaginal delivery of 18 healthy infants. Subsequently, [Herbert and Boehm \(1981\)](#) reported another 18 pregnancies with similar prolonged decelerations during second-stage labor, but now associated with one stillbirth and one neonatal death. These experiences attest to the unpredictability of second-stage labor fetal heart rate. [Spong and colleagues \(1998\)](#) analyzed the characteristics of second-stage variable fetal heart rate decelerations in 250 deliveries and found that as the total number of decelerations to less than 70 bpm increased, the 5-minute Apgar score decreased. Put another way, the longer a fetus was exposed to variable decelerations, the lower the Apgar score at 5 minutes.

[Picquard and co-workers \(1988\)](#) analyzed heart rate patterns during second-stage labor in 234 women in an attempt to identify specific patterns to diagnose fetal compromise. Loss of beat-to-beat variability and baseline fetal heart rate less than 90 bpm were predictive of fetal acidemia. [Krebs and co-workers \(1981\)](#) also found that persistent or progressive baseline bradycardia, as well as baseline tachycardia, were associated with low Apgar scores. [Gull and colleagues \(1996\)](#) observed that abrupt fetal heart rate deceleration to less than 100 bpm, and associated with loss of beat-to-beat variability for 4 minutes or longer, was predictive of fetal acidemia. Thus, abnormal baseline heart rate—either bradycardia or tachycardia, absent beat-to-beat variability, or both—in the presence of second-stage decelerations is associated with increased but not inevitable fetal compromise ([Fig. 14-25](#)).

FETAL SCALP BLOOD SAMPLING

According to the [American College of Obstetricians and Gynecologists \(1995b\)](#), measurements of the pH in capillary scalp blood may help to identify the fetus in serious distress. The College also notes that the procedure is uncommonly used contemporaneously. An illuminated endoscope is inserted through the dilated cervix after ruptured membranes so as to press firmly against the fetal scalp ([Fig. 14-26](#)). The skin is wiped clean with a cotton swab and coated with a silicone gel to cause the blood to accumulate as discrete globules. An incision is made through the skin to a 2 mm depth with a special blade on a long handle. As a drop of blood forms on the surface, it is immediately collected into a heparinized glass capillary tube, and the pH of the blood is promptly measured.

The pH of fetal capillary scalp blood is usually lower than umbilical venous blood and approaches that of umbilical arterial blood. [Zalar and Quilligan \(1979\)](#) recommended the following protocol to try to confirm fetal distress: If the pH is greater than 7.25, labor is observed. If the pH is between 7.20 and 7.25, the pH measurement is repeated within 30 minutes. If the pH is less than 7.20, another scalp blood sample is collected immediately and the mother is taken to an operating room and prepared for surgery. Delivery is performed promptly if the low pH is confirmed. Otherwise, labor is allowed to continue and scalp blood samples are repeated periodically. The only benefits reported for scalp pH testing were estimates of fewer cesarean deliveries for fetal distress ([Young and co-workers, 1980b](#)). [Goodwin and associates \(1994\)](#), however, in a study of 112,000 deliveries, showed a fall in their scalp pH sampling rate from approximately 1.8 percent in the mid-1980s to 0.03 percent by 1992 with no increased delivery rate for fetal distress. They concluded that scalp pH sampling was unnecessary. [Kruger and colleagues \(1999\)](#) have advocated use of fetal scalp blood lactate concentration as an adjunct to pH.

SCALP STIMULATION. [Clark and associates \(1984\)](#) have suggested that scalp stimulation is an alternative to scalp blood sampling. An Allis clamp was used to pinch the fetal scalp just prior to obtaining scalp blood for pH measurement. Acceleration of the heart rate in response to pinching was invariably associated with a normal scalp blood pH. Conversely, failure to provoke acceleration was not uniformly predictive of fetal acidemia. [Elimian and associates \(1997\)](#) reported that of 58 cases in which the fetal heart rate accelerated 10 bpm or more after 15 seconds of gentle digital stroking of the scalp, 100 percent had a scalp pH of 7.20 or greater. Without an acceleration, however, only 30 percent had a scalp pH less than 7.20.

VIBROACOUSTIC STIMULATION. Fetal heart rate acceleration in response to vibroacoustic stimulation has been recommended as a substitute for scalp sampling ([Edersheim and colleagues, 1987](#)). The technique involves use of an electronic artificial larynx placed a centimeter or so from, or directly onto the maternal abdomen ([Chap. 40, p. 1103](#)). Response to vibroacoustic stimulation is considered normal if a fetal heart rate acceleration of at least 15 bpm for at least 15 seconds occurs within 15 seconds after the stimulation with prolonged fetal movements ([Sherer, 1994](#)). [Lin and colleagues \(1999\)](#) prospectively compared vibroacoustic stimulation with fetal scalp sampling in 113 women in labor and concluded that this technique can be used in lieu of measurement of scalp pH. In contrast, others have reported that although vibroacoustic stimulation in second-stage labor is associated with fetal heart rate reactivity, the quality of the response did not predict neonatal outcome or enhance labor management ([Anyaeqbunam and associates, 1994](#)).

FETAL PULSE OXIMETRY. Using technology similar to that of adult pulse oximetry, instrumentation has been developed that may allow assessment of fetal oxyhemoglobin saturation once the membranes are ruptured. A unique padlike (Nellcor Puritan Bennett) sensor shown in [Figure 14-27](#) is inserted through the cervix and positioned against the fetal face where it is held in place by the uterine wall. As reviewed by [Yam and co-authors \(2000\)](#), this device has been used extensively by many investigators and has been reported to reliably register fetal oxygen saturation in 70 to 95 percent of women throughout 50 to 88 percent of their labors. As shown in [Figure 14-28](#), fetal oxygen saturation normally varies between approximately 30 percent and 70 percent throughout labor ([Chua and colleagues, 1997](#)). Based on these results, as well as those in experimental animals, the lower limit for normal oxygen saturation has been determined to be 30 percent ([Yam and colleagues, 2000](#)). [Bloom and colleagues \(1999\)](#) reported that brief, transient fetal oxygen saturations below 30 percent were common during labor because such values were observed in 53 percent of fetuses with normal outcomes. Saturation values below 30 percent, however, when persistent for 2 minutes or longer, were associated with fetal compromise.

[Garite and colleagues \(2000\)](#) randomized 1010 women with term pregnancies, and who developed predefined abnormal fetal heart rate patterns, to either conventional fetal monitoring alone or fetal monitoring plus continuous fetal pulse oximetry. Cesarean delivery for fetal distress was done when pulse oximetry values remained less than 30 percent for the entire interval between two contractions or the fetal heart rate patterns met predefined guidelines. The use of fetal pulse oximetry significantly reduced the rate of cesarean delivery for nonreassuring fetal status from 10.2 percent to 4.5 percent. Alternatively, the cesarean delivery rate for dystocia significantly increased from 9 percent to 19 percent when pulse oximetry was used. There were no neonatal benefits or adverse effects associated with fetal pulse oximetry. In January 2000, the Obstetrics and Gynecology Devices Panel of the Medical Devices Advisory Committee of the Food Drug Administration, based upon this randomized study, recommended marketing of the Nellcor N-400 Fetal Oxygen Monitoring System. The technique currently is being evaluated by the [NICHD⁷ Maternal-Fetal Medicine Units Network](#).

FETAL ELECTROCARDIOGRAPHY. Concerns about the validity of continuous electronic fetal monitoring during labor have prompted searches for better methods of monitoring ([Whittle, 2000](#)). Because as fetal hypoxia worsens, there are changes in the ST segment and PR interval of the fetal [ECG¹](#), several investigators have assessed the value of analyzing these as an adjunct to conventional fetal monitoring. [Westgate and co-workers \(1993\)](#) studied the benefits, if any, of monitoring ST-segment changes in a randomized trial of 2400 pregnancies. Infant outcomes were not improved compared with use of conventional fetal monitoring alone, although there was a reduction in cesarean births for fetal distress. Similarly, [Strachan and co-workers \(2000\)](#) found no benefit for adding PR-interval analysis to conventional monitoring.

INTRAPARTUM DOPPLER VELOCIMETRY. Doppler analysis of the umbilical artery has been studied as another potential adjunct to conventional fetal monitoring. Abnormal Doppler waveforms (Chap. 41, p. 1132), when present, may signify pathological umbilical-placental vessel resistance. [Farrell and co-authors \(1999\)](#) reviewed the literature on the use of intrapartum Doppler velocimetry and concluded that this technique was a poor predictor of adverse perinatal outcomes. They concluded that Doppler velocimetry had little, if any, role in the surveillance of fetal well-being during labor.

COMPLICATIONS FROM ELECTRONIC FETAL MONITORING

Injury to the fetal scalp or breech by the electrode is rarely a major problem, although application at some other site—such as the eye in case of a face presentation—can prove serious. A fetal vessel in the placenta may be ruptured by catheter placement ([Trudinger and Pryse-Davies, 1978](#)). Severe cord compression has been described from entanglement with the catheter. Penetration of the placenta, causing hemorrhage and uterine perforation during catheter insertion, has led to serious morbidity, as well as spurious recordings that resulted in inappropriate management.

Both the fetus and the mother may be at increased risk for *infection* as the consequence of internal monitoring. Scalp wounds from the electrode may become infected and cause osteomyelitis ([McGregor and McFarren, 1989](#)). [Faro and associates \(1990\)](#) observed puerperal infection to be increased from 12 percent in women externally monitored compared with 18 percent when an internal apparatus was used.

FETAL DISTRESS

DEFINITION. The term **fetal distress** is too broad and vague to be applied with any precision to clinical situations. Uncertainty about the diagnosis of fetal distress based upon interpretation of fetal heart rate patterns has given rise to use of descriptions such as *reassuring* or *nonreassuring*. "Reassuring" suggests a restoration of confidence by a particular pattern, whereas "nonreassuring" suggests inability to remove doubt. These patterns during labor are dynamic, such that they can rapidly change from reassuring to nonreassuring and vice versa. In this situation, obstetricians essentially experience surges of both confidence and doubt. Put another way, most diagnoses of fetal distress using heart rate patterns occur when obstetricians lose confidence or cannot assuage doubts about fetal condition. **These fetal assessments are entirely subjective clinical judgments inevitably subject to imperfection and must be recognized as such.**

Why is diagnosis of fetal distress based on heart rate patterns so tenuous? One explanation is that these patterns are more a reflection of fetal physiology than pathology. Physiological control of heart rate includes a variety of interconnected mechanisms that depend on blood flow as well as oxygenation. Moreover, the activity of these control mechanisms is influenced by the preexisting state of fetal oxygenation, as seen, for example, with chronic placental insufficiency. Importantly, the fetus is tethered by an umbilical cord, where blood flow is constantly in jeopardy, which demands that the fetus have a strategy for survival. Moreover, normal labor is a process of increasing acidemia ([Rogers and colleagues, 1998](#)). Thus, normal labor is a process of repeated fetal hypoxic events resulting inevitably in acidemia. Put another way, and assuming that "asphyxia" can be defined as hypoxia leading to acidemia, then normal parturition is an asphyxiating event for the fetus.

DIAGNOSIS. Identification of fetal distress based upon fetal heart rate patterns is imprecise and controversial. Experts in interpretation of these patterns so often disagree with each other that one organizer of the [NICHD⁸ Fetal Monitoring Workshop \(1997\)](#) lightheartedly compared the experts in attendance with marine iguanas of the Galapagos Islands—"all on the same beach but facing different directions and spitting at one another constantly" ([Parer, 1997](#)).

[Ayres-de-Campos and colleagues \(1999\)](#) investigated inter-observer agreement on interpretation of fetal heart rate patterns and found that agreement—or, conversely, disagreement—was related to whether the pattern was normal, suspicious, or pathological. Specifically, experts agreed on 62 percent of normal patterns, 42 percent of suspicious patterns, and only 25 percent of pathological patterns. Indeed, there is some consensus only about the definitions of fetal heart rate at the extremes of normal and severely abnormal patterns ([Table 14-2](#)).

There have been several recent research efforts aimed at testing the utility of well-defined fetal heart rate classification systems. [Berkus and colleagues \(1999\)](#) retrospectively analyzed fetal heart rate patterns during the last 30 minutes of labor in 1859 term pregnancies. The study was designed to determine if specific patterns, or combinations of patterns, predicted neonatal outcome. Indisputably normal fetal heart rate patterns were recorded within 30 minutes of delivery in only 26 percent of cases. Combinations of fetal heart rate patterns that indicated absence of accelerations *plus* severe variable or late decelerations, or prolonged bradycardia or tachycardia, were associated with an increased incidence of adverse infant outcomes. [Low and colleagues \(1999\)](#) analyzed fetal heart rate patterns of term infants born with significant metabolic acidemia (umbilical artery base deficit > 16 mmol/L). Such acidemia was rare, occurring in only 71 of 23,000 births. Patterns with absent baseline variability were the most specific, but identified only 17 percent of the acidemic fetuses. The sensitivity was 17 percent (true positive), and the specificity was 98 percent (true negative).

[Dellinger and colleagues \(2000\)](#) retrospectively analyzed intrapartum fetal heart rate patterns in 898 pregnancies using a classification system of their design. Fetal heart rate patterns during the hour before delivery were classified as "normal," "stress," or "distress." Fetal "distress" was diagnosed in 8 (1 percent) tracings and 70 percent were classified as "normal." Almost a third were intermediate patterns. Fetal "distress" was classified to include zero variability *plus* late or moderate-severe variable decelerations or baseline rate less than 110 bpm for 5 minutes or longer. Outcomes such as cesarean delivery, fetal acidemia, and admission to the neonatal intensive care nursery were significantly related to the fetal heart rate pattern. The authors concluded that their classification system accurately predicted normal outcomes for fetuses as well as discriminating true fetal distress.

In summary, after more than 30 years of experience with interpretation of fetal heart rate patterns, there is finally emerging evidence that some combinations of fetal heart rate characteristics can be meaningfully used to identify normal and severely abnormal fetuses. True fetal distress patterns appear to be those where beat-to-beat variability is *zero* in conjunction with severe decelerations or persistent baseline rate changes or both. Fortunately, such fetal distress is rare. One explanation for the persistent failure to scientifically establish the benefits of fetal heart rate monitoring is the rarity of such fetal distress, effectively precluding sufficiently powerful clinical trials ([Hornbuckle and colleagues, 2000](#)).

MANAGEMENT. Clinical management for significantly variant fetal heart rate patterns consists of correcting the potential fetal insult, if possible. Measures suggested by the [American College of Obstetricians and Gynecologists \(1998\)](#) are shown in [Table 14-3](#). Moving the mother to the lateral position, correcting maternal hypotension due to regional analgesia, and discontinuing oxytocin serve to improve uteroplacental perfusion. Examination to rule out prolapsed cord or impending delivery may be helpful.

TOCOLYSIS. A single intravenous or subcutaneous injection of 0.25 mg of terbutaline sulfate given to relax the uterus has been described as a temporizing maneuver in the management of nonreassuring fetal heart rate patterns during labor. The rationale for this is that inhibition of uterine contractions might improve fetal oxygenation, thus achieving in utero resuscitation. [Cook and Spinnato \(1994\)](#) described their experience with terbutaline tocolysis for fetal resuscitation in 368 pregnancies over a 10-year period. Such resuscitation improved fetal scalp blood pH values, although all of these women were delivered by cesarean. In their review, the investigators concluded that although the studies were small and rarely randomized, most reported favorable results with terbutaline tocolysis for nonreassuring patterns. Small intravenous doses of nitroglycerin (60 to 180 mg) have also been reported to be beneficial ([Mercier and colleagues, 1997](#)).

MECONIUM IN THE AMNIONIC FLUID. Obstetrical teaching throughout this century has included the concept that meconium passage is a potential warning of fetal asphyxia. J. Whitridge [Williams, observed in 1903](#) that "a characteristic sign of impending asphyxia is the escape of meconium." He attributed meconium passage to "relaxation of the sphincter ani muscle induced by faulty aeration of the (fetal) blood." Obstetricians, however, have also long realized that the detection of meconium during labor is problematic in the prediction of fetal distress or asphyxia. In their review, [Katz and Bowes \(1992\)](#) emphasized the prognostic uncertainty of meconium by referring to the topic as a "murky subject." Indeed, although 12 to 22 percent of human labors are complicated by meconium, few such labors are linked to infant mortality. In a recent investigation from Parkland Hospital, meconium was found to be a "low-risk" obstetrical hazard because the perinatal mortality attributable to meconium was 1 death per 1000 live births ([Nathan and co-workers, 1994](#)).

Three theories have been suggested to explain fetal passage of meconium and may, in part, explain the tenuous connection between the detection of meconium and infant mortality. The pathological explanation proposes that fetuses pass meconium in response to hypoxia, and that meconium therefore signals fetal compromise ([Walker, 1953](#)). Alternatively, in utero passage of meconium may represent normal gastrointestinal tract maturation under neural control ([Mathews and Warshaw, 1979](#)). Third, meconium passage could also follow vagal stimulation from common but transient umbilical cord entrapment and resultant increased peristalsis ([Hon and colleagues, 1961](#)). Thus, fetal release of meconium could also represent physiological processes.

[Ramin and co-authors \(1996\)](#) studied almost 8000 pregnancies with meconium-stained amniotic fluid delivered at Parkland Hospital. Meconium aspiration syndrome was significantly associated with fetal acidemia at birth. Other significant correlates of aspiration included cesarean delivery, forceps to expedite delivery, intrapartum heart rate abnormalities, depressed Apgar scores, and need for assisted ventilation at delivery. Analysis of the type of fetal acidemia based on umbilical blood gases

suggested that the fetal compromise associated with meconium aspiration syndrome was an acute event, because most acidemic fetuses had abnormally increased PCO₂ rather than the pure metabolic acidemia.

Interestingly, hypercarbia in fetal lambs has been shown to induce fetal gasping and resultant increased amniotic fluid inhalation ([Dawes and co-workers, 1972](#)). [Jovanovic and Nguyen \(1989\)](#) observed that meconium gasped into the fetal lungs caused aspiration syndrome only in asphyxiated animals. [Ramin and co-authors \(1996\)](#) hypothesized that the pathophysiology of meconium aspiration syndrome includes, but is not limited to, fetal hypercarbia, which stimulates fetal respiration leading to aspiration of meconium into the alveoli, and lung parenchymal injury secondary to acidemia-induced alveolar cell damage. In this pathophysiological scenario, meconium in amniotic fluid is a fetal environmental hazard rather than a marker of preexistent compromise. This proposed pathophysiological sequence is not exclusive, because it does not account for approximately half of cases of meconium aspiration syndrome in which the fetus was not acidemic at birth. It was concluded that the high incidence of meconium observed in the amniotic fluid during labor often represents fetal passage of gastrointestinal contents in conjunction with normal physiological processes. Such meconium, however, can become an environmental hazard when fetal acidemia supervenes. Importantly, fetal acidemia occurs acutely, and therefore meconium aspiration is unpredictable and likely unpreventable.

FETAL HEART RATE PATTERNS AND BRAIN DAMAGE. Attempts to correlate fetal heart rate patterns with brain damage have been based primarily on studies of infants identified as a result of medicolegal actions. For example, [Rosen and Dickinson \(1992\)](#) analyzed intrapartum fetal heart rate patterns in 55 such cases and found no specific pattern that was correlated with neurological injury.

[Shields and Schifrin \(1988\)](#) and [Schifrin and associates \(1994\)](#) described what they considered a unique fetal heart rate pattern characteristic of fetal brain damage. This pattern consisted of a normal baseline rate with persistently absent variability and mild variable decelerations with "overshoot." This pattern was frequently found in close proximity to what had been a reactive nonstress test. Other findings included postmaturity, meconium staining with fetal growth restriction, and reduced amniotic fluid volume. They concluded that such patterns most often represent chronic, intermittent cord compression from oligohydramnios resulting in repetitive antepartum central nervous system ischemia. Follow-up studies showed a high incidence of mental retardation, microcephaly, and seizure activity, in addition to cerebral palsy. [Phelan and Ahn \(1994\)](#) reported that among 48 fetuses later found to be neurologically impaired, a persistent nonreactive fetal heart rate tracing was already present at the time of admission in 70 percent; they concluded that fetal neurological injury occurred predominately prior to arrival to the hospital. When they looked retrospectively at heart rate patterns in 209 brain-damaged infants, only half were nonreactive at the time of admission ([Ahn and co-workers, 1996](#)). They concluded that there was not a single unique pattern that was associated with fetal neurological injury. [Westgate and colleagues \(1999\)](#) found that more than half of term infants with neonatal encephalopathy due to fetal acidemia were associated with events beyond the control of the obstetrician.

EXPERIMENTAL EVIDENCE. Fetal heart rate patterns necessary for perinatal brain damage have been studied in experimental animals. [Myers \(1972\)](#) described the effects of complete and partial asphyxia in rhesus monkeys in studies of brain damage due to perinatal asphyxia. Complete asphyxia was produced by total occlusion of umbilical blood flow that led to prolonged deceleration ([Fig. 14-29](#)). Fetal arterial pH did not reach 7.0 until about 8 minutes after complete cessation of oxygenation and umbilical flow. At least 10 minutes of such prolonged deceleration was required before there was evidence of brain damage in surviving fetuses.

[Myers \(1972\)](#) also produced partial asphyxia in rhesus monkeys by impeding maternal aortic blood flow. This resulted in late decelerations due to uterine and placental hypoperfusion. He observed that several hours of these late decelerations did not damage the fetal brain unless the pH fell below 7.0. Indeed, [Adamsons and Myers \(1977\)](#) reported subsequently that late decelerations were a marker of partial asphyxia long before brain damage occurred.

The most common fetal heart rate pattern during labor, due to umbilical cord occlusion, requires considerable time to significantly affect the fetus in experimental animals. [Watanabe and associates \(1992\)](#) showed that sequential complete occlusion of the umbilical cord for 40 seconds followed by 80 seconds of release for 30 minutes in sheep resulted in only moderate fetal acidemia. Similarly, [Clapp and colleagues \(1988\)](#) partially occluded the umbilical cord for 1 minute every 3 minutes in fetal sheep and observed brain damage after 2 hours. [Ikeda and colleagues \(1998, 2000\)](#) studied partial umbilical cord occlusion producing pH of less than 6.9 for 60 minutes in fetal sheep. Such profound asphyxia produced variable degrees of brain damage and multi-organ damage. Lesser durations, specifically, 10, 15, or 20 minutes of total cord occlusion, did not produce brain damage in fetal sheep ([Keunen and colleagues, 1997](#)).

Using fetal sheep, [Matsuda and co-workers \(1999\)](#) showed that similar brain injuries occurred with acute fetal hemorrhage. These investigators withdrew about a third of fetoplacental blood volume acutely which produced hypotension and subsequent periventricular white-matter changes.

HUMAN EVIDENCE. The contribution of intrapartum events to subsequent neurological handicaps has been greatly overestimated. [Nelson and Grether \(1998\)](#) performed a population-based study of children with disabling spastic cerebral palsy in which the intrapartum records of these children were compared with matched controls. Intrapartum fetal heart rate abnormalities did not distinguish between children with cerebral palsy and normal controls. [Badawi and colleagues \(1998\)](#) also performed a case-control population based study of infants with cerebral palsy in Western Australia. Only 5 percent of the brain-damaged infants had intrapartum factors, which led them to conclude that most cerebral palsy is unrelated to labor events. BR>
[Low and co-workers \(1989\)](#) divided perinatal brain damage into three categories based on microscopic findings:

1. From 18 to 48 hours—neuronal necrosis with pyknosis or lysis of the nucleus in shriveled eosinophilic cells.
2. From 48 to 72 hours—more intense neuronal necrosis with macrophage response.
3. More than 3 days—all the preceding plus astrocyte response with gliosis and, in some, early cavitation.

Abnormal brain histopathology was not observed with acute, lethal asphyxia. Moreover, 43 percent of brain damage episodes occurred prior to labor and 25 percent were in the neonatal period. Similarly, in another investigation, [Low and co-workers \(1984\)](#) estimated that more than 1 hour of fetal hypoxia associated with profound metabolic acidemia (pH less than 7.0) was required before neurological abnormalities could be diagnosed at 6 to 12 months of age. [Low and co-workers \(1988\)](#) followed 37 term infants with profound metabolic acidemia at birth to 1 year and found major neurological deficits in 13 percent of the infants. Minor deficits were diagnosed in 10 infants, and the remaining 60 percent were normal. These investigators further observed that intrapartum fetal asphyxia with metabolic acidemia at delivery in both the term and preterm fetus was marked by severe complications not only of the central nervous system, but also of the respiratory and renal systems ([Low and colleagues, 1994, 1995](#)).

These observations further strengthen the position of the [American College of Obstetricians and Gynecologists \(1996\)](#) on birth asphyxia and cerebral palsy: In assessing a possible relationship between perinatal asphyxia and neurological deficit in an individual patient, all of the following criteria must be present before a plausible link can be made:

1. Profound umbilical artery metabolic or mixed acidemia (pH less than 7.00).
2. Persistence of an Apgar score of 0 to 3 for longer than 5 minutes.
3. Neonatal neurological sequelae (e.g., seizures, coma, or hypotonia).
4. Multiorgan system dysfunction (e.g., cardiovascular gastrointestinal, hematological, pulmonary, or renal).

[Korst and colleagues \(1999\)](#) have challenged this concept.

Clearly, for brain damage to occur, the fetus must be exposed to much more than a brief period of hypoxia. Moreover, the hypoxia must cause profound, just barely sublethal metabolic acidemia. Fetal heart rate patterns consistent with these sublethal conditions are fortunately rare.

BENEFITS OF ELECTRONIC FETAL HEART RATE MONITORING

There are several fallacious assumptions behind expectations of improved perinatal outcome with electronic monitoring. One assumption is that fetal distress is a slowly developing phenomenon and that electronic monitoring makes possible early detection of the compromised fetus. This assumption is illogical, viz, how can all fetuses die slowly? Another presumption is that all fetal damage develops in the hospital. Only recently has attention focused on the reality that most damaged fetuses suffered insults before arrival to labor units. The very term "fetal monitor" implies that this inanimate technology in some fashion "monitors." The assumption is made that if a dead or damaged infant is delivered, the tracing strip must provide some clue, because this device was monitoring fetal condition. All of these assumptions led to great expectations and fostered the belief that all dead or damaged neonates were preventable. [Parer and King \(2000\)](#) reviewed reasons why fetal

heart rate monitoring did not live up to its expectations. These unwarranted expectations have greatly fueled litigation in obstetrics. Indeed, [Symonds \(1994\)](#) reported that 70 percent of all liability claims related to fetal brain damage are based on reputed abnormalities seen in the electronic fetal monitor tracing.

Too many fetuses demonstrate fetal heart rate abnormalities during labor to permit accurate detection of those who are actually compromised. Indeed, most "fetal distress" does not represent an overtly compromised fetus. Importantly, debate continues about interpretation of many heart rate patterns. For example, [Keith and co-workers \(1995\)](#) asked each of 17 experts to review 50 tracings on two occasions, at least 1 month apart. About 20 percent changed their own interpretations, and approximately 25 percent did not agree with the interpretations of their colleagues.

By the end of the 1970s, questions about the efficacy, safety, and costs of electronic monitoring were being voiced from the Office of Technology Assessment, the United States Congress, and the Centers for Disease Control and Prevention. [Banta and Thacker \(1979\)](#) analyzed 158 reports and concluded that "the technical advances required in the demonstration that reliable recording could be done seems to have blinded most observers to the fact that this additional information will not necessarily produce better outcomes." They attributed the apparent lack of benefit to the imprecision of electronic monitoring to identify fetal distress. Moreover, increased usage was linked to more frequent cesarean delivery. They estimated that additional costs of childbirth in the United States, if half of labors had electronic monitoring, was approximately \$400 million per year in 1979 dollars.

The National Institute of Child Health and Human Development ([NICHD](#)⁹) appointed a task force to study these concerns, and a consensus report was published in 1979. After an exhaustive review of electronic monitoring literature, the group concluded that the evidence only suggested a trend toward improved infant outcome in complicated pregnancies. They emphasized that few scientifically conducted investigations had been done to address perinatal benefits. Almost 20 years later, the NICHD Fetal Monitoring Workshop (1997) once again formulated research recommendations intended to assess the reliability and validity of fetal heart rate patterns in the prevention of asphyxial brain damage.

PARKLAND HOSPITAL EXPERIENCE: SELECTIVE VERSUS UNIVERSAL MONITORING. In July 1982, an investigation began at Parkland Hospital to ascertain whether all women in labor should undergo electronic monitoring ([Leveno and co-workers, 1986](#)). In alternating months, universal electronic monitoring was rotated with selective heart rate monitoring, which was the prevailing practice. During the 3-year investigation, 17,410 labors were managed using universal electronic monitoring. No significant differences were found in any perinatal outcomes. There was a significantly small increase in cesarean delivery for fetal distress associated with universal monitoring. Thus, increased application of electronic monitoring at Parkland Hospital did not improve perinatal results, but it increased the frequency of cesarean delivery for fetal distress.

SUMMARY OF RANDOMIZED STUDIES. [Thacker and co-authors \(1995\)](#) identified 12 published randomized clinical trials of electronic fetal monitoring from 1966 to 1994. Total pregnancies included in these studies was 58,624. They concluded that the benefits once claimed for electronic monitoring are clearly more modest than believed, and appear to be primarily in the prevention of neonatal seizures. Long-term implications of this outcome, however, appear less serious than once believed. Abnormal neurological consequences were not consistently higher among children monitored by auscultation compared with electronic methods. They concurred with the current position of the [American College of Obstetricians and Gynecologists \(1995b\)](#) on intrapartum fetal surveillance.

CURRENT RECOMMENDATIONS. The methods most commonly used for intrapartum fetal heart rate monitoring include auscultation with a fetal stethoscope or a Doppler ultrasound device, or continuous electronic monitoring of the heart rate and uterine contractions. There is no scientific evidence that has identified the most effective method, including frequency or duration of fetal surveillance, that ensures optimum results. [Table 14-4](#) gives current recommendations of the [American College of Obstetricians and Gynecologists \(1995b\)](#). Intermittent auscultation or continuous electronic monitoring are considered acceptable methods of intrapartum surveillance in both low- and high-risk pregnancies. The recommended interval between checking the heart rate, however, is longer in the uncomplicated pregnancy. When auscultation is used, it is recommended that it be performed after a contraction and for 60 seconds. It is also recommended that a 1-to-1 nurse-patient ratio be used if auscultation is employed.

INTRAPARTUM SURVEILLANCE OF UTERINE ACTIVITY

Analysis of electronically measured uterine activity permits some generalities concerning the relationship of certain contraction patterns to labor outcome. There is considerable normal variation, however, and caution must be exercised before judging true labor or its absence solely from study of a monitor tracing. Uterine muscle efficiency to effect delivery varies greatly. To use an analogy, 100-meter sprinters all have the same muscle groups yet cross the finish line at different times.

INTERNAL UTERINE PRESSURE MONITORING

Amnionic fluid pressure is measured between and during contractions by a fluid-filled plastic catheter with its distal tip located above the presenting part. The catheter is connected to a strain-gauge pressure sensor adjusted to the same level as the catheter tip in the uterus. The amplified electrical signal produced in the strain gauge by variation in pressure within the fluid system is recorded on a calibrated moving paper strip, simultaneously with fetal heart rate recording. Intrauterine pressure catheters are now available that have the pressure sensor in the catheter tip, which obviates the need for the fluid column.

EXTERNAL MONITORING

Uterine contractions can be measured by a displacement transducer in which the transducer button ("plunger") is held against the abdominal wall. As the uterus contracts, the button moves in proportion to the strength of the contraction. This movement is converted into a measurable electrical signal that indicates the *relative* intensity of the contraction—it does not give an accurate measure of intensity. External monitoring can give a good indication of the onset, peak, and end of the contraction.

PATTERNS OF UTERINE ACTIVITY

[Caldeyro-Barcia and Poseiro \(1960\)](#) from Montevideo, Uruguay, were pioneers who have done much to elucidate the patterns of spontaneous uterine activity throughout pregnancy. Their investigations were made possible by the development of electronic means of recording and quantifying uterine contractions before and during labor. Contractile waves of uterine activity were usually measured using intra-amnionic pressure catheters, but early in their studies as many as four simultaneous intramyometrial microballoons were also used to record uterine pressure. They also introduced the concept of **Montevi-deo units** to define uterine activity ([Chap. 18, p. 441](#)).

By this definition, uterine performance is the product of the intensity—increased uterine pressure above base-line tone—of a contraction in mm Hg multiplied by contraction frequency per 10 minutes. For example, three contractions in 10 minutes, each of 50 mm Hg intensity, would equal 150 Montevideo units.

During the first 30 weeks, uterine activity is comparatively quiescent. Contractions are seldom greater than 20 mm Hg, and these have been equated with those first described in [1872 by John Braxton Hicks](#). Uterine activity increases gradually after 30 weeks and it is noteworthy that these *Braxton Hicks contractions* also increase in intensity and frequency. Further increases in uterine activity are typical of the last weeks of pregnancy, termed **prelabor**. During this phase, the cervix ripens, presumably as a consequence of increasing uterine contractions ([Chap. 11, p. 257](#)).

According to [Caldeyro-Barcia and Poseiro \(1960\)](#), clinical labor usually commences when uterine activity reaches values between 80 and 120 Montevideo units. This translates into approximately three contractions of 40 mm Hg every 10 minutes, or 120 Montevideo units. Importantly, there is no clear-cut division between prelabor and labor, but rather a gradual and progressive transition.

During first-stage labor, uterine contractions increase progressively in intensity from about 25 mm Hg at commencement of labor to 50 mm Hg at the end. At the same time, frequency increases from three to five contractions per 10 minutes, and uterine baseline tone from 8 to 12 mm Hg. Uterine activity further increases during second-stage labor, aided by maternal bearing down. Indeed, contractions of 80 to 100 mm Hg are typical, and occur as frequently at five to six per 10 minutes. Interestingly, the duration of uterine contractions—60 to 80 seconds—does not increase appreciably from early active labor extending through the second-stage ([Pontonnier and colleagues, 1975](#)). Presumably, this constancy of duration serves a fetal respiratory gas-exchange function. That is, functional fetal "breath holding" during a uterine contraction, which results in isolation of the intervillous space where respiratory gas exchange occurs, has a 60- to 80-second limit that remains relatively constant.

[Caldeyro-Barcia and Poseiro \(1960\)](#) also observed empirically that uterine contractions are clinically palpable only after their intensity exceeds 10 mm Hg. Moreover, until their intensity reaches 40 mm Hg, the uterine wall can readily be depressed by the finger. At greater intensity, it then becomes so hard that it resists easy depression. Uterine contractions are usually not associated with pain until their intensity exceeds 15 mm Hg, presumably because this is the minimum pressure

required for distending the lower uterine segment and cervix. It follows that Braxton Hicks contractions exceeding 15 mm Hg may be perceived as uncomfortable because distention of the uterus, cervix, and birth canal is generally thought to elicit discomfort.

[Hendricks \(1968\)](#) observed that "the clinician makes great demands upon the uterus." The uterus is expected to remain well relaxed during pregnancy, to contract effectively but intermittently during labor, and then to remain in a state of almost constant contraction for several hours postpartum. [Figure 14-30](#) demonstrates an example of normal uterine activity during labor. As also described by [Caldeyro-Barcia and Poseiro \(1960\)](#), uterine activity progressively and gradually increases from prelabor through late labor. Interestingly, as shown in [Figure 14-30](#), uterine contractions after birth are identical to those resulting in delivery of the infant. Indeed, the pattern of uterine activity is one of gradual subsidence or reverse of that leading up to delivery. It is therefore not surprising that the uterus that performs poorly before delivery is also prone to atony and puerperal hemorrhage.

ORIGIN AND PROPAGATION OF CONTRACTIONS. The uterus has not been extensively studied in terms of its nonhormonal physiological mechanisms of function. The normal contractile wave of labor originates near the uterine end of one of the fallopian tubes; thus these areas act as "pacemakers" ([Fig. 14-31](#)). The right pacemaker usually predominates over the left and starts the great majority of contractile waves. Contractions spread from the pacemaker area throughout the uterus at 2 cm/sec, depolarizing the whole organ within 15 seconds. This depolarization wave propagates downward toward the cervix. Intensity is greatest in the fundus, and it diminishes in the lower uterus. This phenomenon is thought to reflect reductions of myometrial thickness from the fundus to the cervix. Presumably, this descending gradient of pressure serves to direct fetal descent toward the cervix as well as to efface the cervix. Importantly, all parts of the uterus are synchronized and reach their peak pressure almost simultaneously, giving rise to the curvilinear waveform shown in [Figure 14-31](#).

The pacemaker theory also serves to explain the varying intensity of adjacent coupled contractions shown in panels A and B of [Figure 14-30](#). Such coupling was termed **incoordination** by [Caldeyro-Barcia and Poseiro \(1960\)](#). A contractile wave begins in one cornual-region pacemaker, but does not synchronously depolarize the entire uterus. As a result, another contraction begins in the contralateral pacemaker and produces the second contractile wave of the couplet. These small contractions alternating with larger ones appear to be typical of early labor, and indeed, labor may progress with such uterine activity, albeit at a slower pace. They also observed that labor would progress slowly if regular contractions were hypotonic—that is, contractions with intensity less than 25 mm Hg or frequency less than two per 10 minutes. Similar observations were made by [Seitchik \(1981\)](#) in a computer-aided analysis comparing women in active labor with those with arrested labor. Normal labor was characterized by a minimum of three contractions that averaged greater than 25 mm Hg and less than 4-minute intervals between contractions. A lesser amount of uterine activity was associated with arrest of active labor. Prospective diagnosis of hypotonic labor cannot be reliably based simply on a few uterine pressures.

[Hauth and co-workers \(1986\)](#) quantified uterine contraction pressures in 109 women at term who received oxytocin for labor induction or augmentation. Most of these women achieved 200 to 225 Montevideo units, and 40 percent had up to 300 units to effect delivery. They suggested that these levels of uterine activity should be sought before consideration of cesarean delivery for presumed dystocia—this recommendation was later endorsed by the [American College of Obstetricians and Gynecologists \(1995a\)](#).

TABLE 14-3. Management Criteria for Nonreassuring Fetal Heart Rate Pattern: The Following Actions Should Be Documented in the Medical Record

1. Repositioning of patient
2. Discontinuation of uterine stimulants and correction of uterine hyperstimulation
3. Vaginal examination
4. Correction of maternal hypotension associated with regional analgesia
5. Notification of anesthesia and nursing staff of the need for emergency delivery
6. Monitoring of fetal heart rate—by electronic fetal monitoring or auscultation—in the operating room prior to abdominal preparation
7. Request that qualified personnel be in attendance for newborn resuscitation and care ^a
8. Administration of oxygen to the mother

^a Locally acceptable definitions of qualified personnel should be agreed upon by authorities at each institution.

TABLE 14-4. Guidelines for Intrapartum Fetal Heart Rate Surveillance

Surveillance	Low-Risk Pregnancies	High-Risk Pregnancies
Acceptable methods		
Intermittent auscultation	Yes	Yes
Continuous electronic monitoring (internal or external)	Yes	Yes
Evaluation intervals ^a		
First-stage labor (active)	30 min	15 min ^b
Second-stage labor	15 min	5 min ^b

^aFollowing a uterine contraction.

^bIncludes tracing evaluation and charting with continuous electronic monitoring.

Grades of baseline fetal heart rate variability (irregular fluctuations in the baseline of 2 cycles per minute or greater) together with a sinusoidal pattern. The sinusoidal pattern differs from variability in that it has a smooth, sinelike pattern of regular fluctuation and is excluded in the definition of fetal heart rate variability. (1)

Undetectable, absent variability; (2) minimal = 5 bpm variability; (3) moderate (normal), 6 to 25 bpm variability; (4) marked, > 25 bpm variability; (5) sinusoidal pattern. ([National Institute of Child Health and Human Development Fetal Monitoring Workshop, 1997 .](#))

15. Analgesia and Anesthesia

Pain relief in labor presents unique problems. Labor begins without warning, and obstetrical anesthesia may be required within minutes of a full meal. Moreover, gastric emptying is delayed during pregnancy and prolonged even more during labor, especially after analgesics are given. Vomiting with aspiration of gastric contents is a constant threat and often a major cause of serious maternal morbidity and mortality. Finally, a host of disorders unique to pregnancy, such as preeclampsia, placental abruption, and chorioamnionitis, all superimposed on unique physiological adaptations of pregnancy, are directly affected by the choice of analgesia and anesthesia selected.

Data from the Pregnancy Mortality Surveillance Program of the Centers for Disease Control and Prevention from 1979 through 1990 include 155 maternal deaths caused by anesthesia-related complications ([Hawkins and colleagues, 1997b](#)). These represented 3.8 percent of a total of 4097 pregnancy-related deaths ([Fig. 15-1](#)). Over this 12-year surveillance, anesthesia-related mortality rates decreased from 4.3 to 1.7 per million live births. A similar trend has been reported for England and Wales ([Hawkins and colleagues, 1997b](#); [Hibbard and colleagues, 1994](#)). The most common causes of anesthesia-related deaths in the United States from 1979 through 1990 are summarized in [Table 15-1](#).

The most important single factor associated with anesthesia-related maternal mortality is the experience of the anesthetist ([Breheny and McCarthy, 1982](#)). Fifteen years ago, [Gibbs and colleagues \(1986\)](#) reported that less than half of the hospitals with fewer than 500 deliveries per year had general anesthesia for cesarean delivery provided by an anesthesiologist. In a recent survey supported by both the American Society of Anesthesiologists and the American College of Obstetricians and Gynecologists, [Hawkins and colleagues \(1997a\)](#) reported that fewer hospitals were providing obstetrical care in 1992 compared with 1981. Most of the decrease was in hospitals with less than 500 deliveries. Although there was a significant increase in epidural analgesia, regional techniques were not available in 20 percent of the smallest hospitals. In 60 percent of the smallest hospitals, nurse anesthetists provided anesthesia for cesarean delivery. Almost 85 percent of women undergoing cesarean delivery received regional analgesia. Only 2 percent of labor epidural analgesia was provided by obstetricians compared with 30 percent in the 1981 survey.

GENERAL PRINCIPLES

OBSTETRICAL ANESTHESIA SERVICES

The [American Academy of Pediatrics and the American College of Obstetricians and Gynecologists \(1997\)](#) have published guidelines concerning anesthesia care for obstetrics. The [American Society of Anesthesiologists Task Force on Obstetrical Anesthesia \(1999\)](#) has also recently published practice guidelines for obstetrical anesthesia. Hospitals providing basic obstetrical care should be able to administer anesthesia on a 24-hour basis. A qualified person should be readily available to administer an appropriate anesthetic and to maintain support of vital functions in an obstetrical emergency. In larger facilities with complicated patients, 24-hour in-house anesthesia coverage is recommended. Moreover, hospitals providing obstetrical care should be capable of starting a cesarean delivery when necessary within 30 minutes from the time the decision is made. They also stressed the importance of properly trained individuals capable of managing anesthetic complications. Finally, they emphasize that certain risk factors should be communicated to the anesthesia-care provider in advance of delivery:

1. Marked obesity.
2. Severe edema or anatomical anomalies of the face and neck.
3. Protuberant teeth, small mandible, or difficulty in opening the mouth.
4. Short stature, short neck, or arthritis of the neck.
5. Large thyroid.
6. Asthma, chronic pulmonary disease, or cardiac disease.
7. Bleeding disorders.
8. Severe preeclampsia-eclampsia.
9. Previous history of anesthetic complications.
- ∴ Other significant medical or obstetrical complications.

[Bell and colleagues \(2000\)](#) recently calculated the financial burden that may be incurred when trying to provide around-the-clock obstetrical analgesia. Given the average indemnity and Medicaid reimbursement for epidural analgesia during labor, they concluded that such coverage could not operate profitably at their tertiary referral institution. The [American College of Obstetricians and Gynecologists \(2000\)](#) has issued a joint statement with the American Society of Anesthesiology that reimbursement for regional analgesia should not be denied if given "only" for pain relief, that is, absence of other "medical indications."

PRINCIPLES OF PAIN RELIEF

Three essentials of obstetrical pain relief are simplicity, safety, and preservation of fetal homeostasis. The woman who is given any form of analgesia should be monitored closely. Risks vary according to the type of analgesia selected. Assiduous attention to monitoring after administration of spinal or epidural analgesia includes frequent measurement of blood pressure, anesthetic levels, and measurement of maternal oxygenation by pulse oximeter.

The obstetrician should become proficient in local and pudendal analgesia. Conduction analgesia also may be administered by the properly trained obstetrician in appropriately selected circumstances. In general, however, it is preferable for an anesthesiologist or anesthetist to provide this care, so that the obstetrician can focus attention on the obstetrical concerns. General anesthesia should be available immediately for laparotomy, but should be administered only by those with special training.

NONPHARMACOLOGICAL METHODS OF PAIN CONTROL

Fear and the unknown potentiate pain. A woman who is free from fear, and who has confidence in the obstetrical staff that cares for her, usually requires smaller amounts of analgesia.

[Read \(1944\)](#) emphasized that the intensity of pain during labor is related in large measure to emotional tension. He urged that women be well informed about the physiology of parturition and the various hospital procedures to which they will be subjected during labor and delivery. [Lamaze \(1970\)](#) subsequently described his psychoprophylactic method, which emphasized childbirth as a natural physiological process. Both taught that pain can be minimized by appropriate training in breathing and appropriate psychological support. These concepts have had a considerable impact on the reduction of potent analgesic, sedative, and amnestic drugs used during labor, as well as the reduced use of general anesthesia for delivery.

When motivated women have been prepared for childbirth, pain during labor has been found to be diminished by a third ([Melzack, 1984](#)). The presence of a supportive spouse or other family member, of conscientious labor attendants, and of a considerate obstetrician who instills confidence, contributes greatly to accomplishing this goal. In a study by [Kennell and associates \(1991\)](#), 412 nulliparous women in labor were randomized to two groups; one received continuous emotional support from an experienced companion, and the other was monitored only by an inconspicuous observer who did not interact with the laboring woman. The cesarean delivery rate was significantly lower in the continuous support group (8 versus 13 percent) as was the frequency of epidural analgesia for vaginal delivery (8 versus 23 percent).

ANALGESIA AND SEDATION DURING LABOR

When uterine contractions and cervical dilatation cause discomfort, pain relief with a narcotic such as meperidine, plus one of the tranquilizer drugs such as

promethazine, is usually appropriate. The mother should rest quietly between contractions with a successful program of analgesia and sedation. In this circumstance, discomfort is usually felt at the acme of an effective uterine contraction, but the pain is generally not unbearable. Appropriate drug selection and administration should accomplish these objectives for the great majority of women in labor, without risk to them or their infants.

MEPERIDINE AND PROMETHAZINE

Meperidine, 50 to 100 mg, with promethazine, 25 mg, may be administered intramuscularly at intervals of 2 to 4 hours ([American College of Obstetricians and Gynecologists, 1996](#)). In general, a small dose given more frequently is preferable to a large one administered less often. Then, if delivery follows during the next hour or so after the injection, the neonate is less likely to be depressed by the medication. A more rapid effect is achieved by giving meperidine intravenously in doses of 25 to 50 mg every 1 to 2 hours. Whereas analgesia is maximal about 45 minutes after an intramuscular injection, it develops almost immediately following intravenous administration. The depressant effect in the fetus follows closely behind the peak analgesic effect in the mother. Meperidine readily crosses the placenta, and the half-life is approximately 2¹/₂ hours in the mother and 13 hours in the newborn ([American College of Obstetricians and Gynecologists, 1996](#)).

It is likely that these doses are insufficient for pain relief in many labors. In a randomized investigation of epidural analgesia from Parkland Hospital, patient-controlled intravenous analgesia (PCIA) with meperidine was found to be an inexpensive and effective method for labor analgesia ([Sharma and colleagues, 1997](#)). Women randomized to PCIA¹ received 50 mg meperidine with 25 mg promethazine intravenously as an initial bolus, after which an infusion pump was set up to deliver 15 mg of meperidine every 10 minutes as needed until delivery. The mean and maximum total meperidine dosages were 140 and 500 mg, respectively. A fourth of the women received more than 200 mg of meperidine during their labors. Neonatal sedation, as measured by need for naloxone treatment in the delivery room, occurred in 3 percent.

OTHER DRUGS

The synthetic narcotic **butorphanol**, given in 1- to 2-mg doses, compares favorably with 40 to 60 mg of meperidine ([Quilligan and colleagues, 1980](#)). Neonatal respiratory depression is reported to be less than with meperidine, but care must be taken that the two drugs are not given contiguously because butorphanol antagonizes the narcotic effects of meperidine. [Angel and colleagues \(1984\)](#) and [Hatjis and Meis \(1986\)](#) described a sinusoidal fetal heart rate pattern following butorphanol administration. **Nalbuphine** is also a synthetic narcotic. When given in a dose of 15 to 20 mg intravenously, it does not cause neonatal depression ([Wilson and associates, 1986](#)). **Fentanyl** is a short-acting, very potent synthetic opioid. It is given in doses of 50 to 100 ug intravenously every hour if needed. Butorphanol provided better initial analgesia than fentanyl with fewer requests for more medication or for epidural anesthesia ([Atkinson and associates, 1994](#)).

Intravenous and intramuscular sedation is not without risks. [Hawkins and colleagues \(1997b\)](#) reported that 4 of 129 maternal anesthetic deaths were from such sedation—one from aspiration, two from inadequate ventilation, and one from overdosage.

NARCOTIC ANTAGONISTS

Meperidine or other narcotics used during labor may cause newborn respiratory depression. Newborn respiratory depression is most likely to occur 2 to 3 hours after meperidine administration ([American College of Obstetricians and Gynecologists, 1996](#)). **Naloxone** is a narcotic antagonist capable of reversing respiratory depression induced by opioid narcotics by displacing the narcotic from specific receptors in the central nervous system. Withdrawal symptoms may be precipitated in recipients who are physically dependent on narcotics. The suggested dose for newborns is 0.1 mg/kg injected into the umbilical vein ([American College of Obstetricians and Gynecologists, 1996](#)). This usually acts within 2 minutes with an effective duration of at least 30 minutes. The naloxone injection may have to be repeated in 3 to 5 minutes. In the absence of narcotics, naloxone exhibits no adverse effects on the newborn.

GENERAL ANESTHESIA

Without exception, all anesthetic agents that depress the maternal central nervous system cross the placenta and depress the fetal central nervous system. Another constant hazard with any general anesthetic is aspiration of gastric contents and particulate matter. Fasting before the time of anesthesia is not always an effective safeguard, because fasting gastric juice, even if free of particulate matter, is likely to be strongly acidic and thus can produce severe or even fatal aspiration pneumonitis. At the same time, tracheal intubation is valuable to ensure a satisfactory airway and minimize the risk of aspiration. Failed tracheal intubation fortunately is uncommon, but is still a major cause of anesthesia-related maternal deaths ([Hawkins and colleagues, 1997b](#)). Advances in technology, to include pulse oximetry and capnography, greatly facilitate timely diagnosis of failed intubation prompting corrective measures to restore ventilation. Even so, failure to be able to secure the airway with an endotracheal tube can, at best, be risky and at worst, be a disaster ([Rasmussen and Malinow, 1994](#)). In some cases an awake fiberoptic intubation may be necessary. [Hawksworth and Purdie \(1998\)](#) described such a case after failed spinal-epidural analgesia and failed asleep intubation.

With inhalation, the concentration of the anesthetic agent increases in the lungs of the pregnant woman somewhat more rapidly because the functional residual capacity and residual volume of her lungs are reduced. For the same reason, residual oxygen in the lung after expiration is appreciably less, a factor of importance when there is delay in intubation and oxygenation after injection of a muscle relaxant. Trained personnel and specialized equipment (including fiberoptic intubation) are mandatory for the safe use of general anesthesia.

INHALATION ANESTHESIA

GAS ANESTHETICS. Nitrous oxide (N₂O) may be used to provide pain relief during labor as well as at delivery. This agent produces analgesia and altered consciousness, but by itself does not provide true anesthesia. Nitrous oxide does not prolong labor or interfere with uterine contractions. Self-administered nitrous oxide in a 50 percent mixture with 50 percent oxygen (Nitronox) can provide excellent pain relief during the second stage of labor.

Nitrous oxide is commonly also used as part of a balanced general anesthesia for cesarean delivery and some forceps deliveries. It is given along with the intravenous administration of a short-acting barbiturate (usually thiopental) and a muscle relaxant (usually succinylcholine) just prior to tracheal intubation.

VOLATILE ANESTHETICS. In doses that provide analgesia, volatile anesthetics are likely to cause unconsciousness and there is potential for aspiration with an unprotected airway. Halogenated hydrocarbons are used to supplement nitrous oxide during maintenance of general anesthesia. They cross the placenta readily and are capable of producing narcosis in the fetus. **Isflurane** is the most commonly used volatile anesthetic in the United States. Both it and **halothane** are potent, nonexplosive agents that produce remarkable uterine relaxation when given in high, inhaled concentrations. Their use in high concentrations is restricted to those very uncommon situations in which uterine relaxation is a requisite rather than a hazard. They are used for internal podalic version of the second twin, breech decomposition, and replacement of the acutely inverted uterus. As soon as the maneuver has been completed, anesthetic administration should be stopped and immediate efforts made to promote myometrial contraction to minimize hemorrhage. Because of cardiodepressant and hypotensive effects, these agents may intensify the adverse effects of maternal hypovolemia. Halothane and isflurane have occasionally been associated with hepatitis and massive hepatic necrosis ([Gunarathnam and associates, 1995](#)).

BALANCED GENERAL ANESTHESIA. Nitrous oxide and oxygen given for balanced general anesthesia have been associated with some degree of maternal awareness when these women were interviewed postpartum ([Hodgkinson and colleagues, 1978](#)). For this reason, as well as to be able to increase the inspired concentration of oxygen, many recommend the addition of one of the halogenated agents in concentrations of less than 1 percent ([American College of Obstetricians and Gynecologists, 1996](#)). [Piggott and co-workers \(1990\)](#) studied 200 women undergoing cesarean delivery and randomized them to either nitrous oxide (50 percent) and oxygen (50 percent) or oxygen (100 percent), both supplemented with isflurane. There were no instances of awareness in either group, and infants of mothers who received 100 percent oxygen required less resuscitation and had higher Apgar scores.

The major concern regarding halogenated agents has been their association with increased blood loss ([Combs and associates, 1991](#); [Gilstrap and associates, 1987](#)). [Andrews and colleagues \(1992\)](#) reported significantly lower postpartum hematocrit levels when general anesthesia with a halogenated agent was compared with regional techniques for women undergoing repeat cesarean delivery. Similarly, [Maberry and colleagues \(1992\)](#) evaluated blood loss in elective cesarean delivery using either general anesthesia with isflurane or regional analgesia. They observed a postoperative decrease in hematocrit level of 5 volumes percent in 25 percent of women receiving general anesthesia compared with 7 percent of those given regional analgesia. None required transfusions. Conversely, a number of studies did not report such associations, especially if women at high risk for bleeding were excluded ([Camann and Datta, 1991](#); [Lamont and associates, 1988](#)).

ANESTHETIC GAS EXPOSURE AND PREGNANCY OUTCOME. In some reports, the spontaneous abortion rate of female workers exposed to anesthetic gases was doubled and the minor malformation rate in children of exposed male workers was slightly greater. Although the exact fetal risk of chronic maternal exposure to waste anesthetic gas is unknown, available data suggest that there is not a substantial risk for either pregnancy loss or congenital anomalies ([Cohen, 1994](#)). This is

discussed further in [Chapter 38](#).

INTRAVENOUS DRUGS DURING ANESTHESIA

THIOPENTAL. This thiobarbiturate given intravenously is widely used in conjunction with other agents for general anesthesia. The drug offers the advantages of ease and extreme rapidity of induction, ready controllability, and prompt recovery with minimal risk of vomiting. Thiopental and similar compounds are poor analgesic agents, and the administration of sufficient drug given alone to maintain anesthesia may cause appreciable newborn depression. Thus, thiopental is not used as the sole anesthetic agent, but in a dose that induces sleep, it is given along with a muscle relaxant, usually succinylcholine, and nitrous oxide plus oxygen.

KETAMINE. Given intravenously in low doses of 0.2 to 0.3 mg/kg, this drug is used to produce analgesia and sedation just prior to delivery. Doses of 1 mg/kg induce general anesthesia. It may prove useful in women with acute hemorrhage because, unlike thiopental, it is not associated with hypotension. In fact, it usually causes a rise in blood pressure, and thus it generally should be avoided in women already hypertensive. Unpleasant delirium and hallucinations are commonly induced by this agent.

ASPIRATION DURING GENERAL ANESTHESIA

Pneumonitis from inhalation of gastric contents has in the past been the most common cause of anesthetic deaths in obstetrics. In its survey of over 4097 maternal deaths between 1979 and 1990, the Centers for Disease Control and Prevention ([Hawkins and colleagues, 1997b](#)) identified inhalation of gastric contents to be associated with 23 percent of 129 maternal anesthesia-related deaths ([Table 15-1](#)).

PROPHYLAXIS. Important to effective prophylaxis are the following measures:

1. Fasting from solids for at least 8 hours and preferably longer before anesthesia ([American Society of Anesthesiologists Task Force on Obstetrical Anesthesia, 1999](#)).
2. Use of agents to reduce gastric acidity during the induction and maintenance of general anesthesia.
3. Skillful tracheal intubation accompanied by pressure on the cricoid cartilage to occlude the esophagus—the *Sellick maneuver*.
4. After intubation, and during the surgery, passage of a nasogastric tube to empty the stomach of all contents. Additional antacids can be placed down the nasogastric tube. The stomach should again be emptied and the nasogastric tube (usually) pulled immediately before extubation.
5. Awake extubation with protective airway reflexes intact and without neuromuscular blockade and with the woman lying on her side with her head lowered.
6. Use of regional analgesia techniques when appropriate.

FASTING. There are insufficient data regarding fasting times for clear liquids and pulmonary aspiration during labor ([American Society of Anesthesiologists Task Force on Obstetrical Anesthesia, 1999](#)). Clear liquids such as water, clear tea, black coffee, carbonated beverages, and fruit juices without pulp may be allowed in uncomplicated laboring women. In a survey of 740 hospitals in the United States, [Hawkins and colleagues \(1998\)](#) reported that oral intake during labor is limited mostly to clear liquids. Women with complications such as diabetes and morbid obesity may need further restrictions of oral intake. Obvious solid foods should be avoided in laboring women. The Task Force also recommended that "a fasting period of 8 hours or more is preferable for uncomplicated parturients undergoing elective cesarean delivery." Despite these precautions, it should be assumed that any woman in labor has both gastric particulate matter as well as acidic contents.

ANTACIDS. The practice of administering antacids shortly before induction of anesthesia has probably done more to decrease mortality from general anesthesia than any other single practice. [Gibbs and colleagues \(1984\)](#) reported that 30 mL of sodium citrate with citric acid (Bicitra), given about 45 minutes before surgery, neutralized gastric contents (mean volume 70 mL) in nearly 90 percent of women undergoing cesarean delivery. For many years we have recommended administration of 30 mL of Bicitra within a few minutes of the anticipated time of anesthesia induction, either general or by major regional block. If more than 1 hour has passed between when the first dose was given and when anesthesia is induced, then a second dose is given.

H₂-antagonists, as well as antacids and dopamine antagonists, may be given prophylactically to decrease the risk of aspiration pneumonia ([Rowe, 1997](#)). **Cimetidine**, a histamine H₂-antagonist, given sometime before general anesthesia for delivery, has been recommended ([Hodgkinson and colleagues, 1983](#)). At least 60 minutes are required after parenteral administration to decrease gastric acidity to relatively safe levels. Therefore, in emergency situations, either an antacid or antacid plus cimetidine should be used. [Thornburn and Moir \(1987\)](#) studied 100 women undergoing emergency cesarean delivery who were given cimetidine, 200 mg intravenously, along with 30 mL of sodium citrate orally. The time interval from cimetidine administration to induction of general anesthesia was 5 to 208 minutes. None of the women had a gastric pH of less than 2.7, and all but one had a pH of 3.0 or higher.

A similar agent, **ranitidine**, can be given the night before surgery and will result in decreased gastric secretion through the next morning. This agent might prove useful when given along with a second dose on the morning of surgery for scheduled elective cesarean deliveries ([Burchman, 1992](#)). [Yau and associates \(1992\)](#) studied 49 women undergoing cesarean delivery who received ranitidine and sodium citrate. They reported that only one woman had an intragastric pH of less than 2.5 and a volume greater than 25 mL. In emergency cesarean delivery, co-administration of ranitidine and sodium citrate resulted in a smaller volume of gastric aspirate than in those women given antacid alone ([Lim and Elegbe, 1992](#)).

INTUBATION. Various positions have been tried to minimize aspiration before and during tracheal intubation and cuff inflation, but the disadvantages from positions other than supine outweigh any advantage. Cricoid pressure from the time of induction until intubation—the *Sellick maneuver*—should be performed by a trained associate. Intubation may be performed with the mother awake after adequate topical anesthesia is applied. Topical spray generally will not significantly depress the laryngeal reflex.

EXTUBATION. The tracheal tube may be safely removed only if the woman is conscious to a degree to follow commands and is capable of maintaining oxygen saturation with spontaneous respiration.

PATHOPHYSIOLOGY. Aspiration pneumonitis associated with obstetrical anesthesia was described by [Mendelson in 1946](#). [Teabeaut \(1952\)](#) demonstrated experimentally that if the pH of aspirated fluid was below 2.5, severe chemical pneumonitis developed. In one study the pH of gastric juice of nearly half of women tested intrapartum without treatment was below 2.5 ([Taylor and Pryse-Davies, 1966](#)). The right mainstem bronchus usually offers the simplest pathway for aspirated material to reach the lung parenchyma, and therefore the right lower lobe is most often involved. In severe cases, there is bilateral widespread involvement.

The woman who aspirates may develop evidence for respiratory distress immediately or as long as several hours after aspiration, depending in part upon the material aspirated, the severity of the process, and the acuity of the attendants. Aspiration of a large amount of solid material causes obvious signs of airway obstruction. Smaller particles without acidic liquid may lead to patchy atelectasis and later to bronchopneumonia.

When highly acidic liquid is inspired, decreased oxygen saturation along with tachypnea, bronchospasm, rhonchi, rales, atelectasis, cyanosis, tachycardia, and hypotension are likely to develop. At the sites of injury, pulmonary capillary leakage results in protein-rich fluid containing numerous erythrocytes exuding from capillaries into the lung interstitium and alveoli to cause decreased pulmonary compliance, shunting of blood, and severe hypoxemia. Radiographic changes may not appear immediately and they may be quite variable, although the right lobe is most often affected. Therefore, chest x-ray alone should not be used to exclude aspiration.

TREATMENT. The methods recommended for treatment of aspiration have changed appreciably in recent years, indicating that previous therapy was not very successful. Suspicion of aspiration of gastric contents demands very close monitoring for evidence of any pulmonary damage. Attention to respiratory rate and oxygen saturation as measured by pulse oximetry are the most sensitive and earliest indicators of injury.

As much as possible of the inhaled fluid should be immediately wiped out of the mouth and removed from the pharynx and trachea by suction. Saline lavage may further disseminate the acid throughout the lung and is not recommended. If large particulate matter is inspired, bronchoscopy may be indicated to relieve airway obstruction. There is no convincing clinical or experimental evidence that corticosteroid therapy or prophylactic antimicrobial administration is beneficial ([Guyton and Gibbs, 1994](#)). If clinical evidence of infection develops, however, then vigorous treatment is given.

When acute respiratory distress syndrome (ARDS) develops, mechanical ventilation with positive end-expiratory pressure may prove life saving ([Chap. 43, p. 1164](#)). Oxygen in increased concentration given by continuous positive pressure may be required to raise and maintain the arterial P O₂ at 60 mm Hg or higher.

FAILED INTUBATION

Failed intubation fortunately is uncommon, is often associated with aspiration, and is a major cause of anesthetic-related maternal mortality ([Hawkins and colleagues, 1997b](#); [Wallace and Sidawi, 1997](#)). [Hawkins and colleagues \(1997b\)](#) reported that 22 percent of 67 maternal deaths associated with general anesthesia were secondary to induction or intubation problems ([Table 15-1](#)).

PREVENTION. History of previous difficulties with intubation as well as a careful assessment of anatomical features of the neck, maxillofacial, pharyngeal, and laryngeal structures may help predict a difficult intubation. Even in cases where the initial assessment of the airway was uneventful, edema may develop intrapartum and present considerable difficulties ([Farcon and associates, 1994](#)). Morbid obesity is a major risk factor for failed or difficult intubation. Of paramount importance is appropriate preoperative preparation to include the immediate availability of a short-handled laryngoscope, fiber-optic laryngoscope, and the liberal use of awake oral intubation techniques ([Blass, 1991](#)).

MANAGEMENT. An important principle is to start the operative procedure only after it has been ascertained that tracheal intubation has been successful and that adequate ventilation can be accomplished. Even with an abnormal fetal heart rate pattern, initiation of cesarean delivery will only serve to complicate matters if there is difficulty or failed intubation. Frequently, the woman must be allowed to awaken and a different technique used, such as an awake intubation or regional analgesia.

Following failed intubation, the woman is ventilated by mask and cricoid pressure is applied to reduce the chance of aspiration ([Cooper and colleagues, 1994](#)). Surgery may proceed with mask ventilation or the woman is allowed to awaken. In those cases where the woman has been paralyzed, and where an oral airway cannot be reestablished, a life-threatening emergency exists. Use of a fiber-optic laryngoscope may facilitate tracheal intubation. If not, a laryngeal mask airway is placed or needle cricothyroidotomy and jet ventilation is performed ([American College of Obstetricians and Gynecologists, 1996](#)). This can be accomplished with a 14- or 16-gauge needle connected to wall oxygen at a flow rate of 50 psi or 15 L/min. Alternatively, cricothyroidotomy can be performed using a size 10 scalpel blade and a pediatric endotracheal tube ([Fig. 15-2](#)).

REGIONAL ANALGESIA

A variety of nerve blocks have been developed over the years to provide pain relief for the woman in labor and at delivery. They are correctly referred to as regional analgesics.

SENSORY INNERVATION OF THE GENITAL TRACT

UTERINE INNERVATION. Pain in the first stage of labor is generated largely from the uterus. Visceral sensory fibers from the uterus, cervix, and upper vagina traverse through the Frankenhauser ganglion, which lies just lateral to the cervix, into the pelvic plexus, and then to the middle and superior internal iliac plexuses. From there, the fibers travel in the lumbar and lower thoracic sympathetic chains to enter the spinal cord through the white rami communicantes associated with the 10th, 11th, and 12th thoracic and 1st lumbar nerves. Early in the first stage of labor, the pain of uterine contractions is transmitted predominantly through the 11th and 12th thoracic nerves.

The motor pathways to the uterus leave the spinal cord at the level of the seventh and eighth thoracic vertebrae. Theoretically, any method of sensory block that does not also block the motor pathways to the uterus can be used for analgesia during labor.

LOWER GENITAL TRACT INNERVATION. Pain with vaginal delivery arises from stimuli from the lower genital tract. These are transmitted primarily through the pudendal nerve, the peripheral branches of which provide sensory innervation to the perineum, anus, and the more medial and inferior parts of the vulva and clitoris. The pudendal nerve passes beneath the posterior surface of the sacrospinous ligament just as the ligament attaches to the ischial spine. The sensory nerve fibers of the pudendal nerve are derived from the ventral branches of the second, third, and fourth sacral nerves.

ANESTHETIC AGENTS

Some of the more commonly used local anesthetics, along with their usual concentrations, doses, and durations of action, are shown in [Table 15-2](#). Some preparations suitable for epidural analgesia are not suitable for subarachnoid injection because the preservative may cause inflammation. Some contain dilute epinephrine to prolong the action of the anesthetic or to produce symptoms when a test dose is inadvertently given intravenously. The dose of each agent varies widely, and is dependent upon the particular nerve block and physical status of the woman. When the dose is increased, the onset, duration, and quality of analgesia are enhanced, but only incremental dosage of small-volume boluses allows safety through careful monitoring for early warning signs of toxicity. Administration of these agents must be followed by appropriate monitoring for adverse reactions, and equipment and personnel to manage these reactions must be immediately available.

Most often, serious toxicity follows injection of an anesthetic into a blood vessel, but it may also be induced by administration of excessive amounts. Because many of these agents are manufactured in more than one concentration and ampule size to be used for specific local or regional blocks, a thorough knowledge of the ones selected for use is essential for safety. Two manifestations of systemic toxicity from local anesthetics are those of the central nervous and cardiovascular systems.

CENTRAL NERVOUS SYSTEM TOXICITY. Symptoms include light-headedness, dizziness, tinnitus, bizarre behavior, slurred speech, metallic taste, numbness of the tongue and mouth, muscle fasciculation and excitation, generalized convulsions, and loss of consciousness. The convulsions should be controlled, an airway established, and oxygen delivered. Succinylcholine abolishes the peripheral manifestations of the convulsions and allows tracheal intubation. Thiopental or diazepam act centrally to inhibit convulsions. Magnesium sulfate, administered according to the regimen for eclampsia, also controls convulsions. Abnormal fetal heart rate patterns, such as late decelerations or persistent bradycardia, may develop from maternal hypoxia and lactic acidosis induced by convulsions. With arrest of the convulsions, administration of oxygen, and application of other supportive measures, the fetus likely will recover more quickly in utero than following immediate cesarean delivery. Moreover, maternal well-being is usually better served by waiting until the intensity of the hypoxia and the metabolic acidosis have diminished.

CARDIOVASCULAR TOXICITY. These manifestations do not always follow central nervous system involvement. Generally, they develop later than those from cerebral toxicity, because they are induced by higher blood levels of drug. The notable exception to this rule is bupivacaine, where neurotoxicity and cardiotoxicity develop at virtually identical serum drug levels. Like neurotoxicity, cardiovascular toxicity is characterized first by stimulation and then depression. Accordingly, there is hypertension and tachycardia, which soon is followed by hypotension and cardiac arrhythmias. Hypotension and arrhythmias contribute appreciably to impaired uteroplacental perfusion and fetal distress. Hypotension is initially managed by turning the woman onto either side to avoid aortocaval compression. A crystalloid solution is infused rapidly along with intravenously administered ephedrine. Emergency cesarean delivery should be initiated if maternal vital signs have not been restored within 5 minutes of cardiac arrest ([Chap. 43](#)). As with convulsions, the fetus is likely to recover more quickly in utero once maternal cardiac output is reestablished.

LOCAL INFILTRATION

Local infiltration is of especial value in the following circumstances:

1. Before episiotomy and delivery.
2. After delivery into the site of lacerations to be repaired.
3. Around the episiotomy wound if there is inadequate analgesia.

From the standpoint of safety, local infiltration analgesia is preeminent in the aforementioned settings.

CESAREAN DELIVERY. A rare indication for local infiltration is the need to perform emergency cesarean section to save the life of the fetus in the absence of any anesthesia support. Local block might also be useful to augment an inadequate or "patchy" regional block that was given in an emergency.

TECHNIQUE. The skin is infiltrated in the line of the proposed incision, and the subcutaneous, muscle, and posterior rectus sheath layers as the abdomen is opened. A dilute solution of lidocaine (30 mL of 2 percent with 1:200,000 epinephrine diluted with 60 mL of normal saline) is prepared, and overall 100 to 120 mL is infiltrated. Injection of large volumes into the fatty layers, which are relatively devoid of nerve supply, is avoided to limit total dose of local anesthetic needed. To minimize pain, nausea, and hypotension that may accompany intraperitoneal manipulations, each step is accomplished without haste.

Another technique involves a field block of the major branches supplying the abdominal wall, to include the 10th, 11th, and 12th intercostal nerves and the ilioinguinal and genitofemoral nerves ([Busby, 1963](#)). As shown in [Figure 15-3](#), the former group of nerves is located at a point midway between the costal margin and the iliac crest in the midaxillary line. The latter group is found at the level of the external inguinal ring. Only one skin puncture is made at each of the four sites (right and left sides). At the intercostal block site, the needle is directed horizontally and injection is carried down to the transversalis fascia, avoiding injection of the subcutaneous fat. Approximately 5 to 8 mL of 0.5 percent lidocaine is injected. The procedure is repeated at a 45-degree angle cephalad and caudad at this site. The other side is then injected. At the ilioinguinal and genitofemoral sites, the injection is started at a site 2 to 3 cm from the pubic tubercle at a 45-degree angle. Finally, the skin overlying the planned incision is injected.

PUDENDAL BLOCK

A tubular director that allows 1.0 to 1.5 cm of a 15-cm 22-gauge needle to protrude beyond its tip is used to guide the needle into position over the pudendal nerve ([Fig. 15-4](#)). The end of the director is placed against the vaginal mucosa just beneath the tip of the ischial spine. The needle is pushed beyond the tip of the director into the mucosa and a mucosal wheal is made with 1 mL of 1 percent lidocaine or an equivalent dose of another local anesthetic. Aspiration is attempted before this and all subsequent injections to guard against intravascular infusion. The needle is then advanced until it touches the sacrospinous ligament, which is infiltrated with 3 mL of lidocaine. The needle is advanced farther through the ligament, and as it pierces the loose areolar tissue behind the ligament, the resistance of the plunger decreases. Another 3 mL of the anesthetic solution is injected into this region. Next, the needle is withdrawn into the guide, the tip of the guide is moved to just above the ischial spine. The needle is inserted through the mucosa and the rest of 10 mL of solution is deposited. The procedure is then repeated on the other side.

Within 3 to 4 minutes of the time of injection, the successful pudendal block will allow pinching of the lower vagina and posterior vulva bilaterally without pain. It is often of benefit before pudendal block to infiltrate the fourchette, perineum, and adjacent vagina directly at the site where the episiotomy is to be made with 5 to 10 mL of 1 percent lidocaine solution. Then, if delivery occurs before pudendal block becomes effective, an episiotomy can be made without pain. By the time of the repair, the pudendal block usually has become effective.

Pudendal block usually works well and is an extremely safe and relatively simple method of providing analgesia for spontaneous delivery. It can also be used along with epidural analgesia given during labor. Pudendal block may not provide adequate analgesia for other than outlet forceps delivery or when delivery requires extensive manipulation. Moreover, analgesia limited to pudendal block is usually inadequate for women in whom complete visualization of the cervix and upper vagina, or manual exploration of the uterine cavity, are indicated.

COMPLICATIONS. Intravascular injection of a local anesthetic agent may cause serious systemic toxicity characterized by stimulation of the cerebral cortex leading to convulsions. Hematoma formation from perforation of a blood vessel may develop. This is most likely when there is defective coagulation such as that induced by heparin or by placental abruption. These are discussed in [Chapter 25 \(p. 657\)](#). Rarely, severe infection may originate at the injection site. The infection may spread posterior to the hip joint, into the gluteal musculature, or into the retrosoas space ([Svancarek and associates, 1977](#)).

PARACERVICAL BLOCK

This block usually provides good to excellent pain relief during the first stage of labor. Because the pudendal nerves are not blocked, however, additional analgesia is required for delivery. Usually lidocaine or chlorprocaine, 5 to 10 mL of a 1-percent solution, is injected at 3 and 9 o'clock. Because these anesthetics are relatively short acting, paracervical block may have to be repeated during labor.

COMPLICATIONS. Fetal bradycardia is a worrisome complication that has been reported in 10 to 70 percent of paracervical blocks. Bradycardia usually develops within 10 minutes and may last up to 30 minutes. Several investigators stress that bradycardia is not a sign of fetal asphyxia, because it usually is transient and the newborns are in most instances vigorous at birth. There are reports, however, in which fetal scalp blood pH and Apgar scores were sometimes found to be low, and a few fetuses have died. The effect may be the consequence of transplacental transfer of the anesthetic agent or its metabolites and, in turn, a depressant effect on the heart. Based on studies in pregnant ewes, [Greiss \(1976\)](#) and [Fishburne \(1979\)](#), and their associates, believe that fetal bradycardia results from decreased placental perfusion as the consequence of drug-induced uterine artery vasoconstriction and myometrial hypertonus. For these reasons, paracervical block should not be used in situations of potential fetal compromise.

SPINAL (SUBARACHNOID) BLOCK

Introduction of a local anesthetic into the subarachnoid space to effect spinal block has long been used for delivery. Because of the smaller subarachnoid space during pregnancy, the same amount of anesthetic agent in the same volume of solution produces much higher blockade in parturients than in nonpregnant women. The smaller space is most likely the consequence of engorgement of the internal vertebral venous plexus.

VAGINAL DELIVERY. Low spinal block is a popular form of analgesia for forceps or vacuum delivery. The level of analgesia extends to the 10th thoracic dermatome, which corresponds to the level of the umbilicus. Blockade to this level provides excellent relief from the pain of uterine contractions.

Nearly all local anesthetic agents have been used for spinal analgesia. Lidocaine given in a hyperbaric solution produces excellent analgesia and has the advantage of a relatively short duration ([Table 15-2](#)). Tetracaine in a dose of 4 to 6 mg in a 6 percent dextrose solution provides satisfactory anesthesia in the lower vagina and the perineum for about an hour. Neither is administered for vaginal delivery until the cervix is fully dilated and all other criteria for safe forceps delivery have been fulfilled. Preanalgesic intravenous hydration with a liter of crystalloid solution will prevent hypotension in many cases.

CESAREAN DELIVERY. The level of spinal sensory blockade must extend at least to the eighth thoracic dermatome, which is just below the xiphoid process. Because a larger area is to be anesthetized, a larger dose of anesthetic agent is necessary, and this increases the frequency and intensity of toxic reactions. Depending upon maternal size, 8 to 10 mg of tetracaine, 12 mg of bupivacaine, or 50 to 75 mg of lidocaine are administered. The addition of 0.2 mg of morphine improves pain control during delivery and postoperatively.

COMPLICATIONS. A number of complications may ensue and close clinical monitoring of vital signs, including assessment of the level of analgesia, is imperative.

HYPOTENSION. This may develop very soon after injection of the local anesthetic agent. Defining hypotension as a 20 percent decrease from baseline, [Hall and colleagues \(1994\)](#) reported that 21 of 29 healthy women undergoing elective cesarean delivery developed hypotension. This is the consequence of vasodilatation from sympathetic blockade compounded by obstructed venous return from uterine compression of the vena cava and adjacent large veins. **In the supine position, even in the absence of maternal hypotension measured in the brachial artery, placental blood flow may still be significantly reduced.** As shown in [Table 15-3](#), treatment of spinal block hypotension includes uterine displacement, intravenous hydration, and intravenous bolus injections of 10 to 15 mg of ephedrine ([Morgan, 1994](#)). Some prefer infusions of ephedrine at rates of 1 or 2 mg/min ([Hall and colleagues, 1994](#)).

[Ramin and associates \(1994\)](#) reported that prophylactic infusion of ephedrine was effective to prevent hypotension in healthy women undergoing elective cesarean delivery using spinal analgesia. The mean fetal umbilical arterial pH was lower, albeit of no clinical significance, in the ephedrine-treated group than in the controls. In a follow-up randomized study at Parkland Hospital, [Morgan and colleagues \(2000\)](#) found that the preferred strategy for prevention of maternal hypotension due to spinal analgesia for elective cesarean delivery was 1000 mL Ringer lactate infused over 20 minutes before spinal injection and 5 mg bolus of ephedrine as needed to maintain blood pressure. The mean umbilical artery blood pH with this approach was 7.26. In contrast, continuous prophylactic infusions with various dilute ephedrine solutions were associated with significant fetal acidemia (mean pH 7.11 to 7.13). [Vercauteren and colleagues \(2000\)](#) reported that a single intravenous dose of 5 mg ephedrine given to prehydrated women receiving "small-dose" spinal analgesia for cesarean delivery resulted in significantly less hypotension compared with women receiving placebo (25 percent versus 58 percent).

Although not specifically attributed to hypotension, [Roberts and associates \(1995\)](#) reported that 18 percent of infants exposed to regional analgesia had umbilical arterial blood pH values of 7.19 or less and 3 percent were 7.1 or less. The acidemia was exclusively respiratory, and more often associated with spinal than with epidural analgesia. In contrast, [Valli and associates \(1994\)](#) found no adverse effects on Apgar scores or umbilical arterial or venous blood acid-base status in women

receiving either spinal or epidural analgesia.

TOTAL SPINAL BLOCKADE. Most often, total spinal blockade is the consequence of administration of an excessive dose of analgesic agent. This is certainly not always the case, as accidental total spinal block has even occurred following an epidural test dose ([Palkar and associates, 1992](#)). In complete spinal block, hypotension and apnea promptly develop and must be immediately treated to prevent cardiac arrest. In the undelivered woman, the uterus is displaced laterally to minimize aortocaval compression. Effective ventilation is established, preferably with tracheal intubation. Intravenous fluids and ephedrine are given to increase blood pressure.

SPINAL (POSTPUNCTURE) HEADACHE. Leakage of cerebrospinal fluid from the site of puncture of the meninges is thought to be the major factor in the genesis of spinal headache. When 22- or 24-gauge needles are used, about 1.5 percent of parturients develop postdural puncture headaches ([Sears and co-workers, 1994](#)). Presumably, when the woman sits or stands, the diminished volume of cerebrospinal fluid allows traction on pain-sensitive central nervous system structures. This complication can be reduced by using a small-gauge spinal needle and avoiding multiple punctures. Sprotte or Whitacre needles with noncutting rounded tips are best ([American College of Obstetricians and Gynecologists, 1996](#)).

There is no good evidence that placing the woman absolutely flat on her back for several hours is very effective in preventing headache. Vigorous hydration may be of value, but also without compelling evidence to support its use. Abdominal support with a girdle or abdominal binder does seem to afford relief. Typically, the headache is remarkably improved by the third day and absent by the fifth. In severe cases, a blood patch is effective. A few mL of the woman's blood obtained aseptically without anticoagulant is injected into the epidural space at the site of the dural puncture. Relief is immediate and complications uncommon. [Oh and Camann \(1998\)](#) have reported severe meningeal irritation after a blood patch. [Carter and Pasupuleti \(2000\)](#) reported successful treatment with intravenous cosyntropin when blood patch had been unsuccessful.

CONVULSIONS. In rare instances, postdural puncture cephalgia is associated with blindness and convulsions. [Shearer and colleagues \(1995\)](#) described eight such cases associated with 19,000 regional analgesic procedures. It is presumed that these too are caused by cerebrospinal fluid hypotension.

BLADDER DYSFUNCTION. With spinal analgesia, bladder sensation is likely to be obtunded and bladder emptying impaired for the first few hours after delivery. As a consequence, bladder distention is a frequent postpartum complication, especially if appreciable volumes of intravenous fluid are given.

OXYTOCICS AND HYPERTENSION. Paradoxically, hypertension from ergonovine or methylergonovine injected following delivery is more common in women who have received a spinal or epidural block.

ARACHNOIDITIS AND MENINGITIS. Local anesthetics are no longer preserved in alcohol, formalin, or other toxic solutes, and disposable equipment is used by most. These practices coupled with aseptic technique, have made meningitis and arachnoiditis rarities. Still, these are occasionally documented ([Harding and colleagues, 1994](#); [Newton and associates, 1994](#)).

CONTRAINDICATIONS TO SPINAL ANALGESIA. The most common serious complication from spinal block is hypotension. The supine position late in pregnancy predisposes to a reduction in return of blood from veins below the level of the large pregnant uterus and, in turn, a reduction in cardiac output. Moreover, sympathetic blockade from spinal analgesia is usually extensive, and it leads to further pooling of blood in dilated blood vessels below the blockade. Obstetrical complications that are associated with maternal hypovolemia and hypotension are contraindications to the use of spinal block. Thus, severely decreased blood pressure can be predicted when subarachnoid analgesia is used in the presence of severe hemorrhage or severe preeclampsia. For these reasons, spinal block is felt by some obstetrical anesthesiologists to be contraindicated in severe preeclampsia ([Reisner and Nichols, 1999](#)). Conversely, others prefer spinal analgesia to general anesthesia for cesarean delivery in these women ([Writer, 1994](#)).

[Hood and Curry \(1999\)](#) retrospectively evaluated 138 women with severe preeclampsia undergoing cesarean delivery. They reported that the magnitude of decrease in blood pressure and maternal and fetal outcomes were similar after spinal or epidural analgesia. [Wallace and colleagues \(1995\)](#) randomized 80 women undergoing cesarean delivery with severe preeclampsia to general anesthesia or to either epidural or spinal-epidural analgesia. There were no differences in outcomes, but 30 percent of those given epidural analgesia and 22 percent of those given spinal-epidural blockage developed hypotension.

The cardiovascular effects of spinal block in the presence of acute blood loss, but in the absence of the hemodynamic effects of pregnancy, have been investigated by [Kennedy and co-workers \(1968\)](#). In 15 nonpregnant volunteers, spinal analgesia to the fifth thoracic sensory level was induced twice, the second time after a phlebotomy of 10 mL/kg. In the case of subarachnoid block without hemorrhage, the mean arterial blood pressure fell 10 percent while cardiac output rose slightly. In the case of hemorrhage without subarachnoid block, the mean blood pressure fell to the same degree and again the cardiac output rose slightly. With subarachnoid block after the modest hemorrhage, however, the mean arterial pressure fell nearly 30 percent and cardiac output fell 15 percent.

Disorders of coagulation and defective hemostasis preclude the use of spinal analgesia. Subarachnoid puncture is contraindicated when the skin or underlying tissue at the site of needle entry is infected. Neurological disorders are considered by many to be a contraindication, if for no other reason than exacerbation of the neurological disease might be attributed to the anesthetic agent (see [Chap. 53](#)). Other maternal conditions such as significant aortic stenosis or pulmonary hypertension are also contraindications to the use of spinal analgesia ([Chap. 44, p. 1194](#)). [Akpek and colleagues \(1999\)](#) reported a case of chronic subdural hematoma following spinal anesthesia for cesarean delivery.

EPIDURAL ANALGESIA

Relief from the pain of uterine contractions and delivery, vaginal or abdominal, can be accomplished by injecting a suitable local anesthetic agent into the epidural or peridural space ([Fig. 15-5](#)). This is a potential space that contains areolar tissue, fat, lymphatics, and the internal venous plexus, which becomes engorged during pregnancy so that it appreciably reduces the volume of the space. The portal of entry for obstetrical analgesia is through either a lumbar intervertebral space for lumbar epidural analgesia, or through the sacral hiatus and sacral canal for caudal epidural analgesia. Although one injection may be used, much more often these are repeated through an indwelling catheter, or they are given by continuous infusion using a volumetric pump.

CONTINUOUS LUMBAR EPIDURAL BLOCK. Complete analgesia for the pain of labor and vaginal delivery necessitates a block from the 10th thoracic to the 5th sacral dermatomes. For abdominal delivery, the block is essential beginning at the eighth thoracic level and extending to the first sacral dermatome. The spread of the epidurally injected anesthetic agent will depend upon the location of the catheter tip; the dose, concentration, and volume of anesthetic agent used ([Table 15-2](#)); and whether position is head-down, horizontal, or head-up. The anatomy unique to each individual epidural space will also affect the block; for example, presence of synechiae may preclude establishment of a completely satisfactory block. It should also be recognized that the catheter tip may move from its original location during the course of labor.

Before any injection of the local anesthetic agent, a test dose is given and the woman observed for features of toxicity from intravascular injection and signs of spinal blockade from subarachnoid injection. Then a full dose is given carefully and analgesia is maintained by intermittent boluses of similar volume, or small volumes of the drug are delivered continuously by infusion pump. The addition of small doses of a short-acting narcotic, either fentanyl or sufentanil, has been shown to improve analgesic efficacy for labor or cesarean delivery ([Chestnut and colleagues, 1988](#)). The rationale for opiate use is to avoid motor block by allowing reduction in dose of local anesthetic.

When vaginal delivery is anticipated in 10 to 15 minutes, a rapidly acting agent is given through the epidural catheter to effect perineal analgesia.

TECHNIQUE. The sequential steps and techniques for performance of epidural anesthesia have been described by [Glosten \(1994\)](#) and are detailed in [Table 15-4](#). It is again emphasized that appropriate resuscitation equipment and drugs must be available during administration of epidural analgesia.

COMPLICATIONS. Epidural analgesia for labor and delivery may provide most pleasant relief from the pain of labor. There are certain problems inherent in its use and, as with spinal blockade, it is imperative that close monitoring, including the level of analgesia, be performed by trained personnel. [Table 15-5](#) summarizes the complications.

TOTAL SPINAL BLOCKADE. Dural puncture with inadvertent subarachnoid injection may cause total spinal block. Personnel and facilities must be immediately available to manage this complication as described under spinal block (p. 372). Postdural puncture headache is a less serious but troublesome complication of inadvertent entry.

INEFFECTIVE ANALGESIA. The extent to which pain relief during labor can be obtained with lumbar epidural analgesia varies, and establishment of effective pain relief with maximum safety takes time. Epidural analgesia for women of higher parity in rapid active labor is likely to prove not worth the risk and expense. Using currently popular continuous epidural infusions such as 0.125 percent bupivacaine with 2 ug/mL fentanyl, 90 percent of women rate their pain relief good to excellent and 95 percent express a desire for the same type of analgesia during a future delivery ([Sharma and colleagues, 1997](#)). Alternatively, these results also indicate that a few women find epidural analgesia to be inadequate. If the epidural analgesia is allowed to dissipate before another injection of anesthetic drug, subsequent pain relief may be delayed, incomplete, or both.

At times, perineal analgesia for delivery is difficult to obtain, especially with the lumbar epidural technique. When this condition is encountered, a low spinal or pudendal block, or systemic analgesia is added.

HYPOTENSION. By blocking sympathetic tracts, epidurally injected analgesic agents may cause hypotension and decreased cardiac output. In normal pregnant women, hypotension induced by epidural analgesia can usually be prevented by rapid infusion of 500 to 1000 mL of crystalloid solution, or treated successfully as described for spinal analgesia. [Danilenko-Dixon and associates \(1996\)](#) showed that maintaining a lateral position minimized this compared with the supine position. Despite these precautions, hypotension is the most common side effect and occurs in a third of women ([Sharma and colleagues, 1997](#)).

CENTRAL NERVOUS STIMULATION. Convulsions are an uncommon but serious complication, the immediate management of which was described previously.

MATERNAL PYREXIA. [Fusi and associates \(1989\)](#) observed that the mean temperature in laboring women given epidural analgesia was significantly higher than in those given meperidine. [Lieberman and colleagues \(1997\)](#), in a study of 1657 nulliparous women, reported intrapartum fever in 15 percent of women receiving epidural analgesia versus only 1 percent of those without epidural analgesia. They also found that epidural analgesia was significantly associated with neonatal sepsis evaluation and antibiotic therapy. [Dashe and co-workers \(1999\)](#) studied placental histopathology in women delivered after labor epidural analgesia. Such analgesia was associated with intrapartum fever only in the presence of placental inflammation. This suggests that the fever reported with epidural analgesia is due to infection rather than the analgesia itself. [Sharma \(2000\)](#) has reviewed maternal fever associated with epidural analgesia. It appears that pyrexia is associated with a higher incidence of intrauterine infection from longer first-stage labor ([Halpern and co-workers, 1998](#); [Mayer and associates, 1997](#); [Sharma and colleagues, 1997](#)).

BACK PAIN. Although an association of epidural analgesia and back pain has been reported by some, others have not found such an association ([Breen, 1994](#); [MacArthur, 1990, 1997](#); [Russell, 1993](#), and all their colleagues). In a prospective cohort study, [Butler and Fuller \(1998\)](#) reported that postpartum back pain following epidural analgesia was common, but persistent or chronic back pain was uncommon.

EFFECT ON LABOR. The use of epidural analgesia during labor has greatly increased during the past two decades, coincident with a significant escalation in the maternal cesarean birth rate ([Sachs and colleagues, 1999](#)). As shown in [Tables 15-6](#) and [15-7](#), epidural analgesia usually prolongs the first stage of labor, and increases the need for labor stimulation with oxytocin. It also increases the chance of an instrumental delivery due to prolonged second-stage labor but with no adverse effects on the infant ([Chestnut, 1999](#); [Thorp and Breedlove, 1996](#)). Investigators at Brigham and Women's Hospital observed that epidural analgesia is associated with an increase in the rate of severe perineal trauma because of the more frequent use of operative vaginal delivery ([Robinson and associates, 1999](#)).

A more contentious issue is whether epidural analgesia increases the risk of cesarean delivery. As reviewed by [Sharma and Leveno \(2000\)](#), several retrospective studies and a few randomized studies have suggested that epidural analgesia during labor is associated with increased cesarean deliveries.

Between 1993 and 1996, a total of 3276 women at Parkland Hospital with uncomplicated term pregnancies were randomized in three trials of various labor epidural analgesia techniques using dilute solutions of local anesthetic as well as methods for administration of meperidine intravenously. The results of all three of these trials, as pertains to cesarean deliveries, are shown in [Table 15-8](#). Epidural analgesia did not significantly increase cesarean deliveries in either nulliparous or parous women in any individual trial or in their aggregate. These results are consistent with the belief of many investigators that the epidural administration of dilute solutions of local anesthetic is less likely to increase cesarean rates compared with concentrated solutions ([Chestnut, 1997](#); [Thompson and colleagues, 1998](#)).

There have been several additional recent reports indicating that epidural analgesia is not associated with excess cesarean births. [Halpern and colleagues \(1998\)](#) performed meta-analysis of seven studies of 1183 women who received epidural analgesia versus 1186 who received opioids for labor pain. They reported no increase in the cesarean rate attributable to epidural analgesia. [Yancey and co-workers \(1999\)](#) published a remarkable report on the effects of introduction of an on-demand labor epidural analgesia service at Tripler Army Hospital in Hawaii. In late 1993, a policy change within the Department of Defense required the availability of on-demand labor epidural analgesia in military medical centers. As a result, the incidence of epidural analgesia during labor increased from 1 percent before the policy to 60 percent 2 years after the policy had been implemented. The primary cesarean rate was 13.4 percent before and 13.2 percent after this dramatic change in epidural usage.

In 1993, the American Society of Anesthesiologists and the American College of Obstetricians and Gynecologists issued the following joint statement: "There is no other circumstance where it is considered acceptable for a person to experience severe pain, amenable to safe intervention, while under a physician's care." This implies that all women should have access to effective pain relief during labor. We are of the view that the fear of increasing the risk of cesarean delivery should not preclude women from choosing epidural analgesia during labor.

TIMING OF EPIDURAL PLACEMENT. In a randomized trial, [Chestnut and associates \(1994\)](#) found no increase in either operative vaginal delivery or cesarean delivery with early—at or before 3 cm dilatation—administration of epidural analgesia compared with later administration. Similar results were reported by [Rogers and co-workers \(1999\)](#). In the Parkland Hospital trials described earlier in this section, epidural analgesia was not begun prior to 3 to 5 cm cervical dilatation, and this continues to be our practice unless labor is already being stimulated with oxytocin.

SAFETY. The relative safety of epidural analgesia is attested to by the extraordinary experiences reported by [Crawford \(1985\)](#) from the Birmingham Maternity Hospital in England. From 1968 through 1985, over 26,000 women were given epidural analgesia for labor, and there were no maternal deaths. The nine potentially life-threatening complications followed either inadvertent intravenous or intrathecal injections of lidocaine, bupivacaine, or both.

CONTRAINDICATIONS. As with spinal analgesia, contraindications to epidural analgesia include actual or anticipated serious maternal hemorrhage, infection at or near the sites for puncture, and suspicion of neurological disease. [Rolbin and colleagues \(1988\)](#) advise against epidural analgesia if the platelet count is below 100,000/uL. Conversely, [Rasmus and associates \(1989\)](#) found no cases in which bleeding was caused by regional analgesia in thrombocytopenic women. They recommended consideration of this method if the patient might be difficult to intubate or ventilate.

SEVERE PREECLAMPSIA-ECLAMPSIA. Ideal labor analgesia for women with severe preeclampsia has been controversial. This is discussed in [Chapter 24](#). Obstetrical concerns centered on hypotension induced by sympathetic blockade, dangers from pressor agents given to correct hypotension, and potential for pulmonary edema following infusion of large volumes of crystalloid. Anesthesiologists are concerned that general anesthesia with tracheal intubation may result in severe, sudden hypertension further complicated by pulmonary or cerebral edema or intracranial hemorrhage.

Over the past two to three decades, most obstetrical anesthesiologists have come to favor epidural blockade for labor and delivery in women with severe preeclampsia ([Cheek and Samuels, 1991](#); [Gutsche, 1986](#)). Indeed, the immense popularity and increasing availability of epidural analgesia for labor has led many anesthesiologists as well as obstetricians to develop the viewpoint that epidural analgesia is an important factor in the treatment of these women with severe disease ([Chadwick and Easterling, 1991](#); [Ramanathan, 1991](#)). At the same time, many of these same authorities have criticized the use of general anesthesia. Although the ultimate decision for anesthetic management of cesarean delivery remains with the anesthesiologist, the obstetrician must approve the use of labor epidural analgesia, and both must be knowledgeable about the obstetrical effects of either method used for delivery.

There seems to be no argument that epidural analgesia for women with severe preeclampsia-eclampsia can be safely used when specially trained anesthesiologists and obstetricians are responsible for the woman and her fetus ([American College of Obstetricians and Gynecologists, 1996](#); [Cunningham and Leveno, 1995](#); [Cunningham and Lindheimer, 1992](#); [Moore and colleagues, 1985](#)). In an evaluation of cesarean delivery for women with severe preeclampsia, [Wallace and colleagues \(1995\)](#) randomized 80 such women to receive general anesthesia, epidural analgesia, or combined spinal-epidural analgesia. Although no woman receiving general anesthesia required ephedrine for hypotension, this was necessary in 30 percent of those given epidural analgesia and 22 percent of those given spinal-epidural analgesia. There were no significant differences in neonatal outcomes among the three groups. It was concluded that general anesthesia and regional analgesia are equally acceptable for cesarean delivery in women with severe preeclampsia.

Although epidural analgesia is widely used during labor in women with hypertensive disorders due to pregnancy, the effects of such analgesia in the mother and fetus are just coming under scrutiny. [Lucas and colleagues \(2001\)](#) randomized 738 women with hypertension and term pregnancies to epidural analgesia or

patient-controlled intravenous analgesia during labor. It was concluded that it was safe to use epidural analgesia during labor in women with hypertensive disorders but that epidural analgesia should not be administered as a therapy for this obstetrical complication. In a retrospective analysis of 327 laboring women with severe hypertension, [Hogg and colleagues \(1999\)](#) found no difference in overall cesarean delivery rates (32 versus 28 percent) in women who received epidural analgesia compared with those who did not. The frequencies of pulmonary edema or renal failure were similar between the groups.

INTRAVENOUS FLUID PRELOADING. Most authorities recommend prehydration, usually with 500 to 1000 mL of crystalloid solution ([Hogg and associates, 1999](#)). Importantly, vasodilation produced by epidural blockade is usually less abrupt if the analgesia level is achieved slowly, thus allowing maintenance of blood pressure while simultaneously avoiding infusion of large volumes of crystalloid.

[Newsome and colleagues \(1986\)](#) demonstrated that lowered mean arterial pressure followed epidural blockade in women with severe preeclampsia. Despite this, cardiac index did not fall because vigorous intravenous crystalloid infusion caused elevation of pulmonary capillary wedge pressures as compared with women not given epidural analgesia and in whom fluids were restricted ([Fig. 15-6](#)). Although the intravascular volume of women with severe preeclampsia is not expanded as for normal pregnancy, total body water is increased. It is also generally recognized that there is a capillary leak with severe preeclampsia, and that this is manifested as pathological peripheral edema, proteinuria, and ascites. Aggressive volume replacement in these women increases their risk for pulmonary edema, especially in the first 72 hours postpartum ([Clark and colleagues, 1985](#); [Cotton and associates, 1986](#)). [Hogg and associates \(1999\)](#) reported that 3.5 percent of women had pulmonary edema when pretreated with intravenous fluid without a protocol limitation to volume. By contrast, [Lucas and colleagues \(2001\)](#) reported no instances of pulmonary edema in 738 women in whom crystalloid preload was limited to 500 mL.

With vigorous intravenous crystalloid therapy, there is also concern for development of cerebral edema. Finally, [Heller and co-workers \(1983\)](#) demonstrated that the majority of cases of pharyngolaryngeal edema were related to aggressive volume therapy.

EPIDURAL OPIATE ANALGESIA. Injection of opiates into the epidural space to relieve pain from labor has become popular. Complications with this technique are less worrisome than those seen with epidural injection of local anesthetics alone. The mechanism of action of opiates given epidurally derives from their interaction with specific receptors in the dorsal horn and dorsal roots. Apparently both cerebral and spinal opioid receptors are stimulated by these narcotics ([Ackerman and colleagues, 1992](#)).

Opiates alone usually will not provide adequate analgesia, and they most often are given with a local anesthetic agent such as bupivacaine ([American College of Obstetricians and Gynecologists, 1996](#)). The major advantages of using such a combination are the rapid onset of pain relief, a decrease in shivering, and less dense motor blockade. [Cohen and colleagues \(1992\)](#), in a randomized study of epidural buprenorphine plus bupivacaine versus fentanyl plus bupivacaine, reported that both epidural opioids were equally efficacious. [Steinberg and associates \(1989\)](#) reported that sufentanil may provide adequate epidural analgesia when used alone. By comparison, a single lumbar intrathecal injection of 25 µg of fentanyl and 0.25 mg of morphine sulfate has been reported to result in a satisfactory level of pain relief without disrupting labor. [Meister and colleagues \(2000\)](#), in a randomized study of 50 laboring women, compared epidural analgesia with 0.125 percent ropivacaine and fentanyl to 0.125 percent bupivacaine and fentanyl. Both groups had similar labor analgesia, but the ropivacaine group had significantly less motor block.

Side effects are common ([Herpelshimer and Schretenthaler, 1994](#)). They include pruritus (80 percent), urinary retention (55 percent), nausea and vomiting (45 percent), and headaches (10 percent). [Rust and colleagues \(1994\)](#) reported excellent pain relief (93 percent) using this technique, but again recorded a high incidence of pruritus and/or urinary retention. Immediate or delayed respiratory depression is worrisome ([Ackerman and colleagues, 1992](#)). Naloxone, given intravenously, will abolish these symptoms without affecting the analgesic action. [Horta and colleagues \(2000\)](#) reported a reduction in the incidence of pruritus with droperidol given in doses of up to 5 mg epidurally. This effect was dose-related and was not associated with other serious side effects. [Hunt and colleagues \(1989\)](#) reported a fetal sinusoidal heart rate pattern associated with maternal administration of epidural butorphanol and bupivacaine.

COMBINED SPINAL-EPIDURAL TECHNIQUES. combination of spinal and epidural techniques may provide rapid and effective analgesia for labor or for cesarean delivery. Although neonatal complications are not increased, there is no consensus regarding maternal complications when comparing spinal or epidural analgesia with combined techniques ([American Society of Anesthesiologists Task Force on Obstetrical Anesthesia, 1999](#)). In a randomized trial of 110 laboring women, [Van de Velde and associates \(1999\)](#) compared epidural with combined spinal-epidural analgesia and reported that the combined method produced excellent immediate pain relief for labor. Side effects were similar between the two groups. [Nickells and colleagues \(2000\)](#) compared rapidity of onset of labor analgesia in 69 women given combined spinal-epidural versus 73 women given epidural analgesia. Onset of analgesia was only slightly faster for the combined technique (10.0 versus 12.1 minutes); however, it was associated with more side effects.

The largest study of the combined spinal-epidural technique performed in laboring women was conducted at Parkland Hospital ([Gambling and co-workers, 1998](#)). There were 1223 women with uncomplicated term pregnancies who were randomized to continuous spinal-epidural analgesia or boluses of intravenous meperidine. Emergency cesarean delivery for profound fetal tachycardia was performed in 9 of 616 women assigned to combined spinal-epidural analgesia compared with none of 607 in the meperidine groups ($P < .005$). Fetal bradycardia typically occurred within 30 minutes of the initiation of intrathecal analgesia and was defined as fetal heart rate less than 60 bpm lasting 60 seconds or longer. None of the cases responded to conservative measures such as changing maternal position, oxygen administration, or intravenous ephedrine. Interestingly, none of these cases were associated with maternal hypotension. Although, none of these infants suffered ill effects, we now avoid the combined spinal-epidural technique.

TABLE 15-2. Some Local Anesthetic Agents Used in Obstetrics

Anesthetic Agent	Usual Concentration (%)	Plain Solutions			Onset	Average Duration (min)	Clinical Use
		Usual Volume (mL)	Usual Dose (mg)				
Amino-esters							
2-Chloroprocaine	1-2	20-30	400-600	Rapid	15-30	Local or pudendal block	
	2-3	15-25	300-750		30-60		Epidural for cesarean
Tetracaine	0.2	—	4	Slow	75-150	Low spinal block/6% glucose	
	0.5	—	7-10		75-150		Spinal for cesarean/5% glucose
Amino-amides							
Lidocaine	1	20-30	200-300	Rapid	30-60	Local or pudendal block	
	2	15-30	300-450		60-90		Epidural for cesarean
	5	1-1.5	50-75		45-60		Spinal for cesarean or puerperal tubal ligation/7.5-8.25% glucose
	5	0.5-1	25-50		30-60		Spinal for vaginal delivery/7.5-8.25% glucose
Bupivacaine	0.5	15-20	75-100	Slow	90-150	Epidural for cesarean	
	0.25	8-10	20-25		60-90		Epidural for labor
	0.75	1-1.5	7.5-11		60-120		Spinal for cesarean/8.25% glucose
Ropivacaine	0.5	15-20	75-100	Slow	90-150	Epidural for cesarean	
	0.25	8-10	20-25		60-90		Epidural for labor

TABLE 15-4. Technique for Labor Epidural Analgesia

1. Informed consent is obtained, and the obstetrician consulted.
2. Monitoring includes the following:
 - Blood pressure every 1-2 minutes for 15 minutes after giving a bolus of local anesthetic.
 - Continuous maternal heart rate monitoring during induction of anesthesia.
 - Continuous fetal heart rate monitoring.
 - Continual verbal communication.
3. Hydration with 500-1000 mL of lactated Ringer solution.
4. The woman assumes a lateral decubitus or sitting position.
5. The epidural space is identified with a loss-of-resistance technique.
6. The epidural catheter is threaded 3 cm into the epidural space.
7. A test dose of 3 mL of 1.5% lidocaine with 1:200,000 epinephrine or 3 mL of 0.25% bupivacaine with 1:200,000 epinephrine is injected after careful aspiration and after a uterine contraction (to minimize the chance of confusing tachycardia that results from pain with tachycardia secondary to intravenous injection of the test dose).
8. If the test dose is negative, one or two 5-mL doses of 0.25% bupivacaine are injected to achieve a cephalad sensory T₁₀ level.
9. After 15-20 minutes, the block is assessed using loss of sensation to cold or pinprick. If no block is evident, the catheter is replaced. If the block is asymmetrical, the epidural catheter is withdrawn 0.5-1.0 cm and an additional 3-5 mL of bupivacaine is injected. If the block remains inadequate, the catheter is replaced.
10. The woman is positioned in the lateral or semi-lateral position to avoid aortocaval compression.
11. Subsequently, maternal blood pressure is recorded every 5-15 minutes. The fetal heart rate is monitored continuously.
12. The level of analgesia and intensity of motor block are assessed hourly.

TABLE 15-5. Complications of Epidural Analgesia

Immediate

High or total spinal
Hypotension
Urinary retention
Headache
Postdural puncture seizures
Meningitis
Cardiorespiratory arrest
Vestibulocochlear dysfunction

Long-term (epidural vs controls)

Backache (19 vs 10%)
Frequent headaches (4.6 vs 3%)
Migraine headache (1.9 vs 1.1%)
Neckache (2.4 vs 1.6%)
Tingling in hands or fingers (3 vs 2.2%)

16. The Newborn Infant

ADAPTATION OF THE NEWBORN TO AIR BREATHING

At birth, the infant is subjected to rapid and profound physiological changes. Survival depends upon a prompt and orderly interchange of oxygen and carbon dioxide. For efficient interchange, the fluid-filled alveoli of the lungs must fill with air, the air must be exchanged by appropriate respiratory motion, and a vigorous microcirculation must be established in close proximity to the alveoli.

INITIATION OF AIR BREATHING

Very soon after birth, the breathing pattern shifts from one of shallow episodic inspirations characteristic of the fetus to that of regular, deeper inhalations ([Chap. 40, p. 1098](#)). Aeration of the newborn lung is not the inflation of a collapsed structure, but instead, the rapid replacement of bronchial and alveolar fluid by air. In the lamb, and presumably in the human infant, residual alveolar fluid after delivery is cleared through the pulmonary circulation and, to a lesser degree, through pulmonary lymphatics ([Chernick, 1978](#)). Delay in removal of fluid from the alveoli probably contributes to the syndrome of **transient tachypnea of the newborn**. As fluid is replaced by air, there is considerable reduction in pulmonary vascular compression and, in turn, lowered resistance to blood flow. With the fall in pulmonary arterial blood pressure, the ductus arteriosus normally closes. Closure of the foramen ovale is more variable.

High negative intrathoracic pressures are required to bring about the initial entry of air into fluid-filled alveoli. Normally, from the first breath after birth, progressively more residual air accumulates in the lung, and with each successive breath, lower pulmonary opening pressure is required. In the mature normal infant, by about the fifth breath, pressure-volume changes achieved with each respiration are very similar to those of the adult.

ALVEOLAR SURFACE TENSION AND LUNG SURFACTANT. Surface-active material lowers surface tension in the alveoli and thereby prevents the collapse of the lung with each expiration. Lack of sufficient surfactant, common in preterm infants, leads to the prompt development of the **respiratory distress syndrome** ([Chap. 39, p. 1040](#)).

STIMULI TO BREATHE AIR. Normally, the newborn begins to breathe and cry almost immediately after birth, indicating the establishment of active respiration. All factors involved in the first breath of air have been difficult to elucidate, undoubtedly because many individually subtle stimuli contribute simultaneously. For example, *physical stimulation*, such as handling the infant during delivery, is believed to provoke respiration.

Compression of the thorax during the second stage of labor forces some fluid from the respiratory tract. [Saunders \(1978\)](#) found that considerable pressure is often produced by chest compression during vaginal delivery so that lung fluid is expelled equivalent to about a fourth of ultimate functional residual capacity. Thus, babies delivered by cesarean are likely to have more fluid and less gas in their lungs throughout the first 6 hours of life ([Milner and colleagues, 1978](#)). Thoracic compression incidental to vaginal delivery and the expansion that follows delivery may nevertheless be an auxiliary factor in initiation of respiration.

Deprivation of oxygen and accumulation of carbon dioxide also may stimulate respiration. Blood samples obtained from catheters implanted into vessels of experimental animal fetuses for prolonged periods of time, as well as cordocentesis in humans, contain a low PO_2 compared with adult standards. In animals, a further decrease in PO_2 diminishes or abolishes fetal respiratory motion, whereas an elevation of PCO_2 increases the frequency and magnitude of fetal breathing movements ([Dawes, 1974](#)). For the foregoing reasons, it seems that the fetus-infant most likely responds to hypoxia and to hypercapnia the same way in utero and after birth.

MANAGEMENT OF DELIVERY

IMMEDIATE CARE

With delivery of the head, either vaginally or by cesarean delivery, the face is immediately wiped and the mouth and nares are suctioned. A soft rubber syringe or its equivalent inserted with care is quite suitable. Before clamping and severing the cord, while the infant is still being held head down, it is beneficial to aspirate the mouth and pharynx again. Once the cord has been divided, the infant is placed supine with the head lowered and turned to the side in a heated unit that has appropriate thermal regulation and is equipped for immediate intensive care ([Fig. 16-1](#)). To minimize heat loss, the baby is wiped dry.

The individual who delivers the baby is responsible for immediate postdelivery care until another qualified person assumes this duty. An individual qualified to perform neonatal resuscitation should be immediately available in the hospital at the time of delivery.

INFANT EVALUATION

Before and during delivery, careful considerations must be given to the following determinants of neonatal well-being:

1. Health status of the mother.
2. Prenatal complications.
3. Labor complications.
4. Gestational age.
5. Duration of labor.
6. Duration of ruptured membranes.
7. Types, amounts, times, and routes of administration of medications.
8. Type and duration of anesthesia.
9. Any difficulty with delivery.

The infant is inspected for any visible abnormalities. The cord is cut and the infant then handed to a trained associate for further care.

The person immediately in charge of caring for the neonate should observe respirations closely and identify the heart rate. The heart rate can be determined by auscultation over the chest or by palpating the base of the umbilical cord. A readily discernible heartbeat of 100/min or more is acceptable. Persistent bradycardia requires prompt resuscitation. Next, the mouth, nares, and pharynx are suctioned carefully.

Most normal infants take a breath within a few seconds of birth and cry within half a minute. If respirations are infrequent, suction of the mouth and pharynx, followed by light slapping of the soles of the feet and rubbing of the back, usually together serve to stimulate breathing. Prolongation of these intervals beyond 1 and 2 minutes, respectively, indicates an abnormality. Continued lack of breathing demands active resuscitation.

LACK OF EFFECTIVE RESPIRATIONS

Important causes of failure to establish effective respirations include the following:

1. Fetal hypoxemia or acidosis from any cause.
2. Drugs administered to the mother.

3. Gross fetal immaturity.
4. Upper airway obstruction.
5. Pneumothorax.
6. Other lung abnormalities, either intrinsic (e.g., hypoplasia) or extrinsic (e.g., diaphragmatic hernia).
7. Aspiration of amniotic fluid grossly contaminated with meconium.
8. Central nervous system developmental abnormality.
9. Septicemia.

METHODS USED TO EVALUATE NEWBORN CONDITION

APGAR SCORE

A useful aid to evaluate the need for infant resuscitation is the Apgar scoring system applied at 1 minute and again at 5 minutes after birth ([Table 16-1](#)). The 1-minute Apgar score is used to identify the need for immediate resuscitation. Most infants at birth are in excellent condition, as indicated by Apgar scores of 7 to 10, and they require no aid other than perhaps simple nasopharyngeal suction. An Apgar score of 10 is in practice rarely assigned. An infant with a score of 4 to 6 at 1 minute demonstrates depressed respirations, flaccidity, and pale to blue color. Heart rate and reflex irritability, however, are good. Infants with scores of 0 to 3 usually have slow to inaudible heart rates and depressed or absent reflex responses. Resuscitation, including artificial ventilation, should be started immediately. Such infants are often easy to recognize. They may be flaccid, apneic, and often covered with meconium, and heart rates usually are below 100.

The Apgar score is a useful clinical tool used to identify those neonates who require resuscitation, as well as to indicate the effectiveness of any resuscitative measures. Unfortunately, attempts have also been made—without supporting data—to relate the Apgar score to antenatal events or to long-term outcomes. For reasons that are not entirely clear, erroneous definitions of asphyxia have been established, based upon the Apgar score alone. Because of these misconceptions, in 1986 the American College of Obstetricians and Gynecologists, and the American Academy of Pediatrics, issued a joint statement on the use and misuse of the Apgar score. This statement was reaffirmed most recently in 1996. Because of its importance, and with permission from the American College of Obstetricians and Gynecologists, it is reprinted here in its entirety.

USE AND MISUSE OF THE APGAR SCORE

The Apgar score, devised in 1952 by Dr. Virginia Apgar, is a quick method of assessing the state of the newborn infant ([Apgar, 1953](#); [Apgar and colleagues, 1958](#)). Ease of scoring has led to its use in many studies of outcome. However, its misuse has led to an erroneous definition of asphyxia. Intrapartum asphyxia implies fetal hypercarbia and hypoxemia, which if prolonged will result in eventual metabolic acidemia. Because the intrapartum disruption of uterine or fetal blood flow is rarely, if ever, absolute, *asphyxia* is an imprecise, general term. Terms such as *hypercarbia*, *hypoxia*, and *metabolic, respiratory, or lactic acidemia* are more precise, both for immediate assessment of intrapartum management. Although the Apgar score continues to provide a convenient "shorthand" for reporting the status of the newborn and the effectiveness of resuscitation, the purpose of this statement is to place the Apgar score in its proper perspective.

The Apgar score comprises five components: heart rate, respiratory effort, muscle tone, reflex, irritability, and color, each of which is given a score of 0, 1, or 2 ([Table 16-1](#)). Reliable Apgar scores require assessment of individual components of the score by trained personnel.

Factors That May Affect Apgar Scores

Although rarely stated, it is important to recognize that elements of the Apgar score such as tone, color, and reflex irritability are partially dependent on the physiologic maturity of the infant. The healthy premature infant with no evidence of anoxic insult, acidemia, or cerebral depression may thus receive a low score only because of immaturity ([Amon and associates, 1987](#); [Catlin and co-workers, 1986](#)).

A number of maternal medications and infant conditions may influence Apgar scores, including, but not limited to, neuromuscular or cerebral malformations that may decrease tone and respiratory effort. Cardiorespiratory conditions may also decrease the infant's heart rate, respiration, and tone. Infection may interfere with tone, color and response to resuscitative efforts. Additional information is required to interpret Apgar scores properly in infants receiving resuscitation. Thus, to equate the presence of a low Apgar score solely with asphyxia or hypoxia represents a misuse of the score.

Apgar Score and Subsequent Disability

A low 1-minute Apgar score does not correlate with the infant's future outcome. The 5-minute Apgar score, and particularly the change in the score between 1 and 5 minutes, is a useful index of the effectiveness of resuscitation efforts. However, even a 5-minute score of 0 to 3, although possibly a result of hypoxia, is limited as an indicator of the severity of the problem and correlates poorly with future neurologic outcome ([Nelson and Ellenberg, 1981](#); [Stanley, 1994](#)). An Apgar score of 0 to 3 at 5 minutes is associated with an increased risk of cerebral palsy in term infants, but this increase is only from 0.3 percent to 1 percent ([Nelson and Ellenberg, 1981](#); [Stanley, 1994](#)). A 5-minute Apgar score of 7 to 10 is considered "normal." Scores of 4, 5, and 6 are intermediate and are not markers of high levels of risk of later neurologic dysfunction. As previously mentioned, such scores are affected by physiologic immaturity, medication, the presence of congenital malformations, and other factors.

Because Apgar scores at 1 and 5 minutes correlate poorly with either cause or outcome, the scores alone should not be considered either evidence of or a consequence of substantial asphyxia. Therefore, a low 5-minute Apgar score alone does not demonstrate that later development of cerebral palsy was caused by perinatal asphyxia.

Correlation of the Apgar score with future neurologic outcome increases when the score remains 0 to 3 at 10, 15, and 20 minutes but still does not indicate the cause of future disability ([Freeman and Nelson, 1988](#); [Nelson and Ellenberg, 1981](#)). The term *asphyxia* in a clinical context should be reserved to describe a combination of damaging acidemia, hypoxia, and metabolic acidosis. A neonate who has had "asphyxia" proximate to delivery that is severe enough to result in acute neurologic injury should demonstrate all of the following:

- Profound metabolic or mixed acidemia (pH < 7.0) on an umbilical cord arterial blood sample, if obtained.
- An Apgar score of 0-3 for longer than 5 minutes.
- Neonatal neurologic manifestations (e.g., seizures, coma, or hypotonia).
- Multisystem organ dysfunction (e.g., cardiovascular, gastrointestinal, hematologic, pulmonary, or renal system).

The Apgar score alone cannot establish hypoxia as the cause of cerebral palsy. A term infant with an Apgar score of 0 to 3 at 5 minutes whose 10-minute score improved to 4 or higher has a 99 percent chance of not having cerebral palsy at 7 years of age ([Nelson and Ellenberg, 1981](#)). Conversely, 75 percent of children with cerebral palsy had normal Apgar scores at birth ([Nelson and Ellenberg, 1981](#)).

Cerebral palsy is the only neurologic deficit clearly linked to perinatal asphyxia. Although mental retardation and epilepsy may accompany cerebral palsy, there is no evidence that they are caused by perinatal asphyxia unless cerebral palsy is also present, and even then a relationship is in doubt ([Levene and collaborators, 1986](#); [Paneth, 1993](#)).

Conclusion

Apgar scores are useful in assessing the condition of the infant at birth. Their use in other settings, such as collection of a child's Apgar score upon entry to school, is inappropriate. Low Apgar scores may be indicative of a number of maternal and infant factors. Apgar scores alone should not be used as evidence that neurologic damage was caused by hypoxia that results in neurologic damage or by inappropriate intrapartum management. Hypoxia as a cause of acute neurologic injury and adverse neurologic outcome occurs in infants who demonstrate the four perinatal findings listed in this Committee Opinion and in whom other possible causes of neurologic damage have been excluded. In the absence of such evidence, subsequent neurologic deficiencies cannot be ascribed to perinatal asphyxia or hypoxia ([Brann and Dykes, 1977](#); [Nelson and Leviton, 1991](#)).

UMBILICAL CORD BLOOD ACID-BASE STUDIES

Blood taken from umbilical vessels is used for acid-base studies to examine the metabolic status of the fetus in the minutes and hours prior to birth. Fetal oxygenation and pH generally decline during the course of normal labor ([Dildy and co-workers, 1994](#)). Normal umbilical cord blood pH and blood gas values in term newborns are summarized in [Table 16-2](#).

Using data from over 19,000 deliveries, the lower limits of normal pH in the newborn are from 7.04 to 7.10 ([Boylan and Parisi, 1994](#)). Thus, these values should be considered to define **neonatal acidemia**. Most fetuses will tolerate intrapartum acidemia with a pH as low as 7.00 without incurring neurological impairment ([Freeman and Nelson, 1988](#); [Gilstrap and associates, 1989](#)). [Goldaber and associates \(1991\)](#) found that there were significantly more neonatal deaths and neurological dysfunction if a pH cutoff value of less than 7.00 was used ([Table 16-3](#)).

EFFECTS OF GESTATIONAL AGE ON APGAR SCORE AND pH. [Ramin and colleagues \(1989\)](#) reported observations from 77 preterm and 1292 term neonates and found no significant difference in the frequency of acidemia based on gestational age. They also observed that preterm neonates had significantly lower Apgar scores than had been reported by other investigators ([Catlin and associates, 1986](#); [Goldenberg and colleagues, 1984](#)). Using the erroneous International Classification of Disease (ICD-9-CM, 1980) coding for asphyxia based merely on a 1-minute Apgar score of less than 7 (see "Use and Misuse of the Apgar Score" earlier in the chapter), 36 percent of preterm infants in this latter study would have been labeled as having mild birth asphyxia (Apgar score of 6 or less) and 12 percent as having severe birth asphyxia (1-minute Apgar score of 3 or less). Conversely, only 8 percent of these infants had acidemia based on a high cutoff pH value of 7.20 or less. Thus, in the study by [Ramin and associates \(1989\)](#), it is apparent that a most important factor influencing the Apgar score is gestational age. [Dickinson and colleagues \(1992\)](#), in a larger study of the effect of preterm birth on umbilical cord blood gases, arrived at the same conclusion. This again emphasizes that an Apgar score of 7 in a preterm neonate may represent the upper normal value. **More importantly, umbilical cord gas indices may be of more value than Apgar scores in preterm infants.** Normal umbilical artery blood pH and blood gas values in preterm infants are shown in [Table 16-4](#).

FETAL ACID-BASE PHYSIOLOGY. The fetus produces carbonic and organic acids. Carbonic acid (H_2CO_3) is formed by oxidative metabolism of CO_2 . The fetus can rapidly clear CO_2 through the placental circulation; but when H_2CO_3 accumulates in fetal blood without an increase in organic acids, this is known as a **respiratory acidemia**. Organic acids primarily are formed by anaerobic metabolism and include lactic and β -hydroxybutyric acids. These organic acids are cleared slowly from fetal blood, and when they accumulate without an increase in H_2CO_3 , this results in a **metabolic acidemia**. With the development of metabolic acidemia, bicarbonate (HCO_3) decreases as it is used to buffer the organic acid. An increase in H_2CO_3 and an increase in the organic acid (seen as a decrease in HCO_3) is known as a **mixed respiratory-metabolic acidemia**.

In the fetus, respiratory and metabolic acidemia and ultimately tissue acidosis are most likely part of a progressively worsening continuum. This is different from the adult, in which there are distinct conditions that result in either respiratory (pulmonary disease) or metabolic (diabetes) acidemia. In the fetus, the placenta serves as both the lungs and, to a certain degree, the kidneys. One principal cause for developing acidemia in the fetus is a decrease in uteroplacental perfusion. This results in the retention of CO_2 (respiratory acidemia), and if protracted and severe enough, this ultimately leads to a mixed or metabolic acidemia.

The actual pH of blood is dependent upon the proportion of carbonic acid and organic acids as well as the amount of bicarbonate that is the major buffer in blood. This can best be illustrated by the Henderson-Hasselbach equation:

For clinical purposes, HCO_3 represents the metabolic component and is reported as HCO_3 in mEq/L. The H_2CO_3 concentration represents the respiratory component and is reported as the PCO_2 in mm Hg. Thus:

Delta base is a calculated number used as a measure of the change in buffering capacity of bicarbonate (HCO_3). For example, bicarbonate will be decreased in concentration with a metabolic acidemia as it is consumed in order to maintain a normal pH. A **base deficit** occurs when HCO_3 concentration decreases to below normal levels, and a **base excess** occurs when HCO_3 values are above normal. It must be emphasized again that a large base deficit and a low HCO_3 (less than 12 mEq/L) associated with mixed respiratory-metabolic acidemia is more often associated with a depressed neonate than is a mixed acidemia with a minimal base deficit and a more nearly normal HCO_3 ([American College of Obstetricians and Gynecologists, 1995](#); [Gilstrap and Cunningham, 1994](#)).

All of these considerations are based upon the assumption that maternal pH and blood gases are normal.

CLINICAL DIAGNOSIS OF SIGNIFICANT ACIDEMIA. In the fetus, metabolic acidemia develops when oxygen deprivation is of sufficient duration and magnitude to require anaerobic metabolism for fetal cellular energy needs. Metabolic acidosis, defined as an umbilical artery buffer base of less than 30 mmol/L, is rare; [Low and associates \(1994\)](#) described such acidosis in only 0.4 percent in a study of over 14,000 term births. They later proposed that the threshold for fetal acidosis is a base deficit of greater than 12 mmol/L ([Low and co-workers, 1997](#)). They considered a base deficit greater than 16 mmol/L to indicate severe fetal acidosis.

Metabolic acidemia is associated with a high rate of multiorgan dysfunction, and in rare cases such hypoxia-induced metabolic acidemia may be so severe as to cause subsequent neurological impairment. By definition, a fetus without such acidemia cannot have suffered recent hypoxic-induced injury. Even severe metabolic acidosis, however, is poorly predictive of subsequent neurological impairment in the term infant. Although more severe metabolic acidosis was associated with an increase in immediate neonatal complications in a group of infants with depressed 5-minute Apgar scores, [Socol and colleagues \(1994\)](#) found no difference in umbilical artery blood gas measurements among those individuals who developed cerebral palsy and those with subsequent normal neurological outcome. Such findings cast further doubt upon the relationship between intrapartum hypoxia and acidosis and subsequent cerebral palsy in term infants. In very-low-birthweight infants—those less than 1000 g—newborn acid-base status may be more closely linked to long-term neurological outcome ([Gaudier and co-workers, 1994](#); [Low and associates, 1995](#)).

In contrast to metabolic acidemia, respiratory acidemia generally develops as a result of an acute interruption in placental gas exchange, with subsequent CO₂ retention. Transient umbilical cord compression is the most common antecedent factor in the development of fetal respiratory acidemia. In general, respiratory acidemia does not reflect an insult of potential harm to the fetus. [Low and co-workers \(1994\)](#) found no increase in newborn complications after respiratory acidosis. The degree to which pH is affected by PCO₂, the respiratory component of the acidosis, can be calculated by the following relationship: 10 additional units of PCO₂ will lower the pH by 0.08 units ([Eisenberg and colleagues, 1987](#)). Thus in a mixed respiratory-metabolic acidemia, the benign respiratory component may be easily calculated:

During labor, an acute cord prolapse occurred and the fetus was delivered by cesarean 20 minutes later. The umbilical artery pH at birth was 6.95, with a PCO₂ of 89 mm Hg. To calculate the degree to which the cord compression and subsequent impairment of CO₂ exchange affected the pH, the rules given earlier are applied: 89 mm Hg - 49 mm Hg (normal newborn PCO₂) = 40 mm Hg (excess CO₂). To correct pH: $(40 \div 10) \times 0.08 = 0.32$; $6.95 + 0.32 = 7.27$. Therefore, the pH prior to cord prolapse was approximately 7.27, well within normal limits, thus confirming the clinical interpretation of the fetal heart rate record as reassuring prior to this unpredictable event.

As emphasized by the [American College of Obstetricians and Gynecologists \(1995\)](#), the term **birth asphyxia** is imprecise and should not be used. Furthermore, acidemia alone is not sufficient evidence to establish that there has been hypoxic injury. In order to establish that hypoxia near delivery was severe enough to cause hypoxic ischemic encephalopathy, all of the following must be present:

1. Umbilical artery metabolic or mixed respiratory-metabolic acidemia with pH less than 7.00.
2. A persistent Apgar score of 0 to 3 for more than 5 minutes.
3. Neonatal neurological sequelae, such as seizures, coma, or hypotonia.
4. Multiorgan system dysfunction.

UMBILICAL CORD BLOOD COLLECTION. A 10- to 20-cm segment of umbilical cord is clamped **immediately** following delivery with two clamps near the neonate and two clamps nearer the placenta. The importance of clamping the cord is underscored by the fact that delays of 20 to 30 seconds can alter both the PCO₂ and pH ([Lievaart and deJong, 1984](#)). The cord is then cut between the two proximal and two distal clamps. *Arterial blood* is drawn from the isolated segment of cord into a 1- to 2-mL commercially prepared plastic syringe containing lysophilized heparin or a similar syringe that has been flushed with a heparin solution containing 1000 U/mL. The needle is then capped, and the capped syringe is placed into a plastic sack containing crushed ice and immediately transported to the laboratory. There is little change in PCO₂ or pH in blood kept at room temperature for up to 60 minutes ([Duerbeck and associates, 1992](#)). [Chauhan and associates \(1994\)](#) developed mathematical models allowing reasonable prediction of birth acid-base status in properly collected cord samples analyzed as late as 60 hours after delivery.

RECOMMENDATIONS FOR CORD BLOOD GAS DETERMINATIONS

A cost-effectiveness analysis for universal cord blood gas measurements has not been conducted. In some centers, cord gas determination is made in all fetuses at the time of birth. The [American College of Obstetricians and Gynecologists \(1995\)](#) recommends that cord blood gas and pH analyses be used in select neonates with low Apgar scores to distinguish metabolic acidemia from hypoxia or other causes that might result in a low Apgar score. Although umbilical cord acid-base blood determinations have a low predictability for either immediate or long-term adverse neurological outcome, they are helpful to exclude intrapartum or birth events that may cause acidosis ([Gilstrap and Cunningham, 1994](#)).

ACTIVE RESUSCITATION

When infants become asphyxiated, either before or after birth, they demonstrate a well-defined sequence of events, leading to primary or secondary apnea ([American Academy of Pediatrics and American Heart Association, 1994](#)). Initial oxygen deprivation results in a transient period of rapid breathing. If such deprivation persists, breathing movements cease and the fetus-infant enters a stage of apnea known as **primary apnea**. This is accompanied by a fall in heart rate and loss of neuromuscular tone. Simple stimulation and exposure to oxygen will reverse primary apnea. If oxygen deprivation and asphyxia persist, the fetus-infant will develop deep gasping respirations, followed by **secondary apnea**. This is associated with a further decline in heart rate, falling blood pressure, and loss of neuromuscular tone. Infants in secondary apnea will not respond to stimulation and will not spontaneously resume respiratory efforts. Unless ventilation is assisted, death will occur ([Fig. 16-2](#)). Clinically, primary and secondary apnea are indistinguishable. For this reason, secondary apnea must be assumed, and resuscitation of the apneic infant must be started immediately.

The first rule of resuscitation is to recognize rapidly the neonate who requires these measures. Also, it should be remembered that suctioning of the mouth, nares, and trachea can result in significant vagal stimulation and reflex slowing of the heart rate; thus *unnecessary* or *overvigorous* suctioning of these areas should be avoided.

Successful active resuscitation requires:

1. Skilled personnel who are immediately available.
2. A suitably heated, well-lighted, appropriately large work area such as shown in [Figure 16-1](#).
3. Equipment to deliver oxygen by intermittent positive pressure through a face mask and to carry out tracheal intubation with suction and positive-pressure oxygenation.
4. Drugs, syringes, needles, and catheters for possible intravenous administration of volume expanders (normal saline, Ringer lactate, blood, or 5 percent albumin), naloxone (Narcan), sodium bicarbonate, and epinephrine.

Equipment for resuscitation should be readily available, and the equipment should be checked often. A useful method to ensure that such supplies are available is a wall clipboard system arranged so that any missing equipment or drug is immediately apparent ([Fig. 16-3](#)).

RESUSCITATION PROTOCOL

Resuscitation will be most effective when an established protocol is followed. The following protocol for neonatal resuscitation is recommended by the [American Academy of Pediatrics and the American Heart Association \(1994\)](#):

1. **Prevent heat loss.** Place the infant in a radiant warmer on its back and dry off amniotic fluid.
2. **Open the airway.** The airway is opened by suctioning the mouth and nares if no meconium is present. If meconium is present, the trachea may require direct suctioning ([Fig. 16-4](#)).
3. **Evaluate the infant.** Observe for respirations, heart rate, and color to determine what further steps are necessary. These initial three steps should be performed in 20 seconds or less.

4. **Respiratory effort.** Evaluate respiratory effort first. If absent, positive pressure ventilation is carried out. If present, heart rate is evaluated.
5. **Heart rate.** Evaluate heart rate next. If the rate is less than 100 beats/min, positive pressure ventilation is instituted (skip to step 7). If the rate is greater than 100, infant color is evaluated next.
6. **Color.** Evaluate color last. If the infant is pink, or demonstrates only peripheral cyanosis, simple observation continues. If the infant exhibits central cyanosis, free-flowing oxygen is provided at concentrations of 80 to 100 percent. This is continued as long as the baby remains cyanotic.
7. **Heart rate (continued).** Heart rate is evaluated after 15 to 30 seconds of positive pressure ventilation. If the heart rate is now above 100, evaluate color, as in step 6. If the heart rate is 60 to 100 and increasing, ventilation is continued. If the heart rate is below 60, or below 80 and not increasing, ventilation is continued and chest compressions are begun. Under these circumstances, tracheal intubation should be considered.
8. **Chest compressions.** Initiate chest compressions at a rate of 2 per second with a 1/2-second pause every third compression for ventilation. Compression is stopped every 30 seconds for 6 seconds while the heart rate is checked. If the heart rate remains below 80 beats/min after 30 seconds of ventilation and chest compressions, chemical resuscitation is begun.
9. **Chemical resuscitation.** Chemical resuscitation consists of epinephrine, volume expansion, and possibly naloxone ([Fig. 16-5](#)). Epinephrine 1:10,000 is given rapidly, either intravenously or via the tracheal tube in a dose of 0.1 to 0.3 mL/kg. Volume expansion with 10 mL/kg whole blood, 5 percent albumin, normal saline, or Ringer lactate is given intravenously over 5 to 10 minutes in cases where hypovolemia is suspected. Sodium bicarbonate, 4.2 percent solution (0.5 mEq/mL) is given slowly, over at least 2 minutes (1 mEq/kg per min) in cases of prolonged arrest that do not respond to other therapy or if arterial blood gases are indicative of severe metabolic acidemia. Bicarbonate must only be given after effective ventilation has been established. Naloxone hydrochloride is indicated with marked respiratory depression and a maternal history of recent narcotic administration ([American College of Obstetricians and Gynecologists, 1996b](#)). For either the preterm or term neonate, it is administered preferably intravenously or intratracheally at a dose of 0.1 mg/kg. Repeated doses are often necessary because the duration of action of some narcotics exceeds that of naloxone (1 to 4 hours). When given intramuscularly or subcutaneously, absorption may be delayed if the infant has vasoconstriction.
10. **Tracheal intubation.** Tracheal intubation is necessary in four circumstances: when prolonged positive pressure ventilation is required, when bag and mask ventilation is ineffective, when tracheal suctioning is required, and when diaphragmatic hernia is suspected.

TECHNIQUE OF INTUBATION. The head of the supine infant is kept level. The laryngoscope is introduced into the right side of the mouth and then directed posteriorly toward the oropharynx ([Fig. 16-6](#)). The laryngoscope is next gently moved into the space between the base of the tongue and the epiglottis. Gentle elevation of the tip of the laryngoscope will pick up the epiglottis and expose the glottis and the vocal cords. The endotracheal tube is introduced through the right side of the mouth and is inserted through the vocal cords until the shoulder of the tube reaches the glottis. It is essential that the appropriate-sized endotracheal tube be used ([Table 16-5](#)). Steps are taken to ensure that the tube is in the trachea and not the esophagus by listening for breath sounds or a gurgling sound if air is introduced into the stomach. Any foreign material encountered in the tracheal tube is immediately removed by suction. Meconium, blood, mucus, and particulate debris in amniotic fluid or in the birth canal may have been inhaled in utero or while passing through the birth canal.

The resuscitator, using an appropriate ventilation bag attached to the tracheal tube, should deliver puffs of oxygen-rich air into the tube at 1- to 2-second intervals with a force adequate to lift the chest wall gently. Pressures of 25 to 35 cm H₂O are desired to expand the alveoli yet not cause pneumothorax or pneumomediastinum. If the stomach expands, the tube is almost certainly in the esophagus rather than in the trachea. Once adequate spontaneous respirations have been established, the tube can usually be removed safely.

COMMON ERRORS IN RESUSCITATION OF THE NEWBORN

If resuscitation efforts are not rapidly successful, the apparent failure may be the consequence of an easily correctable technical error. Even the most skilled and experienced operator can experience difficulties, and the possibility of technical errors should always be kept in mind when an infant fails to respond to resuscitation. Common errors include the following:

1. Failure to check resuscitation equipment beforehand:
 - a. Damaged resuscitation bag.
 - b. Laryngoscope with dull or flickering light.
2. Use of a cold resuscitation table.
3. Unsuccessful intubation:
 - a. Hyperextension of neck.
 - b. Inadequate suctioning.
 - c. Excessive force.
 - d. Use of an incorrect-sized endotracheal tube.
4. Inadequate ventilation:
 - a. Improper head position.
 - b. Improper application of mask.
 - c. Placement of tracheal tube into esophagus or right mainstem bronchus.
 - d. Failure to secure the tracheal tube.
5. Failure to detect and determine cause of poor chest movement or persistent bradycardia.
6. Failure to detect and treat hypovolemia.
7. Failure to perform cardiac massage.

ROUTINE NEWBORN CARE

ESTIMATION OF GESTATIONAL AGE

A rapid estimate of gestational age of the newborn between gestational weeks 32 to 40 may be made very soon after delivery by examining:

1. Sole creases.
2. Breast nodules.
3. Scalp hair.

4. Ear lobes.

5. For males, testes and scrotum ([Table 16-6](#)).

A more definitive estimate can be made in a few days with the help of neurological examination. Unfortunately, estimates of gestational age based upon physical and neurological examination are frequently unacceptably inaccurate in preterm and growth-restricted infants ([Spinnato and co-workers, 1984](#)).

EYE INFECTION PROPHYLAXIS

Because of the possibility of neonatal eye infection during passage through the birth canal of a mother with gonorrhea, in 1884, Crede introduced the practice of instilling into each eye immediately after birth one drop of a 1 percent solution of silver nitrate, which was later washed out with saline. In most states, the use of an efficacious regimen as discussed subsequently is required by law. The efficacy of these regimens for gonococcal infection prophylaxis is less clear for chlamydial eye infections.

GONOCOCCAL OPHTHALMIA NEONATORUM. Fortunately, since the introduction of 1 percent silver nitrate solution, blindness due to neonatal infection from *Neisseria gonorrhoeae* has been largely eliminated. A variety of antibiotics have also proven to be effective in preventing gonococcal ophthalmia. These regimens shown in [Table 16-7](#) are not 100 percent effective. [Babi and colleagues \(2000\)](#) described neonatal gonococcal arthritis despite a negative maternal genital screening culture and newborn eye prophylaxis. Current recommendations by the [Centers for Disease Control and Prevention \(1998\)](#) and by [Smith and Finn \(1999\)](#) include aqueous silver nitrate (1 percent), or erythromycin ophthalmic ointment (0.5 percent), or tetracycline ophthalmic ointment (1 percent).

For infants born to mothers with untreated gonorrhea, single dose ceftriaxone, 25 to 50 mg/kg is given intramuscularly or intravenously, not to exceed 125 mg.

CHLAMYDIAL CONJUNCTIVITIS/OPHTHALMIA NEONATORUM. The problem of providing adequate neonatal prophylaxis against chlamydial infection is much more complex. Although it is reasonable to expect that tetracycline and erythromycin ophthalmic ointments applied at birth should reduce the incidence of chlamydial conjunctivitis/ophthalmia, results with these agents and silver nitrate solution have been disappointing ([Table 16-7](#)). In a study from Kenya, [Isenberg and colleagues \(1995\)](#) showed that 2.5 percent povidone-iodine solution was superior to either 1 percent silver nitrate solution or 0.5 percent erythromycin ointment to prevent chlamydial conjunctivitis. Truly effective prophylaxis against chlamydial conjunctivitis/ophthalmia neonatorum is not available currently ([Centers for Disease Control, 1998](#)). Any case of conjunctivitis in an infant less than 30 days old should prompt consideration for chlamydial infection.

Perhaps the best method of preventing neonatal infection is screening and treatment of women with chlamydial infection. These regimens are discussed in [Chapter 57](#) and were reviewed recently by [Brocklehurst and Rooney \(2000\)](#).

PERMANENT INFANT IDENTIFICATION

A foolproof infant identification system must be operative at all hours. Except under unusual circumstances, mother and infant should not be separated until identification is complete. The system should provide a record easily recognized by the mother, such as an identification band. A permanent record should be kept on file at the hospital. Most hospitals today use footprints rather than fingerprints or palmprints in identifying infants, because the ridges in the feet are more pronounced and it is easier to obtain prints. Too often, however, the ridges are not discrete and therefore the print is of no value ([Clark and associates, 1981](#)). After discovering that identification by footprint was considered invalid by the Federal Bureau of Investigation, we discontinued this practice at Parkland Hospital in 1985.

SUBSEQUENT CARE

TEMPERATURE. The temperature of the infant drops rapidly immediately after birth. Thus, the infant must be cared for in a warm crib in which temperature control is regulated closely. During the first few days of life, the infant's temperature is unstable, responding to slight stimuli with considerable fluctuations above or below the normal level.

VITAMIN K. Routine administration of vitamin K is recommended, as described in [Chapter 39 \(p. 1072\)](#).

HEPATITIS B IMMUNIZATION. Routine immunization of all newborns against hepatitis B prior to hospital discharge was started about 10 years ago as recommended by the [Centers for Disease Control \(1991\)](#). Recently, there has been unsubstantiated evidence of a link with vaccination and susceptibility to a variety of autoimmune complications, including neurological syndromes similar to multiple sclerosis. United States Representative Daniel Burton of Indiana in 2000 is conducting hearings to ascertain the severity and magnitude of this issue. As of late 2000, the [Centers for Disease Control and Prevention \(2000\)](#) continues to recommend routine newborn vaccination. If the mother is hepatitis B surface-antigen positive, the neonate should also be passively immunized with hepatitis B immune globulin (see also [Chap. 48, p. 1290](#)).

UMBILICAL CORD. Loss of water from Wharton jelly leads to mummification of the cord shortly after birth. Within 24 hours it loses its characteristic bluish white, moist appearance and soon becomes dry and black. Gradually the line of demarcation appears just beyond the skin of the abdomen, and in a few days the stump sloughs, leaving a small, granulating wound, which after healing forms the umbilicus. Separation usually takes place within the first 2 weeks, with a range of 3 to 45 days ([Novack and colleagues, 1988](#)). The umbilical cord dries more quickly and separates more readily when exposed to the air; therefore, a dressing is not recommended.

Serious umbilical infections are sometimes encountered. The most likely offending organisms are *Staphylococcus aureus*, *Escherichia coli*, or group B *Streptococcus*. Because the umbilical stump in such cases may present no outward sign of infection, the diagnosis cannot be made with certainty except by autopsy. Strict aseptic precautions therefore should be observed in the immediate care of the cord. Most practitioners apply triple dye or bacitracin ointment. [Gladstone and colleagues \(1988\)](#) found that povidone-iodine applied daily was effective and acceptable.

Neonatal *tetanus* continues to kill infants in developing countries. Active immunization of the mother against tetanus with passage of antibody to the fetus, along with hygienic practices applied to the cutting and subsequent management of the umbilical cord, can serve to reduce this risk to the neonate.

SKIN CARE. Infants should be promptly patted dry to minimize heat loss caused by evaporation. Excess vernix, as well as blood and meconium, is gently wiped off. The remaining vernix is readily absorbed by the skin and disappears entirely within 24 hours. Newborns should not be washed until their temperature has stabilized, and handling of babies during this time should be minimized.

STOOLS AND URINE. For the first 2 or 3 days after birth, the contents of the colon are composed of soft, brownish-green *meconium*, which is composed of desquamated epithelial cells from the intestinal tract, mucus, and epidermal cells and lanugo (fetal hair) that have been swallowed along with amniotic fluid. The characteristic color results from bile pigments. During intrauterine life and for a few hours after birth, the intestinal contents are sterile, but bacteria soon gain access. The passage of meconium and urine in the minutes immediately after birth or during the next few hours indicates patency of the gastrointestinal and urinary tracts. Meconium stooling is seen in 90 percent of newborns within the first 24 hours; most of the rest do so within 36 hours. Voiding, although usually occurring shortly after birth, may not occur until the second day of life. Failure of the infant to stool or urinate after these times suggests a congenital defect, such as imperforate anus or a urethral valve.

After the third or fourth day, as the consequence of ingesting milk, meconium is replaced by light yellow homogenous feces with a characteristic odor. For the first few days, the stools are unformed, but soon thereafter they assume a cylindrical shape.

ICTERUS NEONATORUM. About a third of all babies, between the second and fifth day of life, develop so-called **physiological jaundice of the newborn**. Serum bilirubin levels at birth are 1.8 to 2.8 mg/dL. These levels increase during the next few days but with wide individual variation. Between the third and fourth day, the bilirubin in mature infants commonly reaches somewhat more than 5 mg/dL, the concentration at which jaundice usually becomes noticeable. Most of the bilirubin is free, or unconjugated. One cause is immaturity of the hepatic cells, resulting in less conjugation of bilirubin with glucuronic acid and reduced excretion in bile ([Chap. 39, p. 1067](#)). Reabsorption of free bilirubin as the consequence of the enzymatic splitting of bilirubin glucuronide by intestinal conjugase activity in the newborn intestine also appears to contribute significantly to the transient hyperbilirubinemia. In preterm infants, jaundice is more common and usually more severe and prolonged than in term infants, because of less hepatic enzymatic maturity. Increased erythrocyte destruction from any cause also contributes to hyperbilirubinemia.

INITIAL WEIGHT LOSS. Because most infants receive little nutriment for the first 3 or 4 days of life, they progressively lose weight until the flow of maternal milk or other feeding has been established. Preterm infants lose relatively more weight and regain their birthweight more slowly than do term infants. Infants that are small for gestational age but otherwise healthy regain their initial weight more quickly when fed than do preterm infants.

If the normal infant is nourished properly, birth-weight is usually regained by the end of the 10th day. Subsequently, the weight typically increases steadily at the rate of about 25 g/day for the first few months, to double the birthweight by 5 months of age and to triple it by the end of the first year.

FEEDING. It is advisable to commence regular nursing within the first 12 hours postpartum. In many hospitals, infants begin breast feeding in the delivery room. Most term infants thrive best when fed at intervals of every 2 to 4 hours. Preterm or growth-restricted infants require feedings at shorter intervals. In most instances, a 3-hour interval is satisfactory. The proper length of each feeding depends on several factors, such as the quantity of breast milk, the readiness with which it can be obtained from the breast, and the avidity with which the infant nurses. It is generally advisable to allow the baby to remain at the breast for 10 minutes at first. Four to 5 minutes are sufficient for some infants; however, 15 to 20 minutes are required by others. It is satisfactory for the baby to nurse for 5 minutes at each breast for the first 4 days, or until the mother has a supply of milk. After the fourth day, the baby nurses up to 10 minutes on each breast. Breast feeding and formula choices are also discussed in [Chapter 17 \(p. 407\)](#).

CIRCUMCISION. The Committee on the Fetus and Newborn of the American Academy of Pediatrics recommended in 1971 that routine circumcision of newborn males not be performed. This was reaffirmed in their 1983 publication, *Guidelines for Perinatal Care*. These recommendations were widely adopted throughout the United States, and by 1987 only 61 percent of newborn males were circumcised ([Poland, 1990](#)).

In the 1992 *Guidelines for Perinatal Care* (American Academy of Pediatrics and American College of Obstetricians and Gynecologists), circumcision was no longer condemned, but it also was not recommended. This change likely resulted from the [American Academy of Pediatrics Report of the Task Force on Circumcision \(1989\)](#). The Task Force concluded that properly performed newborn circumcision prevented phimosis, paraphimosis, and balanoposthitis, and it decreased the incidence of penile cancer. The committee could not agree that circumcision resulted in a decreased incidence of urinary infections in babies because of the lack of well-designed studies. It cited an increased incidence of cervical cancer reported in sexual partners of uncircumcised men infected with human papillomavirus. The Task Force, however, could not agree on whether circumcision resulted in a decreased incidence of sexually transmitted diseases.

The Task Force concluded—without a recommendation—that newborn circumcision was generally a safe procedure when performed by an experienced operator, and should be an elective procedure performed in a healthy, stable neonate. Local anesthetic (dorsal penile nerve block) appeared to reduce the pain of the procedure, but the anesthetic was not without its own complications. The Task Force also concluded that circumcision has potential medical benefits and advantages as well as disadvantages and risks. They recommended that the benefits and risks be explained to the parents and informed consent obtained.

More recently, a similar conclusion was reached by the [American Academy of Pediatrics Task Force on Circumcision \(1999\)](#). It also concluded that there were not sufficient data to recommend routine circumcision because of potential benefits and risks. Thus, parents should determine what is in the best interest of the child and should make an informed choice after being given accurate and unbiased information. The Task Force considered it legitimate for parents to take into account cultural, religious, and ethnic traditions, in addition to medical factors, when making their decision. Similar conclusions were reached by the [Canadian Paediatric Society \(1996\)](#), which also concluded that newborn circumcision should not be routinely performed.

ANESTHESIA FOR CIRCUMCISION. [Stang and colleagues \(1988\)](#) reported that dorsal penile nerve block reduced behavioral distress and modified adrenocortical stress response in neonates undergoing circumcision. This observation was confirmed in subsequent clinical studies ([Arnett and co-workers, 1990](#); [Fontaine and Toffler, 1991](#)).

A variety of techniques for pain relief have been described, including lidocaine-prilocaine topical cream, local analgesia infiltration, dorsal penile nerve block, and ring blocks. The results of these studies clearly favor the nerve block over topical analgesia and the ring block over both ([Butler-O'Hara, 1998](#); [Hardwick-Smith, 1998](#); [Lander, 1997](#); [Masciello, 1990](#); [Taddio, 1997](#), and their colleagues). We agree with the view expressed by [Maxwell and Yaster \(1999\)](#) concerning analgesia—no more studies, just do it!

TECHNIQUE. The preferred technique of ring block is illustrated in [Figure 16-7](#). After appropriate penile cleansing, the technique consists of placing a wheal of 1 percent lidocaine at the base of the penis and advancing the needle in a 180-degree arc around the base of the penis first to one side and then the other to achieve a circumferential ring of analgesia. The maximum dose of lidocaine is 1.0 mL. The addition of a buffering agent does not appear to offer a benefit ([Newton and co-workers, 1999](#)). **No vasoactive compounds such as epinephrine should ever be added to the local analgesic agent.**

COMPLICATIONS OF CIRCUMCISION. As with any surgical procedure, there is a risk of bleeding, infection, and hematoma formation. These risks, however, are low ([Christakis and colleagues, 2000](#); [Holman and colleagues, 1995](#)). More unusual complications have been reported as isolated cases, including amputation of the distal penile glans during neonatal ritual circumcision ([Neulander and colleagues, 1996](#)), infection with human immunodeficiency virus-1 (HIV-1) and other sexually transmitted disease ([Nicoll, 1997](#)), postcircumcision meatal stenosis ([Upadhyay and associates, 1998](#)); denudation of the penis ([Orozco-Sanchez and Neri-Vela, 1991](#)), penile destruction with electrocautery ([Gearhart and Rock, 1989](#)), and ischemia following the **inappropriate use of lidocaine with epinephrine** ([Berens and Pontus, 1990](#)).

It cannot be overemphasized that circumcision is an elective procedure. It should never be performed in a neonate with:

1. A family history of or a known clotting abnormality.
2. Ambiguous genitalia.
3. Hypospadias.
4. A febrile illness.

ROOMING-IN. In part, rooming-in stems from a trend to make all phases of childbearing as natural as possible and to foster proper mother-child relationships at an early date. By the end of 24 hours, the mother is generally fully ambulatory. Thereafter, with rooming-in, she can conduct for herself and her infant practically all routine care. An obvious advantage is her increased ability to assume full care of the baby when she arrives home.

HOSPITAL DISCHARGE. Traditionally, the newborn infant is discharged with its mother; in most cases, maternal stay has determined that of the child. In the past decade, the length of stay for the mother following uncomplicated vaginal delivery has declined. Currently, stays of 24 hours or less are common. Although it is clear that most newborns can also be safely discharged within 24 hours, this is not uniformly true. For example, using data from the Canadian Institute for Health Information, [Liu and colleagues \(2000\)](#) examined neonatal readmission rates in over 2.1 million discharges. As the length of hospital stay decreased from 4.2 days in 1990 to 2.7 days in 1997, the readmission rate increased from 27.3 to 38 per 1000 births. Dehydration and jaundice accounted for most of these readmissions. [Danielsen and associates \(2000\)](#) confirmed a similar association in statewide California births from 1992 to 1995. They did not, however, find an excessive rehospitalization due to early-infant discharge defined as an overnight stay. There was increased rehospitalization associated with same-day discharge. Using Washington state infant discharge data, [Malkin and co-workers \(2000\)](#) found about a fourfold increased 28-day mortality rate and a twofold increased 1-year mortality rate in infants discharged within 30 hours of birth. These practices need ongoing close scrutiny.

17. The Puerperium

Puerperium is strictly defined as the period of confinement during and just after birth. By popular use, however, the meaning usually includes the 6 subsequent weeks during which normal pregnancy involution occurs ([Hughes, 1972](#)). Of course, and as described in [Chapter 8](#), maternal adaptations to pregnancy do not necessarily all subside completely by 6 weeks postpartum.

CLINICAL AND PHYSIOLOGICAL ASPECTS OF THE PUERPERIUM

UTERINE CHANGES

CHANGES IN THE UTERINE VESSELS. Successful pregnancy requires a great increase in uterine blood flow. To provide for this, arteries and veins within the uterus, and especially to the placental site, enlarge remarkably, as do transport vessels to and from the uterus. Within the uterus, growth of new vessels also provides for the marked increase in blood flow. After delivery, the caliber of extrauterine vessels decreases to equal, or at least closely approximate, that of the pre-pregnant state.

Within the puerperal uterus, blood vessels are obliterated by hyaline changes, and vessels that are smaller replace them. Resorption of the hyalinized residue is accomplished by processes similar to those observed in the ovaries following ovulation and corpus luteum formation. Minor vestiges, however, may persist for years.

CHANGES IN THE CERVIX AND LOWER UTERINE SEGMENT. The outer cervical margin, which corresponds to the external os, is usually lacerated, especially laterally. The cervical opening contracts slowly, and for a few days immediately after labor it readily admits two fingers. By the end of the first week, it has narrowed. As the opening narrows, the cervix thickens, and a canal reforms. At the completion of involution, however, the external os does not resume its pregravid appearance completely. It remains somewhat wider, and typically, bilateral depressions at the site of lacerations remain as permanent changes that characterize the parous cervix. It should also be kept in mind that the cervical epithelium undergoes considerable remodeling as a result of childbirth. For example, [Ahdoot and colleagues \(1998\)](#) found that approximately 50 percent of women with high-grade squamous intraepithelial cells showed regression as a result of vaginal delivery.

The markedly thinned-out lower uterine segment contracts and retracts but not as forcefully as the body of the uterus. Over the course of a few weeks, the lower segment is converted from a clearly evident structure, large enough to contain most of the fetal head, into a barely discernible uterine isthmus located between the uterine corpus above and the internal cervical os below ([Fig. 17-1](#)).

INVOLUTION OF THE UTERINE CORPUS. Immediately after placental expulsion, the fundus of the contracted uterus is slightly below the umbilicus. The uterine body then consists mostly of myometrium covered by serosa and lined by basal decidua. The anterior and posterior walls, in close apposition, each measure 4 to 5 cm in thickness. Because its vessels are compressed by the contracted myometrium, the puerperal uterus on section appears ischemic when compared with the reddish-purple hyperemic pregnant organ. After the first 2 days, the uterus begins to shrink, so that within 2 weeks it has descended into the cavity of the true pelvis. It regains its previous nonpregnant size within about 4 weeks. The immediately postpartum uterus weighs approximately 1000 g. As the consequence of *involution*, 1 week later it weighs about 500 g, decreasing at the end of the second week to about 300 g, and soon thereafter to 100 g or less. The total number of muscle cells does not decrease appreciably; instead, the individual cells decrease markedly in size. The involution of the connective tissue framework occurs equally rapidly.

Because separation of the placenta and membranes involves the spongy layer, the decidua basalis remains in the uterus. The decidua that remains has striking variations in thickness, an irregular jagged appearance, and is infiltrated with blood, especially at the placental site.

AFTERPAINS. In primiparas the puerperal uterus tends to remain tonically contracted. Particularly in multiparas, the uterus often contracts vigorously at intervals, giving rise to *afterpains*. Occasionally these pains are severe enough to require an analgesic. Afterpains are noticeable particularly when the infant suckles, likely because of oxytocin release. Usually, they decrease in intensity and become mild by the third postpartum day.

LOCHIA. Early in the puerperium, sloughing of decidual tissue results in a vaginal discharge of variable quantity; this is termed *lochia*. Microscopically, lochia consists of erythrocytes, shreds of decidua, epithelial cells, and bacteria. Microorganisms are found in lochia pooled in the vagina and are present in most cases even when the discharge has been obtained from the uterine cavity.

For the first few days after delivery, blood in the lochia is sufficient to color it red— *lochia rubra*. After 3 or 4 days, lochia becomes progressively pale in color— *lochia serosa*. After about the 10th day, because of an admixture of leukocytes and reduced fluid content, lochia assumes a white or yellowish-white color— *lochia alba*.

Conventional obstetrical wisdom has for many years taught that lochia lasted for approximately 2 weeks after delivery. Recent studies, however, have indicated that lochia persists for up to 4 weeks and may stop and resume up to 56 days after delivery ([Oppenheimer and colleagues, 1986](#); [Visness and co-workers, 1997](#)). Maternal age, parity, infant weight, and breast feeding do not influence the duration of lochia.

In some centers, it is routine to prescribe an oxytocic agent to hasten uterine involution by promoting uterine contractility. This also presumably diminishes bleeding complications. [Newton and Bradford \(1961\)](#), however, concluded that after the period immediately following delivery, routine administration of intramuscular oxytocin to normal women was of no value in decreasing blood loss or hastening uterine involution.

ENDOMETRIAL REGENERATION. Within 2 or 3 days after delivery, the remaining decidua becomes differentiated into two layers. The superficial layer becomes necrotic, and it is sloughed in the lochia. The basal layer adjacent to the myometrium remains intact and is the source of new endometrium. The endometrium arises from proliferation of the endometrial glandular remnants and the stroma of the interglandular connective tissue.

Endometrial regeneration is rapid, except at the placental site. Within a week or so, the free surface becomes covered by epithelium, and the entire endometrium is restored during the third week. [Sharman \(1953\)](#) identified fully restored endometrium in all biopsy specimens obtained from the 16th postpartum day onward. So-called endometritis identified histologically during the puerperium is only part of the normal reparative process. Similarly, in almost half of postpartum women, fallopian tubes, between 5 and 15 days, demonstrate microscopical inflammatory changes characteristic of acute salpingitis. This, however, is not infection, but only part of the involutional process ([Andrews, 1951](#)).

SUBINVOLUTION. This term describes an arrest or re-tardation of involution, the process by which the puerperal uterus is normally restored to its original proportions. It is accompanied by prolongation of lochial discharge and irregular or excessive uterine bleeding and sometimes by profuse hemorrhage. On bimanual examination, the uterus is larger and softer than normal for the particular period of the puerperium. Among the recognized causes of subinvolution are retention of placental fragments and pelvic infection. Because most cases of subinvolution result from local causes, they are usually amenable to early diagnosis and treatment. Ergonovine (Ergotrate) or methylergonovine (Methergine), 0.2 mg every 3 to 4 hours for 24 to 48 hours, is recommended by some clinicians, but its efficacy is questionable. On the other hand, metritis responds to oral antimicrobial therapy. [Wager and colleagues \(1980\)](#) reported that almost a third of cases of later postpartum uterine infection are caused by *Chlamydia trachomatis*; thus tetracycline therapy may be appropriate.

[Andrew and colleagues \(1989\)](#) described 25 cases of hemorrhage between 7 and 40 days postpartum associated with noninvolved uteroplacental arteries. These abnormal arteries were characterized by no detectable endothelial lining and the vessels were filled with thrombi. Periauricular trophoblasts were also present in the walls of these vessels and the authors postulated that subinvolution, at least with regard to the placental vessels, may represent an aberrant interaction between uterine cells and trophoblast.

PLACENTAL SITE INVOLUTION. According to [Williams \(1931\)](#), complete extrusion of the placental site takes up to 6 weeks. This process is of great clinical importance, for when it is defective, late-onset puerperal hemorrhage may ensue. Immediately after delivery, the placental site is about the size of the palm of the hand, but it rapidly decreases thereafter. By the end of the second week, it is 3 to 4 cm in diameter. Within hours of delivery, the placental site normally consists of many thrombosed vessels that ultimately undergo the typical organization of a thrombus ([Fig. 17-1](#)).

[Williams \(1931\)](#) explained involution of the placental site as follows:

Involution is not effected by absorption in situ, but rather by a process of exfoliation which is in great part brought about by the undermining of the implantation site by growth of endometrial tissue. This is affected partly by extension and downgrowth of endometrium from the margins of the placental site and partly by the development

of endometrial tissue from the glands and stroma left in the depths of the decidua basalis after placental separation. Such exfoliation should be regarded as very conservative, and as a wise provision; otherwise great difficulty might be experienced in sloughing obliterated arteries and organized thrombi which, if they remained in situ, would soon convert a considerable part of the uterine mucosa and subjacent myometrium into a mass of scar tissue.

[Anderson and Davis \(1968\)](#) concluded that placental site exfoliation is brought about as the consequence of sloughing of infarcted and necrotic superficial tissues followed by a reparative process.

LATE POSTPARTUM HEMORRHAGE. Serious uterine hemorrhage occasionally develops 1 to 2 weeks into the puerperium. Hemorrhage most often is the result of abnormal involution of the placental site, but it may also be caused by retention of a portion of the placenta. Usually the retained piece of placenta undergoes necrosis with deposition of fibrin, and may eventually form a so-called *placental polyp*. As the eschar of the polyp detaches from the myometrium, hemorrhage may be brisk.

In a study by [Lee and associates \(1981\)](#) of 3822 women delivered during a 1-year period at Henry Ford Hospital, 27 women, or 0.7 percent, had significant uterine bleeding after the first 24 postpartum hours. In 20 of these women the uterus was judged to be empty by sonographic evaluation, and importantly, only one woman had retained placental tissue.

It has generally been accepted that with late postpartum hemorrhage from the uterus, prompt curettage is necessary. However, curettage subsequent to late puerperal hemorrhage usually does not remove identifiable placental tissue, and hemorrhage frequently is intensified. Thus, rather than reducing hemorrhage, curettage is more likely to traumatize the implantation site and incite more bleeding. Especially where there is good reason to preserve the uterus for future childbearing, initial treatment may best be directed to control of the bleeding, using intravenous oxytocin, ergonovine, methylergonovine, or prostaglandins ([Adrinopoulos and Mendenhall, 1983](#)). In general, curettage is carried out only if appreciable bleeding persists or recurs after such management.

URINARY TRACT CHANGES

Normal pregnancy is associated with an appreciable increase in extracellular water, and puerperal diuresis is a physiological reversal of this process. Diuresis regularly occurs between the second and fifth days, even when intravenous fluids were not infused vigorously during labor and delivery. The fluid-retaining stimuli of pregnancy-induced hyperestrogenism and elevated venous pressure in the lower half of the body dissipate after delivery, and residual hypervolemia is lost. In preeclampsia, both retention of fluid antepartum and diuresis postpartum may be greatly increased ([Chap. 24](#)).

The puerperal bladder has an increased capacity and a relative insensitivity to intravesical fluid pressure. Overdistention, incomplete emptying, and excessive residual urine are common. The paralyzing effect of anesthesia, especially conduction analgesia, and the temporarily disturbed bladder neural function, are undoubtedly contributory factors. Residual urine and bacteriuria in a traumatized bladder, coupled with the dilated renal pelvis and ureters, create optimal conditions for development of urinary infection. Dilated ureters and renal pelvis return to their prepregnant state from 2 to 8 weeks after delivery ([Chap. 8, p. 186](#)).

[Kerr-Wilson and colleagues \(1984\)](#) studied the effect of labor on postpartum bladder function using urodynamic techniques. They concluded that, as long as prolonged labors were avoided and if catheterization was done promptly for bladder distention, there was no evidence for bladder hypotonia. [Andolf and co-investigators \(1994\)](#) used ultrasonography to measure residual bladder volumes 3 days after vaginal delivery in 539 unselected consecutive women. Only 12 (1.5 percent) had abnormal volumes and only four needed urinary catheters. Urinary retention was more common after instrumental delivery or epidural analgesia. These same women were rescanned 4 years later and a third had voiding difficulties.

[Viktrup and colleagues \(1992\)](#) followed 305 nulliparous women during pregnancy and postpartum and 7 percent developed stress incontinence after delivery. Obstetrical factors such as length of second-stage labor, infant head circumference, birthweight, and episiotomy were associated with the development of stress incontinence after delivery. Impaired muscle function in or around the urethra during vaginal delivery was proposed as the pathophysiology underlying puerperal incontinence. Most women returned to normal micturition by 3 months postpartum. **Careful attention to all postpartum women, with prompt catheterization for those who cannot void, will prevent most urinary problems.**

RELAXATION OF THE VAGINAL OUTLET AND PROLAPSE OF THE UTERUS

Early in the puerperium, the vagina and vaginal outlet form a capacious, smooth-walled passage that gradually diminishes in size but rarely returns to nulliparous dimensions. Rugae reappear by the third week. The hymen is represented by several small tags of tissue, which during cicatrization are converted into the *myrtiliform caruncles*.

Extensive lacerations of the perineum during delivery are followed by relaxation of the vaginal outlet. Even when external lacerations are not visible, over-stretching may lead to marked relaxation. Moreover, changes in the pelvic supports during parturition predispose to prolapse of the uterus and to urinary stress incontinence. In general, operative correction is postponed until childbearing is ended, unless, of course, serious disability, notably urinary stress incontinence, results in symptoms sufficient to require intervention.

PERITONEUM AND ABDOMINAL WALL

The broad and round ligaments are much more lax when nonpregnant, and they require considerable time to recover from the stretching and loosening that occurred during pregnancy.

As a result of the rupture of elastic fibers in the skin and the prolonged distention caused by the pregnant uterus, the abdominal wall remains soft and flabby. Return to normal for these structures requires several weeks, but recovery is aided by exercise. Except for silvery striae, the abdominal wall usually resumes its prepregnancy appearance. When muscles remain atonic, however, the abdominal wall also remains lax. There may be a marked separation, or diastasis, of the rectus muscles. In this condition, the abdominal wall in the vicinity of the midline is formed only by peritoneum, attenuated fascia, subcutaneous fat and skin.

BLOOD AND FLUID CHANGES

Rather marked leukocytosis and thrombocytosis occur during and after labor. The leukocyte count sometimes reaches 30,000/uL, with the increase predominantly from granulocytes. There is also a relative lymphopenia and an absolute eosinopenia. Normally, during the first few postpartum days, hemoglobin concentration and hematocrit fluctuate moderately. If they fall much below the levels present just prior to labor, a considerable amount of blood has been lost ([Chap. 25, p. 635](#)). By 1 week after delivery, the blood volume has returned nearly to its nonpregnant level. [Robson and colleagues \(1987\)](#) showed that cardiac output remains elevated for at least 48 hours postpartum. Most likely this is due to increased stroke volume from venous return, because the heart rate falls at the same time. By 2 weeks, these changes have returned to normal nonpregnant values.

Pregnancy-induced changes in blood coagulation factors persist for variable periods during the puerperium. Elevation of plasma fibrinogen and hence the sedimentation rate are maintained at least through the first week, and as a consequence, the elevated sedimentation rate normally found during pregnancy remains high.

WEIGHT LOSS. In addition to the loss of about 5 to 6 kg due to uterine evacuation and normal blood loss, there is usually a further decrease of 2 to 3 kg through diuresis. [Chesley and co-workers \(1959\)](#) demonstrated a decrease in sodium space of about 2 L, or 2 kg during the first week postpartum.

According to [Schauberger and co-investigators \(1992\)](#), most women approach their self-reported prepregnancy weight 6 months after delivery but still retain an average surplus of 1.4 kg (3 lbs). Factors that increased puerperal weight loss included weight gain during pregnancy, primiparity, early return to work outside the home, and smoking. Breast feeding, age, or marital status did not affect weight loss. [Greene and colleagues \(1988\)](#) analyzed data from the collaborative perinatal study, and found that prenatal weight gain in excess of 20 lbs was associated with postpartum weight retention.

MAMMARY GLANDS

BREAST ANATOMY

Anlagen of mammary glands are contained in ectodermal ridges that form on the ventral surface of the embryo and extend laterally from forelimb to hindlimb. The multiple pairs of buds normally disappear from the embryo except for one pair in the pectoral region that eventually develops into the two mammary glands ([Fig. 17-2](#)).

At times, however, the buds elsewhere may not completely disappear, but instead they may participate to an amazing degree in the pattern of growth that characterizes the two normal mammary glands.

At midpregnancy, each of the two fetal mammary buds destined to form the breasts begins to grow and divide. This results in the formation of 15 to 25 secondary buds that provide the basis for the duct system in the mature breast. Each secondary bud elongates into a cord, bifurcates, and differentiates into two concentric layers of cuboidal cells and a central lumen. The inner layer of cells eventually gives rise to the secretory epithelium, which synthesizes the milk. The outer cell layer becomes myoepithelium, which provides the mechanism for milk ejection ([Fig. 17-3](#)).

Thelarche is the onset of rapid breast growth that begins about the time of puberty when estrogen production rises. The previously infantile mammary glands respond to estrogen with growth and development of mammary ducts and fat deposition. With ovulation, progesterone stimulates development of the alveoli for future lactation.

Anatomically, each mature mammary gland is composed of 15 to 25 lobes that arose from the secondary buds described previously. The lobes are arranged radially and are separated from one another by varying amounts of fat. Each lobe consists of several lobules, which in turn are made up of large numbers of alveoli ([Fig. 17-3](#)). Every alveolus is provided with a small duct that joins others to form a single larger duct for each lobe. These lactiferous ducts open separately upon the nipple, where they may be distinguished as minute but distinct orifices. The alveolar secretory epithelium synthesizes the various milk constituents.

BREAST FEEDING

LACTATION. Colostrum is the deep lemon-yellow colored liquid secreted initially by the breasts. It usually can be expressed from the nipples by the second postpartum day.

COLOSTRUM. Compared with mature milk, colostrum contains more minerals and protein, much of which is globulin, but less sugar and fat. Colostrum nevertheless contains large fat globules in so-called colostrum corpuscles. These are thought by some investigators to be epithelial cells that have undergone fatty degeneration and by others to be mononuclear phagocytes containing fat. Colostrum secretion persists for about 5 days, with gradual conversion to mature milk during the ensuing 4 weeks. Antibodies are demonstrable in the colostrum, and its content of immunoglobulin A may offer protection for the newborn against enteric pathogens. Other host resistance factors, as well as immunoglobulins, are found in human colostrum and milk. These include complement, macrophages, lymphocytes, lactoferrin, lacto-peroxidase, and lysozymes.

MILK. Human milk is a suspension of fat and protein in a carbohydrate-mineral solution. A nursing mother easily makes 600 mL of milk per day. Milk is isotonic with plasma, with lactose accounting for half of the osmotic pressure. Major proteins, including α -lactalbumin, β -lactoglobulin, and casein, are also present. Essential amino acids are derived from blood, and nonessential amino acids are derived in part from blood or synthesized in the mammary gland. Most milk proteins are unique and not found elsewhere. Whey has been shown to contain large amounts of interleukin-6 ([Saito and co-workers, 1991](#)). Peak levels of this cytokine were found in colostrum, and there was a positive correlation between its concentration and the number of mononuclear cells in human milk. Additionally, interleukin-6 was associated closely with local immunoglobulin A production by the breast. Prolactin appears to be actively secreted into breast milk ([Yuen, 1988](#)). Epidermal growth factor (EGF) has also been identified in human milk ([Koldovsky and associates, 1991](#); [McCleary, 1991](#)). Because this factor is not destroyed by gastric proteolytic enzymes, it may be absorbed orally and promote growth and maturation of intestinal mucosa.

There are major changes in milk composition by 30 to 40 hours postpartum, including a sudden increase of lactose concentration. Lactose synthesis from glucose in alveolar secretory cells is catalyzed by lactose synthase ([Fig. 17-4](#)). Some lactose enters the maternal circulation and is excreted by the kidney. This may be misinterpreted as glucosuria unless specific glucose oxidase is used in testing. Fatty acids are synthesized in the alveoli from glucose and are secreted by an apocrine-like process.

All vitamins except vitamin K are found in human milk, but in variable amounts, and maternal dietary supplementation increases the secretion of most of these ([American Academy of Pediatrics, 1981](#)). Vitamin K administration to the infant soon after delivery is required to prevent hemorrhagic disease of the newborn ([Chap. 39, p. 1082](#)).

Human milk contains a low iron concentration and maternal iron stores do not seem to influence the amount of iron in breast milk. Therefore, the use of supplemental iron-fortified infant formulas, or a weaning formula also fortified with iron, is recommended ([American Academy of Pediatrics, 1997](#)). Such formulas apparently have eliminated iron-deficiency anemia during childhood ([Yip and associates, 1987](#)). These formulas are well tolerated by most infants and there is no evidence that they impair absorption of zinc or copper ([Nelson and associates, 1988](#); [Yip and colleagues, 1985](#)).

[Mennella and Beauchamp \(1991\)](#) documented what experienced nursing mothers have long known: breast-fed infants are aware of what their mothers eat and drink. They studied the effects of maternal ethanol ingestion equivalence to one can of beer. This caused the infants to suck more frequently during the first minute of feeding, but ultimately they consumed significantly less milk.

The mammary gland, like the thyroid gland, concentrates iodine and several other minerals, including gallium, technetium, indium, and possibly sodium. Radioactive isotopes of these minerals should not be given to nursing women because they rapidly appear in breast milk. [The American Academy of Pediatrics \(1997\)](#) recommends consultation with a nuclear medicine physician before performing a diagnostic study, so that a radionuclide with the shortest excretion time in breast milk can be used. They further recommend that the mother pump her breasts before the study and store enough milk in a freezer for feeding the infant. After the study, she should pump her breasts to maintain milk production, but discard all milk produced during the time that radioactivity is present. This ranges from 15 hours up to 2 weeks, depending upon the isotope used.

The approximate concentrations of the more important components of human colostrum, mature human milk, and cow milk are presented in [Table 17-1](#). These concentrations vary depending upon maternal diet and when studied in the puerperium ([Brasil and co-workers, 1991](#); [Giovannini and colleagues, 1991](#); [Ogunleye and associates, 1991](#)). Gestational weight gain has little, if any, impact on the subsequent milk quantity or quality ([Institute of Medicine, 1990](#)).

ENDOCRINOLOGY OF LACTATION. The precise humoral and neural mechanisms involved in lactation are complex. Progesterone, estrogen, and placental lactogen, as well as prolactin, cortisol, and insulin, appear to act in concert to stimulate the growth and development of the milk-secreting apparatus of the mammary gland ([Porter, 1974](#)). With delivery, there is an abrupt and profound decrease in the levels of progesterone and estrogen, which removes the inhibitory influence of progesterone on the production of α -lactalbumin by the rough endoplasmic reticulum ([Fig. 17-4](#)). The increased α -lactalbumin serves to stimulate lactose synthase and ultimately increased milk lactose. Progesterone withdrawal also allows prolactin to act unopposed in its stimulation of α -lactalbumin production.

The intensity and duration of subsequent lactation are controlled, in large part, by the repetitive stimulus of nursing. Prolactin is essential for lactation; women with extensive pituitary necrosis, as in Sheehan syndrome, do not lactate. Although plasma prolactin falls after delivery to lower levels than during pregnancy, each act of suckling triggers a rise in levels ([McNeilly and associates, 1983](#)). Presumably a stimulus from the breast curtails the release of prolactin-inhibiting factor from the hypothalamus; this, in turn, transiently induces increased prolactin secretion.

The neurohypophysis, in pulsatile fashion, secretes oxytocin. This stimulates milk expression from a lactating breast by causing contraction of myoepithelial cells in the alveoli and small milk ducts. Milk ejection, or "letting down," is a reflex initiated especially by suckling, which stimulates the neurohypophysis to liberate oxytocin ([McNeilly and associates, 1983](#)). It may be provoked even by the cry of the infant or inhibited by fright or stress.

In women who continue lactating but who resume ovulation, there are acute alterations in breast milk composition 5 to 6 days before and 6 to 7 days following ovulation ([Hartmann and Prosser, 1984](#)). These changes are abrupt and characterized by increased concentrations of sodium and chloride, along with decreased potassium, lactose, and glucose concentrations. In women who become pregnant but who continue to breast feed, milk composition undergoes progressive alterations suggesting gradual loss of metabolic and secretory breast activity ([Hartmann and Prosser, 1984](#)).

IMMUNOLOGICAL CONSEQUENCES OF BREAST FEEDING. Antibodies are present in human colostrum and milk but are poorly absorbed, if at all, from the infant's gut. For example, no anti-D antibodies have been detected in the sera of infants fed milk containing a high titer of antibodies. This circumstance, however, does not lessen the importance of at least some of the antibodies in breast milk. The predominant immunoglobulin in milk is secretory IgA, a macromolecule that is important in antimicrobial processes in mucous membranes across which it is secreted. Milk contains secretory IgA antibodies against *Escherichia coli*, and it is known that breast-fed infants are less prone to enteric infections than bottle-fed babies ([Cravioto and associates, 1991](#)). It has been suggested that IgA exerts its action by preventing bacterial adherence to epithelial cells surfaces, thus preventing tissue invasion ([Samra and associates, 1991](#)). Moreover, human milk also provides protection against rotavirus infections, which cause up to 50 percent of cases of gastroenteritis among infants in the United States ([Newburg and associates, 1998](#)).

Much attention has been directed to an elucidation of the role of maternal breast milk lymphocytes in fetal immunological processes. Milk contains both the T and B lymphocytes, but the T lymphocytes appear to differ from those found in blood. Specifically, milk T lymphocytes are almost exclusively composed of cells that exhibit specific membrane antigens including the LFA-1 high-memory T-cell phenotype. These memory T cells appear to be another mechanism by which the neonate benefits from maternal immunological experience ([Bertotto and associates, 1990](#)). Lymphocytes in colostrum undergo blastoid transformation in vitro following exposure to specific antigens. In experimental animals, [Beer and Billingham \(1976\)](#) observed a transmission of viable lymphocytes from mother to infant through breast milk. As mentioned earlier, interleukin-6 is present in colostrum and appears to stimulate an increase in mononuclear cells in breast milk ([Saito and co-workers, 1991](#)).

NURSING. Between 1930 and the late 1960s, there was a dramatic decline in the percentage of American mothers who breast fed ([Yaffe, 1994](#)). The incidence declined from approximately 80 percent of children born between 1926 and 1930 to only 20 percent of births in 1972. At the present time in the United States, a number of surveys indicate that more than 60 percent of babies discharged from the hospital are breast fed, and the number is increasing ([American College of Obstetricians and Gynecologists, 2000](#)).

Human milk is ideal food for neonates. As reviewed by the [American College of Obstetricians and Gynecologists \(2000\)](#), it provides species- and age-specific nutrients for the infant. In addition to the right balance of nutrients, immunological factors, and antibacterial properties, human milk contains factors that act as biological signals for promoting cellular growth and differentiation. In 1997, the American Academy of Pediatrics published the policy statement on the infant benefits of nursing shown in [Table 17-2](#). The United States Public Health Service goal for year 2010 is to increase the proportion of mothers who breast feed to 75 percent ([American College of Obstetricians and Gynecologists, 2000](#)).

In most instances, even though the supply of milk at first appears insufficient, it becomes adequate if suckling is continued. An exception is that 65 percent of women with augmentation mammoplasty have lactation insufficiency ([Hurst, 1996](#)). This depends on whether the implant incision was periareolar or not ([Chez and Friedmann, 2000](#)). Nursing also accelerates uterine involution, because repeated stimulation of the nipples releases oxytocin, which contracts uterine muscle. **Aerobic exercise** performed four or five times per week beginning 6 to 8 weeks postpartum had no adverse effect on lactation and significantly improved the cardiovascular fitness of the mothers ([Dewey and co-workers, 1994](#)). Weight loss of approximately 0.5 kg per week in the first 3 months postpartum does not affect infant growth in exclusively breast feeding, overweight women ([Love-lady and co-workers, 2000](#)).

According to [Chez and Friedmann \(2000\)](#), a number of internet website resources are available for more information for breast feeding mothers; these include the American Academy of Pediatrics (www.aap.org) and LeLeche League International (www.laleche.league.org).

LACTATION INHIBITION. Approximately 40 percent of American women currently elect to not breast feed, and many experience considerable breast pain and engorgement. Milk leakage, engorgement, and breast pain peak at 3 to 5 days postpartum ([Spitz and associates, 1998](#)). As many as 10 percent of women may report severe pain up to 14 days postpartum and a fourth to half of all women use analgesia for relief of puerperal breast pain.

In 1989, an advisory committee of the Food and Drug Administration, taking the view that there is no need for pharmacological therapy for lactation suppression, recommended that medicinals should no longer be used for lactation suppression. Bromocriptine, a commonly used drug for lactation inhibition, had been associated with strokes, myocardial infarctions, seizures, and psychiatric disturbances in puerperal women, although the evidence used to support these associations is tenuous ([Morgans, 1995](#)). Despite this, the manufacturer voluntarily removed lactation suppression in 1994 as an indication for bromocriptine ([Food and Drug Administration, 1994](#)).

The woman who does not desire to breast feed should be reassured that stopping milk production is not a major problem. During the stage of engorgement, the breasts become painful and should be supported with a well-fitting brassiere. Ice packs and oral analgesics for 12 to 24 hours may be required to relieve discomfort. Breast binders, rather than hormonal suppression of lactation, are routinely used at Parkland Hospital in women not desiring to nurse their infant.

CONTRACEPTION. There are many considerations, primarily theoretical, that govern recommendations for use of hormonal methods of contraceptions during lactation and the puerperium ([Chap. 58](#)). Contraception is not needed in the first 3 weeks postpartum because of a delay in return of ovulation in all women ([American College of Obstetricians and Gynecologists, 2000](#)). After this time, depending on individual biological variation as well as the intensity of breast feeding, ovulation may unpredictably resume in lactating women. Progestin-only contraceptives, including mini-pills, depot med-roxyprogesterone, and levonorgestrel implants do not affect the quality of milk and increase, only very slightly, the volume of milk; therefore they are the contraceptives of choice for breast feeding women ([American College of Obstetricians and Gynecologists, 2000](#)). Recommendations for use of progestin-only contraceptives are shown in [Table 17-3](#).

Estrogen-progestin contraceptives have been shown to reduce the quantity and quality of breast milk. Another concern is the predisposition puerperal women have to venous thrombosis, which could be increased by combination contraceptive pills. Accordingly, low-dose estrogen tablets (35 ug or lower) are preferred if combination hormonal contraceptives are to be used in lactating women ([Table 17-3](#)).

CONTRAINDICATIONS. Nursing is contraindicated in women who take street drugs or do not control alcohol use; have an infant with galactosemia; have HIV infection; have active, untreated tuberculosis; take certain medications; or are undergoing breast cancer treatment ([American College of Obstetricians and Gynecologists, 2000](#)). Cytomegalovirus and hepatitis B virus are excreted in milk, however, breast feeding is not contraindicated if hepatitis B immune globulin is given to infants of seropositive mothers.

Breast feeding has been recognized for over a decade as a mode of HIV transmission ([Ziegler and colleagues, 1985](#)). More recent data confirm that some mother-to-infant transmission occurs through breast feeding. [Nduati and colleagues \(2000\)](#) randomized 401 HIV-seropositive mother-infant pairs in Kenya to formula or breast feeding. The frequency of breast milk transmission of HIV was 16 percent. Use of breast milk substitutes prevented 44 percent of infant HIV infections during the first 2 years of life.

Women with active herpes simplex virus may suckle their infants if there are no breast lesions, and if particular care is directed to hand washing before nursing.

CARE OF THE BREASTS AND NIPPLES. The nipples require little attention in the puerperium other than cleanliness and attention to fissures. Because dried milk is likely to accumulate and irritate the nipples, cleaning of the areola with water and mild soap is helpful before and after nursing. Occasionally with irritated nipples it is necessary to use a nipple shield for 24 hours or longer. Inverted or retracted nipples may be troublesome; however, these can usually be teased out by gently pulling with the finger and thumb. This is best done during pregnancy to prepare the nipples for subsequent nursing.

Proper technique for positioning the mother and infant during nursing has been reviewed by the [American College of Obstetricians and Gynecologists \(2000\)](#). This includes proper techniques for "latch-on" of the infant during suckling.

DRUGS SECRETED IN MILK. Most drugs given to the mother are secreted in breast milk. Many factors influence their excretion, including the concentration of drugs in plasma, degree of protein binding, plasma and milk pH, degree of ionization, lipid solubility, and molecular weight. The amount of drug ingested by the infant typically is small. The ratio of drug concentrations in breast milk to those in maternal plasma is called the milk-to-plasma drug-concentration ratio. Most drugs have a milk-to-plasma ratio of 1 or less; about 25 percent have ratios of more than 1, and about 15 percent have ratios greater than 2 ([Ito, 2000](#)).

The [American Academy of Pediatrics and the American College of Obstetricians and Gynecologists \(1997\)](#) have provided a list of drugs and other chemicals that are contraindicated during pregnancy ([Table 17-4](#)). Shown in [Table 17-5](#) is a list of drugs of choice for breast feeding women.

BREAST FEVER. For the first 24 hours after the development of the lacteal secretion, it is not unusual for the breasts to become distended, firm, and nodular. These findings may be accompanied by a transient elevation of temperature. Puerperal fever from breast engorgement is common. [Almeida and Kitay \(1986\)](#) reported that 13 percent of all postpartum women had fever from this cause, and it ranged from 37.8 to 39°C. Fever seldom persisted for longer than 4 to 16 hours. The incidence and severity of breast engorgement, and fever associated with it, were lower if treatment was given for lactation suppression. Such fevers are particularly worrisome if infection cannot be excluded in women who have recently undergone cesarean delivery. **Other causes of fever, especially those due to infection, must be excluded.**

Treatment consists of supporting the breasts with a binder or brassiere, applying an ice bag, and an analgesic. Pumping of the breast or manual expression of milk may be necessary at first, but in a few days the condition is usually alleviated and the infant is able to nurse normally.

MASTITIS. Parenchymatous infection of the mammary glands is a rare complication antepartum but is occasionally observed during the puerperium and lactation. [Stehman \(1990\)](#) cited an incidence of 2 percent, which is much higher than our experiences. Symptoms of suppurative mastitis seldom appear before the end of the first week postpartum and, as a rule, not until the third or fourth week. Infection almost invariably is unilateral and marked engorgement usually precedes the inflammation, the first sign of which is chills or actual rigor, soon followed by fever and tachycardia. The breast becomes hard and reddened, and the woman complains of pain. About 10 percent of women with mastitis develop an abscess, and constitutional symptoms attending a mammary abscess are severe. The breast is somewhat harder than usual and more or less painful, but constitutional symptoms are either lacking or very slight. In such circumstances, the first indication of the true diagnosis often is afforded by the detection of fluctuation. Sonography may be helpful to detect an abscess.

ETIOLOGY. The most common offending organism is *Staphylococcus aureus*, and [Matheson and colleagues \(1988\)](#) cultured this organism from 40 percent of women with mastitis. Other commonly isolated organisms are coagulase-negative staphylococci and viridans streptococci. [Rench and Baker \(1989\)](#) reported an unusual case in which mother and male infant both developed mastitis and the mother a breast abscess caused by group B streptococcus. The immediate source of the organisms that cause mastitis is almost always the nursing infant's nose and throat. At the time of nursing, the organism enters the breast through the nipple at the site of a fissure or abrasion, which may be quite small. Whether the bacteria commonly cause mastitis simply by entering the lactiferous ducts of the breast with completely intact integument is not clear. In cases of true mastitis, the offending organism can usually be cultured from breast milk. Toxic shock syndrome has been reported in a woman with a puerperal breast abscess from which *S. aureus* was cultured ([Demey and associates, 1989](#)).

Suppurative mastitis among nursing mothers has at times reached epidemic levels. Such outbreaks most often coincide with the appearance of a new strain of antibiotic-resistant *Staphylococcus*, an example being methicillin-resistant *S. aureus* (MRSA). Typically, the infant becomes infected after contact with nursery personnel who are colonized. Attendants' hands are the major source of contamination of the newborn. The colonization of staphylococci in the infant may be totally asymptomatic or may locally involve the umbilicus or the skin. Occasionally the organisms cause a life-threatening systemic infection.

TREATMENT. Abscess formation is more common if *S. aureus* causes infection ([Matheson and associates, 1988](#)). Provided that appropriate therapy is started before suppuration begins, the infection usually resolves within 48 hours. Before initiating antimicrobial therapy, milk should be expressed from the affected breast onto a swab and cultured. By so doing, the organism can be identified and its antimicrobial sensitivities ascertained. Results of such cultures also provide information mandatory for a successful program for surveillance of nosocomial infections. The initial choice of antimicrobial will undoubtedly be influenced to a considerable degree by the current experiences with staphylococcal infections at the institution. Many staphylococcal infections are caused by organisms sensitive to penicillin or a cephalosporin. Dicloxacillin (500 mg orally four times daily) may be started empirically ([Hindle, 1994](#)). Erythromycin is given to women who are penicillin sensitive. If the infection is caused by resistant, penicillinase-producing staphylococci, or if resistant organisms are suspected while awaiting the results of culture, an antimicrobial such as vancomycin, which is effective against methicillin-resistant staphylococci, should be given. Even though clinical response may be prompt and striking, treatment should be continued for about 7 to 10 days.

[Marshall and colleagues \(1975\)](#) demonstrated the importance of continued breast feeding. They reported that the only three abscesses that developed in 65 women with mastitis were in 15 women who chose to wean their infants. [Thomsen and co-workers \(1984\)](#) observed that vigorous milk expression was sufficient treatment alone in half of women with mastitis. Early therapy and continued lactation was successful in avoiding abscess formation in all 20 women described by [Niebyl and co-investigators \(1978\)](#). If the infected breast is too tender to allow suckling, gently pumping until nursing can be resumed is recommended. Sometimes the infant will not nurse on the inflamed breast. This is probably not related to any changes in the taste of the milk, but is secondary to engorgement and edema, which can make the areola harder to grip. Pumping can alleviate this. When nursing bilaterally, it is best to begin suckling on the uninvolved breast. This allows let-down to commence before moving to the tender breast.

BREAST ABSCESS. Clinical suspicion for abscess development is either from failure of defervescence within 48 to 72 hours or development of a palpable mass. Sonography may be helpful. Surgical drainage is essential and general anesthesia is usually required. The incision should be made corresponding to skin lines for a good cosmetic result ([Stehman, 1990](#)). In early cases, a single incision over the most dependent portion of the area of fluctuation is usually sufficient, but multiple abscesses require several incisions and a finger should be inserted to break up the walls of the locules. The resulting cavity is loosely packed with gauze, which should be replaced at the end of 24 hours by a smaller pack.

More recently, ultrasonic-guided aspiration using local anesthesia has been described. [Karstrup and colleagues \(1993\)](#) successfully treated 18 of 19 women with such an approach, and 10 were treated on an outpatient basis.

GALACTOCELE. Very exceptionally, as the result of the clogging of a duct by inspissated secretion, milk may accumulate in one or more lobes of the breast. The amount is ordinarily limited, but an excess may form a fluctuant mass that may give rise to pressure symptoms. They may resolve spontaneously or require aspiration.

SUPERNUMERARY BREASTS. One in every few hundred women has one or more accessory breasts (*polymastia*). The supernumerary breasts may be so small as to be mistaken for pigmented moles, or when without a nipple, for a lipoma. They rarely attain considerable size. They are likely to be situated in pairs on either side of the midline of the thoracic or abdominal walls, usually below the main breasts. They are also found in the axillae, and more rarely on other portions of the body such as the shoulder, flank, groin, or thigh. When arranged symmetrically, two or four are most common, although 10 have been described. Polymastia has no obstetrical significance, although occasionally the enlargement of supernumerary breasts in the axillae may result in considerable discomfort.

ABNORMALITIES OF THE NIPPLES. In some women, the lactiferous ducts open directly into a depression at the center of the areola. In marked cases of depressed nipple, nursing is out of the question. When the depression is not very deep, the breast may occasionally be made available by use of a breast pump.

More frequently, the nipple, although not depressed, is greatly inverted. In such a case, daily attempts should be made during the last few months of pregnancy to draw the nipple out, using traction with fingers.

Nipples that are normal in shape and size may become fissured. In such cases, the fissures almost invariably render nursing painful, sometimes with a deleterious influence upon the secretory function. Moreover, such lesions provide a convenient portal of entry for pyogenic bacteria. For these reasons, every effort should be made to heal such fissures, particularly by protecting them from further injury with a nipple shield and topical medication. If such measures are of no avail, the infant should not be permitted to nurse on the affected side. Instead, the breast should be emptied regularly with a suitable pump until the lesions are completely healed.

ABNORMALITIES OF SECRETION. There are marked individual variations in the amount of milk secreted, many of which are dependent not upon the general health and appearance of the woman but upon the development of the glandular portions of the breasts. Very rarely, there is complete lack of mammary secretion (*agalactia*). As a rule, it is possible to express a small amount from the nipple on the third or fourth day of the puerperium. Occasionally, the mammary secretion is excessive (*polygalactia*).

CARE OF THE MOTHER DURING THE PUERPERIUM

HOSPITAL CARE

ATTENTION IMMEDIATELY AFTER LABOR. For the first hour after delivery, blood pressure and pulse should be taken every 15 minutes, or more frequently if indicated. The amount of vaginal bleeding is monitored, and the fundus should be palpated to ensure that it is well contracted. If relaxation is detected, the uterus should be massaged through the abdominal wall until it remains contracted. Blood may accumulate within the uterus without external bleeding. This may be detected early by identifying uterine enlargement through frequent fundal palpation during the first few hours postpartum. Because the likelihood of significant hemorrhage is greatest immediately postpartum, even in normal cases, a trained attendant should remain with the mother for at least 1 hour after completion of the third stage of labor. Identification and management of postpartum hemorrhage is discussed in [Chapter 25](#).

Following regional analgesia or general anesthesia, the mother should be observed in an appropriately equipped and staffed recovery area.

EARLY AMBULATION. Immediately after World War II, early ambulation became an accepted puerperal practice. Women are now out of bed within a few hours after delivery. The many advantages of early ambulation are confirmed by numerous well-controlled studies. Bladder complications and constipation are less frequent. Importantly, early ambulation has also reduced the frequency of puerperal venous thrombosis and pulmonary embolism ([Togliola and Weg, 1996](#); see also [Chap. 46](#)). For at least the first ambulation, an attendant should be present if the woman should become syncopal.

CARE OF THE VULVA. The patient should be instructed to cleanse the vulva from anterior to posterior (vulva toward anus). An ice bag applied to the perineum may help reduce edema and discomfort during the first several hours after episiotomy repair. Beginning about 24 hours after delivery, moist heat as provided with warm

sitz baths can be used to reduce local discomfort. Tub bathing after uncomplicated delivery is allowed.

BLADDER FUNCTION. Bladder filling after delivery may be quite variable. In most hospitals, intravenous fluids are infused during labor and for an hour after delivery. Oxytocin, in doses that have an antidiuretic effect, is commonly infused after placental delivery. As a consequence of infused fluid and the sudden withdrawal of the antidiuretic effect of oxytocin, rapid bladder filling is common. Moreover, both bladder sensation and its capability to empty spontaneously may be diminished by anesthesia, especially conduction analgesia, as well as by episiotomy, lacerations, or hematomas. It is not surprising, therefore, that urinary retention with bladder overdistention is a common complication of the early puerperium.

Prevention of overdistention demands observation after delivery to ensure that the bladder does not overflow and that with each voiding it empties adequately. The bladder may be palpated as a cystic mass suprapubically, or the enlarged bladder may be evident abdominally only indirectly as a consequence of elevating the uterine fundus above the umbilicus.

If the woman has not voided within 4 hours after delivery, it is likely that she cannot. The woman who has trouble voiding initially is likely to have further trouble. At times, an indwelling catheter is necessary to prevent overdistention. The likelihood of hematomas of the genital tract must be considered when the woman cannot void. Whenever the bladder becomes overdistended, an indwelling catheter should be left in place until the factors causing the retention have abated. [Harris and colleagues \(1977\)](#) reported that 40 percent of such women will develop bacteriuria; thus, a short course of antimicrobial therapy seems reasonable after catheter removal.

In cases of bladder overdistention, it usually is best to leave an indwelling catheter in place for at least 24 hours, so as to empty the bladder completely and prevent prompt recurrence as well as to allow recovery of normal bladder tone and sensation. When the catheter is removed, it is necessary subsequently to demonstrate ability to void appropriately. If the woman cannot void after 4 hours, she should be catheterized and urine volume measured. If there is more than 200 mL of urine, it is apparent that the bladder is not functioning appropriately. The catheter should be left in place and the bladder drained for another day. If less than 200 mL of urine is obtained, the catheter can be removed and the bladder rechecked subsequently as described.

BOWEL FUNCTION. At times, the lack of a bowel movement is no more than the expected consequence of an efficient cleansing enema administered before delivery. With both early ambulation and early feeding, constipation has become much less of a problem.

SUBSEQUENT DISCOMFORT. The discomfort from cesarean delivery, its causes, and its management are considered in [Chapter 23](#). During the first few days after vaginal delivery, the mother may be uncomfortable for a variety of reasons, including afterpains, episiotomy and lacerations, breast engorgement, and at times, postspinal puncture headache. It is helpful to provide codeine, 60 mg; aspirin, 600 mg; or acetaminophen, 500 mg, at intervals as frequent as every 3 hours during the first few days after delivery. Uterine contractions are commonly accentuated during nursing, giving rise at times to troublesome afterpains.

An episiotomy or lacerations may be uncomfortable, as discussed in [Chapter 13 \(p. 325\)](#). Early application of an ice bag may minimize swelling and discomfort. Most women also appear to obtain a measure of relief from the periodic application of a local anesthetic spray. Severe discomfort may indicate that a sizable hematoma has formed in the genital tract and warrants careful examination, especially whenever analgesics do not provide relief. The episiotomy incision normally is firmly healed and nearly asymptomatic by the third week.

MILD DEPRESSION. It is fairly common for a mother to exhibit some degree of depression a few days after delivery. The transient depression, or *postpartum blues*, most likely is the consequence of a number of factors. Prominent in its genesis are:

1. The emotional letdown that follows the excitement and fears that most women experience during pregnancy and delivery.
2. The discomforts of the early puerperium.
3. Fatigue from loss of sleep during labor and postpartum in most hospital settings.
4. Anxiety over her capabilities for caring for her infant after leaving the hospital.
5. Fears that she has become less attractive.

In the great majority of cases, effective treatment need be nothing more than anticipation, recognition, and reassurance.

This mild disorder is self-limited and usually remits after 2 to 3 days, although it sometimes persists for up to 10 days. Should postpartum blues persist, or worsen, then careful attention is given to searching for symptoms of depression, which may require prompt consultation ([Chap. 53, p. 1421](#)). In a preliminary study from Parkland Hospital, we found that symptoms of depression were actually present during pregnancy in 50 percent of women who developed postpartum depression. This raises the possibility that postpartum depression may be a manifestation of an underlying depressive disorder ([Nielsen and colleagues, 2000](#)).

ABDOMINAL WALL RELAXATION. An abdominal binder is unnecessary. It does not help restore the mother's figure. If the abdomen is unusually flabby or pendulous, an ordinary girdle is often satisfactory. Exercises to restore abdominal wall tone may be started any time after vaginal delivery and as soon as abdominal soreness diminishes after cesarean delivery.

DIET. There are no dietary restrictions for women who have been delivered vaginally. Two hours after a normal vaginal delivery, if there are no complications likely to necessitate an anesthetic, the woman should be given something to drink and eat if she desires. The diet of lactating women, compared with that consumed during pregnancy, should be increased in calories and protein, as recommended by the Food and Nutrition Board of the National Research Council ([Chap. 8, p. 173](#)). If the mother does not breast feed, her dietary requirements are the same as for a nonpregnant woman.

It is standard practice in our hospitals to continue iron supplementation for at least 3 months after delivery and to check the hematocrit at the first postpartum visit.

IMMUNIZATIONS. The D-negative woman who is not isoimmunized and whose baby is D-positive is given 300 ug of anti-D immune globulin shortly after delivery ([Chap. 39, p. 1066](#)). Women who are not already immune to rubella are excellent candidates for vaccination before discharge ([Chap. 10, p. 240](#)). Unless it is contraindicated, a diphtheria-tetanus toxoid booster injection may be administered at this time. Beginning in 1991, women delivered at Parkland Hospital have also been given measles (rubeola) immunization prior to postpartum discharge. This recommendation is based upon:

1. The failure of previously immunized persons to develop protective immunity ([Centers for Disease Control, 1989](#)).
2. Significant outbreaks of measles in the community.
3. Maternal morbidity and mortality due to measles pneumonitis.

TIME OF DISCHARGE. Following vaginal delivery, if there are **no complications**, hospitalization is seldom warranted for more than 48 hours. Before discharge, the woman should receive instructions concerning the anticipated normal physiological changes of the puerperium, including lochia patterns, weight loss due to diuresis, and when to expect milk let-down. She also should receive instructions concerning what to do if she becomes febrile, has excessive vaginal bleeding, or develops leg pain, swelling, or tenderness. Any shortness of breath or chest pains warrant immediate concern.

EARLY DISCHARGE. As discussed in [Chapter 1](#), the issue of third-party payers dictating inappropriately short lengths of hospital stays following labor and delivery has been regulated by Federal law. In 2000, medical consensus recommends hospital stays of up to 48 hours following uncomplicated vaginal delivery and up to 96 hours following uncomplicated cesarean delivery ([American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 1997](#)). In 1980, the average stay for a vaginal delivery was 3.2 days. This had decreased to 1.7 days by 1995, but then increased to 2.1 days by 1997 ([Neergaard, 1999](#)). Despite this, in 1997, a fourth of new mothers (951,000) had a hospital stay of one day or less. This seems acceptable if this was indeed their choice and not forced upon these women. It is likely, however, that the timing of discharge has greater significance for the newborn infant.

CONTRACEPTION. During the hospital stay, a concerted effort should be made to provide family planning education. Steroidal contraception and its effects on lactation are discussed on page 412. Other forms of contraception are discussed in [Chapters 58 and 59](#).

CARE AT HOME

COITUS. There is no definite time after delivery when coitus should be resumed. Resumption of intercourse **too soon** may prove to be unpleasant, if not frankly painful, due to incomplete uterine involution and incomplete healing of the episiotomy or lacerations. [Glazener \(1997\)](#) surveyed resumption of sexual activity in 1075 British women and found that 70 percent had intercourse within 8 weeks of delivery. The median interval between delivery and intercourse was 5 weeks but the range was 1 to 12 weeks. Difficulties frequently cited for not resuming intercourse included concern about perineal pain, bleeding, and fatigue.

In another survey, [Barrett and colleagues \(2000\)](#) reported that almost 90 percent of 484 primiparous women had resumed sexual activity by 6 months. Although 65 percent of these reported problems, only 15 percent discussed these with a professional.

The best rule to follow is one of common sense. After 2 weeks, coitus may be resumed *based upon the patient's desire and comfort*. The women should be advised that breast feeding will cause a prolonged period of suppressed estrogen production with a resulting vaginal atrophy and dryness. Such a physiological state results in decreased vaginal lubrication during sexual arousal.

INFANT FOLLOW-UP. Arrangements must be made to insure that the neonate receives appropriate follow-up care. Any neonate discharged early should be term, normal, and have stable vital signs. All laboratory studies should be normal, including direct Coombs test, bilirubin, hemoglobin and hematocrit, and blood glucose. The maternal serological test for syphilis and hepatitis B surface antigen should be nonreactive. Initial hepatitis B vaccine should be administered, and all screening tests required by law should be performed. These always include testing for phenylketonuria (PKU) and hypothyroidism. If subsequent phenylketonuria retesting is required after the neonate has consumed milk the mother must be so instructed. Finally, the importance of subsequent neonatal and well-baby care should be stressed and an emphasis placed on infant immunizations.

RETURN OF MENSTRUATION AND OVULATION. If the woman does not nurse her child, menses usually return within 6 to 8 weeks. At times, however, it is difficult clinically to assign a specific date to the first menstrual period after delivery. A minority of women bleed small to moderate amounts intermittently, starting soon after delivery. Menses may not appear so long as the infant is nursed, but great variations are observed. In lactating women, the first period may occur as early as the second or as late as the 18th month after delivery.

[Sharman \(1966\)](#), by means of histological dating of the endometrium, identified ovulation as early as 42 days after delivery; [Perez and associates \(1972\)](#) did so as early as 36 days. Moreover, a corpus luteum has been observed 6 weeks after delivery at the time of sterilization. Thus, the necessity for instituting contraceptive techniques for sexually active women is obvious.

Ovulation is much less frequent in women who breast feed compared with those who do not. Nonetheless, pregnancy can occur with lactation. [Campbell and Gray \(1993\)](#) used daily urine specimens to determine ovulation in 92 women. This study is the first detailed description of the return of postpartum ovarian activity in breast feeding and non-breast feeding women in the United States. Shown in [Figure 17-5](#) is the cumulative proportion of women spontaneously ovulating postpartum. Clearly, there is delayed resumption of ovulation with breast feeding, although as already mentioned, early ovulation is not precluded by persistent lactation. Other findings included the following:

1. Resumption of ovulation was frequently marked by return of normal menstrual bleeding.
2. Breast feeding episodes lasting 15 minutes seven times each day delayed resumption of ovulation.
3. Ovulation can occur without bleeding.
4. Bleeding can be anovulatory.

They estimated that the risk of pregnancy in breast feeding women was approximately 4 percent per year.

LATE MATERNAL MORBIDITY. Maternal morbidity after discharge is poorly characterized and underresearched. [MacArthur and colleagues \(1991\)](#), while studying the sequelae of labor epidural analgesia, uncovered a vast reservoir of previously unreported morbidity of considerable duration in puerperal women. [Glazener and co-workers \(1995\)](#), in an unprecedented investigation, surveyed health problems in 1249 British women after discharge and up to 18 months following delivery. Although only 3 percent of these women required readmission to the hospital within 8 weeks of delivery, 87 percent had lesser health problems during the first 8 weeks postpartum, and 76 percent of the women continued to have a variety of problems for up to 18 months ([Table 17-6](#)). Overall, the proportion of women with self-perceived health problems declined with time, indicating health did improve, although more slowly than generally assumed. Clearly, maternal morbidity following delivery is extensive and heretofore underrecognized. [Glazener and co-authors \(1995\)](#) called for a greater awareness of the needs of puerperal women as they convalesce from birthing.

FOLLOW-UP CARE. By the time of discharge, women who had a normal delivery and puerperium can resume most activities, including bathing, driving, and household functions. [Jimenez and Newton \(1979\)](#) tabulated cross-cultural information on 202 societies from different international geographic regions. Postnatally, most societies did not restrict maternal work activity, and about half expected a return to full duties within 2 weeks. [Tulman and Fawcett \(1988\)](#) reported, however, that only half of women regained their usual level of energy by 6 weeks postpartum. Women who delivered vaginally were twice as likely to have normal energy levels at this time compared with those who had cesarean deliveries. Ideally, the care and nurturing received by the neonate should be provided by the mother with ample help from the father. For the mother to provide this care, her presence at home with the infant precludes her early return to full-time work or school.

Since 1969, puerperal women at Parkland Hospital have been given appointments for follow-up examination during the third postpartum week. This has proven quite satisfactory both to identify any abnormalities of the later puerperium as well as to initiate contraceptive practices. Estrogen plus progestin oral contraceptives started at this time have proven to be effective without increased morbidity. Moreover, the frequencies of uterine perforation, expulsions, and pregnancies when intrauterine devices were inserted during the third week postpartum were no greater than when the devices were inserted 3 months or more postpartum. Family planning techniques and follow-up care are further discussed in [Chapters 58](#) and [59](#).

THROMBOEMBOLIC DISEASE. Thromboembolic disease traditionally was considered unique to the puerperium; however, this is no longer true. The frequency of deep-vein thrombosis complicating pregnancy and the puerperium has decreased in recent years, and now more cases are identified during the antepartum period ([Gherman and colleagues, 1999](#)). Deep-vein thrombosis and pulmonary embolism are discussed in [Chapter 46 \(p. 1235\)](#).

PELVIC VENOUS THROMBOSIS. During the puerperium, a thrombus may transiently form in any of the dilated pelvic veins, and possibly does so relatively often. Without associated thrombophlebitis, these thrombi likely do not incite clinical signs or symptoms unless the thrombosis is extensive or pulmonary embolism follows. Unfortunately, these vessels appear to be the source of many of the massive and fatal pulmonary emboli that develop without warning in the puerperium. As discussed in [Chapter 26 \(p. 681\)](#), symptomatic puerperal pelvic thrombosis is most commonly associated with uterine infection.

OBSTETRICAL PARALYSIS. Pressure on branches of the lumbosacral plexus during labor may be manifest by complaints of intense neuralgia or cramplike pains extending down one or both legs as soon as the head begins to descend the pelvis. In some instances, the pain continues after delivery and is accompanied by paralysis of the muscles supplied by the external popliteal nerve. These include the flexors of the ankles and the extensors of the toes, and result in weakened ankle dorsiflexion and footdrop. Less commonly, the femoral, obturator, or sciatic nerves may be involved. In some instances, the gluteal muscles are affected.

Separation of the symphysis pubis or one of the sacroiliac synchondroses during labor may be followed by pain and marked interference with locomotion.

TABLE 17-2. American Academy of Pediatrics Policy Statement on the Infant Benefits of Nursing

Research on Established and Potential Protective Effects of Human Milk and Breast Feeding on Infants

Research in the United States, Canada, Europe and other developed countries, among predominantly middle-class populations, provides strong evidence that human milk feeding decreases the incidence and/or severity of diarrhea, lower respiratory infection, otitis media, bacteremia, bacterial meningitis, botulism, urinary tract infection, and necrotizing enterocolitis. There are a number of studies that show a possible protective effect of human milk feeding against sudden infant death syndrome, insulin-dependent diabetes mellitus, Crohn's disease, ulcerative colitis, lymphoma, allergic diseases, and other chronic digestive diseases. Breastfeeding has also been related to possible enhancement of cognitive development.

SECTION V - ABNORMAL LABOR

18. Dystocia Abnormal Labor and Fetopelvic Disproportion

Dystocia literally means difficult labor and it is characterized by abnormally slow progress of labor. As a generalization, abnormal labor is common whenever there is disproportion between the presenting part of the fetus and the birth canal. It is the consequence of four distinct abnormalities that may exist singly or in combination:

1. Abnormalities of the expulsive forces—either uterine forces insufficiently strong or inappropriately coordinated to efface and dilate the cervix (uterine dysfunction), or inadequate voluntary muscle effort during the second stage of labor.
2. Abnormalities of the maternal bony pelvis—that is, pelvic contraction.
3. Abnormalities of presentation, position, or development of the fetus, which are presented in [Chapter 19](#).
4. Abnormalities of soft tissues of the reproductive tract that form an obstacle to fetal descent, which are presented in [Chapter 35](#).

The Greek antonym for *eutocia*, or normal labor, is *dystocia* to signify abnormal labor or difficult childbirth. Dystocia can result from several distinct abnormalities involving the cervix, uterus, fetus, maternal bony pelvis, or other obstructions in the birth canal. These abnormalities have been mechanistically simplified by the [American College of Obstetricians and Gynecologists \(1995a\)](#) into three categories:

1. Abnormalities of the *powers* (uterine contractility and maternal expulsive effort).
2. Abnormalities involving the *passenger* (the fetus).
3. Abnormalities of the *passage* (the pelvis).

Common clinical findings in women with these labor abnormalities are summarized in [Table 18-1](#).

OVERDIAGNOSIS OF DYSTOCIA

Quite often combinations of abnormalities shown in [Table 18-1](#) interact to produce dysfunctional labor. Today, expressions such as *cephalopelvic disproportion* and *failure to progress* are often used to describe ineffective labors when cesarean delivery is necessary.

The expression *cephalopelvic disproportion* came into use prior to the 20th century to describe obstructed labor due to disparity between the dimensions of the fetal head and maternal pelvis such as to preclude vaginal delivery. This term, however, originated at a time when the main indication for cesarean delivery was overt pelvic contracture due to rickets ([Olah and Neilson, 1994](#)). Such true disproportion is now rare, and most disproportions are due to malposition of the fetal head—asynclitism or extension of the bony diameters of the fetal head, or to ineffective uterine contractions. True cephalopelvic disproportion is a tenuous diagnosis because two thirds or more of women diagnosed as having this disorder and delivered by cesarean subsequently deliver even larger infants vaginally ([Chap. 23, p. 541](#)).

Failure to progress in either spontaneous or stimulated labor has become an increasingly popular description of ineffectual labor. This term is used to include lack of progressive cervical dilatation or lack of fetal descent.

Dystocia is the most common current indication for primary cesarean delivery. [Gifford and colleagues \(2000\)](#) reported that lack of progress in labor was the reason for 68 percent of unplanned cesarean deliveries in cephalic presentations. [Notzon and associates \(1994\)](#) found that 12 percent of American women without prior cesarean were diagnosed as having dystocia requiring abdominal delivery in 1990, and the rate had increased from 7 percent in 1980. A similar change was also reported in the United Kingdom ([Leitch and Walker, 1998](#)). Because many repeat cesareans are done in pregnancies subsequent to primary operations done for dystocia, an estimated 50 to 60 percent of all cesarean births in the United States may be attributable to this diagnosis ([Gifford and colleagues, 2000](#)).

It is generally agreed that dystocia leading to cesarean delivery is overdiagnosed in the United States and elsewhere. Factors leading to increased use of cesarean delivery for dystocia, however, are controversial. Those implicated have included incorrect diagnosis of dystocia, epidural analgesia ([Thorp and colleagues, 1993a](#)), fear of litigation, and even obstetrician convenience ([Fraser and co-workers, 1987](#); [Lieberman and co-workers, 1996](#); [Savage and Francome, 1994](#)).

Variability in the criteria for diagnosis is a major determinant of the increase in cesarean deliveries for dystocia. For example, [Gifford and colleagues \(2000\)](#) found that almost 25 percent of the cesarean deliveries performed annually in the United States for lack of progress were in women with cervical dilatation of only 0 to 3 cm ([Fig. 18-1](#)). According to [Stephenson \(2000\)](#), this practice is contrary to recommendations of the [American College of Obstetricians and Gynecologists \(1995a\)](#) that the cervix be dilated to 4 cm or more before a diagnosis is made. Thus, the diagnosis is often made before the active phase of labor and, therefore, before an adequate trial of labor. Another factor implicated in the increase in the diagnosis of dystocia is insufficient oxytocin stimulation of labor in women with slow labor ([Rouse and colleagues, 1999](#)). [King \(1993\)](#) found that cesareans for dystocia in private patients in the United Kingdom were related to office hours and surgery schedules, whereas the timing of procedures for fetal distress were evenly distributed throughout the day.

NORMAL LABOR

Dystocia is very complex, and although its definition—abnormal progress in labor—seems simple, there is no consensus as to what "abnormal progress" means. Thus, it seems prudent to attempt a better understanding of normal labor in order to determine departure(s) from normal.

The greatest impediment to understanding normal labor is recognizing its start. The strict definition of labor—*uterine contractions that bring about demonstrable effacement and dilatation of the cervix*—does not easily aid the clinician in determining when labor has actually begun, because this diagnosis is confirmed only after the event. Several options may be used to deal with this dilemma. One is to instruct the woman to quantify contractions for some specified period, and then define labor onset as the clock time when painful contractions become regular. This is very subjective and frequently causes considerable frustration for both obstetrician and patient. Indeed, uterine irritability that causes discomfort, but that does not represent true labor, may develop at any time during pregnancy. As shown in [Figure 18-2](#), contractions increase progressively during the third trimester, undoubtedly causing maternal uncertainty as to when labor has commenced. False labor often stops spontaneously, or it may proceed rapidly into effective contractions.

A second option is to define the onset of labor as beginning at the time of admission to the labor unit. At the National Maternity Hospital in Dublin, efforts have been made to codify admission criteria, following which labor management is disciplined ([O'Driscoll and colleagues, 1993](#)). These criteria at term require painful uterine contractions accompanied by any one of the following:

1. Ruptured membranes.
2. Bloody "show."
3. Complete cervical effacement.

In the Irish scheme, the duration of labor is determined based on time elapsed from admission to delivery.

In the United States, admission for labor is frequently based on the extent of dilatation accompanied by painful contractions. When the woman presents with intact membranes, cervical dilatation of 3 to 4 cm or greater is presumed to be a reasonably reliable threshold for diagnosis of labor. In this case, onset of labor commences with the time of admission. This presumptive method of diagnosing true labor obviates many of the uncertainties in diagnosing labor during earlier stages of cervical dilatation.

FIRST STAGE OF LABOR

Assuming that the diagnosis has been confirmed, then what are the expectations for progress of normal labor? Historically, this was usually described by simple elapsed time, with the realization that normal labor could be diagnosed only after the fact. A scientific approach was begun by [Friedman \(1954\)](#), who described a characteristic sigmoid pattern for labor when analyzed statistically and then graphing cervical dilatation against time ([Chap. 11, p. 260](#)). This graphic approach, based on statistical observations, eventually resulted in a change in labor management.

Friedman developed the concept of three functional divisions of labor to describe the physiological objectives of each division ([Fig. 18-3](#)). Although little cervical dilatation occurs during the **preparatory division**, considerable changes take place in the connective tissue components of the cervix. This division of labor may be sensitive to sedation and conduction analgesia. The **dilatational division**, during which time dilatation proceeds at its most rapid rate, is unaffected by sedation or conduction analgesia. The **pelvic division** commences with the deceleration phase of cervical dilatation. The classical mechanisms of labor that involve cardinal fetal movements in the cephalic presentation—engagement, flexion, descent, internal rotation, extension, and external rotation—take place principally during the pelvic division ([Chap. 12, p. 301](#)). In actual practice, however, the onset of the pelvic division is seldom clearly identifiable.

As shown in [Figure 18-4](#), the pattern of cervical dilatation during the preparatory and dilatational divisions of normal labor is a sigmoid curve. Two phases of cervical dilatation are defined: the **latent phase** corresponds to the preparatory division and the **active phase** to the dilatational division. Friedman subdivided the active phase into the *acceleration phase*, the *phase of maximum slope*, and the *deceleration phase*.

LATENT PHASE. The onset of latent labor is defined according to [Friedman \(1972\)](#) as the point at which the mother perceives regular contractions. During this phase, orientation of uterine contractions takes place along with cervical softening and effacement. His minimum criteria for entry into the active phase are cervical dilatation rates of 1.2 cm/hr for nulliparas and 1.5 cm/hr for parous women. **These rates of cervical dilatation do not start at a specific dilatation.** For example, [Peisner and Rosen \(1986\)](#) found that 30 percent of women reached 5 cm dilatation before their dilatation rates conformed to active-phase labor. Conversely, other women dilated more rapidly and had active-phase dilatation rates at 3 cm. Thus, the latent phase commences with maternal perception of regular contractions that is accompanied by progressive, albeit slow, cervical dilatation, and ends at between 3 and 5 cm of dilatation. This threshold may be clinically useful, for it defines cervical dilatation limits beyond which active labor can be expected. [Rosen \(1990\)](#) recommended that all women be classified as "in active labor" when at a maximum of 5 cm dilatation, so that in the absence of progressive change, intervention should be considered.

[Friedman and Sachtleben \(1963\)](#) defined a **prolonged latent phase** to be greater than 20 hours in the nullipara and 14 hours in the parous woman. These are the 95th percentiles. In an earlier report, [Friedman \(1955\)](#) provided data on the duration of latent labor in nulliparas. Its mean duration was 8.6 hours (+2 SD 20.6 hours) and the range was 1 to 44 hours. Thus, the duration of latent phase of 20 hours for nulliparas and 14 hours for parous women represents a statistical maximum.

Factors that affect duration of the latent phase include excessive sedation or conduction analgesia, poor cervical condition (e.g., thick, uneffaced, or undilated), and false labor. Friedman claimed that either rest or oxytocin stimulation were equally efficacious and safe in correcting prolonged latent phases. Rest was preferable because unrecognized false labor was common. With strong sedatives, 85 percent of these women begin active labor. Another 10 percent cease contracting, and thus had false labor. Finally, 5 percent experience recurrence of an abnormal latent phase and require oxytocin stimulation. Amniotomy was discouraged because of the 10 percent incidence of false labor. [Sokol and colleagues \(1977\)](#) reported a 3 to 4 percent incidence of prolonged latent phase, regardless of parity. [Friedman \(1972\)](#) reported that prolongation of the latent phase did not adversely influence fetal or maternal morbidity or mortality, but [Chelmon and co-workers \(1993\)](#) disputed the long-held belief that prolongation of the latent phase is benign.

This concept of a latent phase has great significance in understanding normal human labor because labor is considerably longer when a latent phase is included. To better illustrate this, [Figure 18-5](#) shows eight labor curves from nulliparas where labor was diagnosed beginning with admission, rather than with onset of regular contractions. When defined as such, there is remarkable similarity of individual labor curves. The principal difference between the labor curves, contingent upon when labor is defined to begin, is the presence or absence of a latent period.

ACTIVE LABOR. As shown in [Figure 18-5](#), the progress of labor in nulliparous women has particular significance because these curves all reveal a rapid change in the slope of cervical dilatation between 3 and 4 cm. That is, the "active" phase of labor, in terms of most rapid rates of cervical dilatation, consistently begins when the cervix is 3 to 4 cm dilated. These rather remarkable similarities serve to define active labor and provide useful guideposts in management. **Thus, cervical dilatation of 3 to 4 cm or more, in the presence of uterine contractions, can be taken to reliably represent the threshold for active labor.** Similarly, these curves permit the clinician to ask, given that labor can be reliably diagnosed to have commenced, how much time should elapse in normal active labor?

Turning again to [Friedman \(1955\)](#), the mean duration of active phase labor in nulliparas was 4.9 hours. The standard deviation of 3.4 hours is quite large. Hence, the active phase was reported to have a statistical maximum of 11.7 hours (mean +2 SD) with considerable variation in the duration. Indeed, rates of cervical dilatation ranged from 1.2 to 6.8 cm/hr. Thus, when the rate of dilatation considered normal for active-phase labor in the nullipara is reported to be 1.2 cm/hr, this is the *minimum* normal rate, not the maximum. Multiparas progress somewhat faster in active-phase labor with a minimum normal rate of 1.5 cm/hour ([Friedman, 1972](#)).

Another feature shared by the several labor curves depicted in [Figure 18-5](#) is the remarkable tendency for similar durations of active labor. Specifically, nulliparous women who enter the active phase at 3 to 4 cm can reliably be expected to reach 8 to 10 cm dilatation within 3 to 4 hours. This observation might have potential usefulness. For example, if cervical dilatation reaches 4 cm, the clinician could expect complete dilatation to be achieved in approximately 4 hours if spontaneous labor is "normal." Active labor phase abnormalities, however, are quite common. [Sokol and co-workers \(1977\)](#) reported that 25 percent of nulliparous labors were complicated by active-phase abnormalities while 15 percent of multigravidas developed this problem.

Understanding Friedman's analysis of active-phase labor is somewhat arduous because rates of fetal descent are considered in addition to cervical dilatation rates, and both of these are occurring concomitantly ([Fig. 18-3](#)). Descent begins in the later stage of active dilatation, commencing at about 7 to 8 cm in nulliparas and becoming most rapid after 8 cm. [Friedman \(1972\)](#) subdivided active-phase problems into **protraction** and **arrest** disorders. He defined protraction as a *slow rate* of cervical dilatation or descent, which for nulliparas was less than 1.2 cm dilatation per hour or less than 1 cm descent per hour. For multiparas, protraction was defined as less than 1.5 cm dilatation per hour or less than 2 cm descent per hour. He defined arrest as a *complete cessation* of dilatation or descent. **Arrest of dilatation** was defined as 2 hours with no cervical change, and **arrest of descent** as 1 hour without fetal descent. The prognosis for protraction and arrest disorders differed considerably, and he found that about 30 percent of women with protraction disorders had cephalopelvic disproportion, whereas this was diagnosed in 45 percent of women in whom an arrest disorder developed. Abnormal labor patterns, diagnostic criteria, and methods of treatment according to [Cohen and Friedman \(1983\)](#) are summarized in [Table 18-2](#).

Other associations or factors contributing to both protraction and arrest disorders were excessive sedation, conduction analgesia, and fetal malposition such as persistent occiput posterior. In both protraction and arrest disorders, Friedman recommended fetopelvic examination to diagnose cephalopelvic disproportion. Recommended therapy for protraction disorders was expectant management, whereas oxytocin was advised for arrest disorders in the absence of cephalopelvic disproportion. The latter is not defined precisely in Friedman's 1955 report, other than to note that 8 of 39 diagnosed cases of disproportion had x-ray pelvimetry evidence of pelvic incapacity, and the remaining 31 women were considered to have "relative disproportion for a variety of reasons such as persistent occiput posterior." Remarkably, of the 500 women studied, only 2 percent had cesarean deliveries. Put another way, the great majority of active-phase disorders did not result in cesarean delivery. This fact must be kept in mind when considering the significance of Friedman's various labor abnormalities in the context of the current implication that cephalopelvic disproportion mandates cesarean delivery.

[Hendricks and co-workers \(1970\)](#) challenged Friedman's conclusions about the course of normal human labor. Their principal differences included:

1. Absence of a latent phase.
2. No deceleration phase.
3. Brevity of labor.
4. Dilatation at similar rates for nulliparas and multiparas after 4 cm.

They disputed the concept of a latent phase because they observed that cervical dilatation and effacement occurred slowly during the 4 weeks preceding labor. According to them, the "latent phase" actually occurred over several weeks. [Hendricks and colleagues \(1970\)](#) did observe that labor was relatively rapid; specifically, the average time from admission to complete dilatation was 4.8 hours for nulliparas and 3.2 hours for multiparas.

SECOND STAGE OF LABOR

This stage begins when cervical dilatation is complete and ends with fetal expulsion. Its median duration is 50 minutes for nulliparas and 20 minutes for multiparas, but it is also highly variable. In a woman of higher parity with a previously dilated vagina and perineum, two or three expulsive efforts after full cervical dilatation may suffice to complete delivery. Conversely, in a woman with a contracted pelvis or a large fetus, or with impaired expulsive efforts from conduction analgesia or intense sedation, the second stage may become abnormally long. [Kilpatrick and Laros \(1989\)](#) reported that average second-stage labor, prior to spontaneous fetal expulsion, was lengthened about 25 minutes by regional analgesia. As previously noted, the pelvic or fetal descent division of labor largely occurs following complete dilatation. Moreover, the second stage incorporates many of the cardinal movements necessary for the fetus to negotiate the birth canal ([Chap. 12, p. 301](#)). Given the mechanical requirements of these fetal movements, it is logical for disproportion of the fetus and pelvis to become apparent during the second stage. Indeed, in earlier times, cephalopelvic disproportion was diagnosed only after complete cervical dilatation had occurred and attempts to deliver the fetus with forceps had failed.

Until very recently, there have been unquestioned second-stage rules that limited its duration. The second stage in nulliparas was limited to 2 hours and extended to 3 hours when regional analgesia was used. For multiparas, 1 hour was the limit, extended to 2 hours with regional analgesia. At Parkland Hospital during 1999, only 6 percent of second-stage labors in nulliparas at term exceeded 2 hours.

The origin of the second-stage rule, which in essence limits its duration to 2 hours, cannot be assigned to any one individual ([Hellman and Prystowsky, 1952](#)). This rule seems to have been established fairly definitely in American obstetrics, however, by the turn of the century. The first edition of *Williams Obstetrics* in 1903 states that forceps are usually indicated if the second stage lasts more than 2 hours. This rule appears to have been derived from concerns about fetal health, and indeed, the concept of prophylactic forceps delivery to shorten the second stage was popular earlier in this century ([Chap. 21, p. 490](#)). This practice often led to the performance of difficult forceps operations, although the question was raised whether prolongation of the second stage until such a time as an easy forceps delivery might be accomplished would be of some advantage. This more conservative attitude is the contemporary practice.

[Cohen \(1977\)](#) investigated the fetal effects of second-stage labor length at Beth Israel Hospital during more modern times. He included 4403 term nulliparas in whom electronic fetal heart rate monitoring was performed. Infant mortality was not increased in women whose second-stage labor exceeded 2 hours. Epidural analgesia was used commonly, and this likely accounts for the large number of pregnancies with a prolonged second stage. These data influenced permitting an additional hour for the second stage when regional analgesia was used. This report also influenced the [American College of Obstetricians and Gynecologists \(1995a\)](#) to qualify the previous dictums about the duration of second-stage labor.

[Menticoglou and colleagues \(1995b\)](#) challenged the prevailing dictums on the duration of the second stage based on their experiences in Winnipeg. These dictums came under scrutiny at their hospitals because of grave neonatal injuries associated with forceps rotations to shorten second-stage labor ([Menticoglou and colleagues, 1995a](#)). As a result, they have allowed longer second stages in the hope that fewer vaginal operative deliveries would be necessary. Between 1988 and 1992, the second stage of labor exceeded 2 hours in a fourth of 6041 nulliparas at term. Labor epidural analgesia was used in 55 percent. As shown in [Table 18-3](#), the length of the second stage, even in those lasting up to 6 hours or more, was not related to infant outcome. These good results were attributed to careful use of electronic monitoring and scalp pH measurements. They concluded that there is no compelling reason to intervene with a possibly difficult forceps or vacuum extraction because a certain number of hours has elapsed. They offered, however, an important caveat; after 3 hours in the second stage, delivery by cesarean or other operative method increased progressively such that by 5 hours the prospects for spontaneous delivery in the subsequent hour are only 10 to 15 percent.

DURATION OF LABOR

Our understanding of the normal duration of human labor may be clouded by the many clinical variables that affect conduct of labor in modern obstetrical units, and also by the complexities of the graphicostatistical labor curves discussed in the preceding sections. Specifically, how long is normal spontaneous labor and delivery?

[Kilpatrick and Laros \(1989\)](#) reported that the mean length of first- and second-stage labor was approximately 9 hours in nulliparous women without regional analgesia, and that the 95th percentile upper limit was 18.5 hours. Corresponding times for multiparous women were a mean of about 6 hours with a 95th percentile of 13.5 hours. They defined labor onset as the time when the woman recalled regular, painful contractions every 3 to 5 minutes, and leading to cervical change. Cervical dilatation at admission is not stated.

Spontaneous labor was analyzed in almost 25,000 women delivered at term at Parkland Hospital in the early 1990s. Almost 80 percent of women were admitted with dilatation of 5 cm or less. Labor and delivery times did not follow a normal distribution, indicating that use of parametric statistics (means) would falsely lengthen perceptions of labor duration. Parity (nulliparous versus multiparous) and cervical dilatation at admission were significant determinants of the length of spontaneous labor. The median time from admission to spontaneous delivery was 3.5 hours, and 95 percent of all women delivered within 10.1 hours. These results suggest that normal human labor is relatively short.

SUMMARY OF NORMAL LABOR

Labor is characterized by brevity, considerable biological variation, and less complexity than anticipated based on contemporary graphic statistical interpretations. Active labor can be reliably diagnosed when cervical dilatation is 3 cm or more in the presence of uterine contractions. Once this cervical dilatation threshold is reached, normal progress to delivery can be expected, depending on parity, in the ensuing 4 to 6 hours or so. Anticipated progress during a 1- to 2-hour second stage is governed by rules intended to ensure fetal safety. Finally, most women in spontaneous labor, regardless of parity and if left unaided, will deliver within approximately 10 hours after admission for spontaneous labor. **When time breaches in normal labor boundaries are the only pregnancy complications, interventions other than cesarean delivery must be considered before resorting to this method of delivery for failure to progress.** Insufficient uterine activity is a common and correctable cause of abnormal labor progress.

INADEQUATE LABOR

According to [Williams \(1903\)](#) in the first edition of this text, and still true today (brackets cite corresponding chapter of the 21st edition):

Dystocia or difficult labour may be due to various aetiological factors, and is most commonly encountered in the following groups of cases: (1) those in which the expulsive forces [Chap. 18, uterine dysfunction] are subnormal and are not sufficiently strong enough to overcome the natural resistance offered to the birth of the child by the bony canal and maternal soft parts; (2) those in which, although the expulsive forces may be of normal strength, abnormalities in the structure or character of the birth canal offer an insuperable mechanical obstacle [Chap. 18, pelvic contracture] to the descent of the presenting part; (3) those in which the foetus, on account of faulty presentation [[Chap. 19](#)] or excessive development [Chap. 18, excessive fetal size] cannot be extruded by the *vis a tergo* (sic, a force operating from behind or a propulsive force).

[Figure 18-6](#), from the first edition of *Williams Obstetrics* (1903), is useful for conceptualizing the mechanical process of labor and the potential obstacles to successful pelvic passage of the fetal passenger. The cervix and lower uterus are shown at the end of pregnancy as well as at the end of labor. At the end of pregnancy, the fetal head, to traverse the birth canal, must encounter a relatively thicker lower uterine segment and undilated cervix, while the uterine fundus muscle is less developed and presumably therefore less powerful in its propulsive effectiveness. At this stage, uterine muscle contractions, cervical resistance, and the forward pressure exerted by the leading fetal head are factors influencing the progress of the first stage of labor ([Chap. 13, p. 313](#)).

After complete cervical dilatation ([Fig. 18-6B](#)), however, the mechanical relationship between fetal head size and position and pelvic capacity, or fetopelvic proportion, becomes clearer as the passenger (fetus) descends the pelvic passage unimpeded by the cervical obstacle. The uterine fundus muscle is much thicker, and thus more powerful in its propulsive effectiveness, which is undoubtedly enhanced by complete cervical dilatation. In regard to inadequate progress of labor, abnormalities in uterine function, viz., uterine dysfunction, likely predominate before complete cervical dilatation whereas abnormalities in fetopelvic proportions, viz., disproportion, likely become more apparent once the second stage is reached.

Possible explanations for malfunction of uterine muscle include overdistention due to excessive fetal size and/or uterine fatigue when labor is obstructed by inadequate pelvic capacity, excessive fetal size, or both. Thus, ineffective labor is generally accepted as a possible warning sign of fetopelvic disproportion. Such a simplistic understanding of labor abnormalities, divided into pure *uterine dysfunction* and *fetopelvic disproportion*, is incorrect because these two abnormalities are closely interlinked. For example, fetopelvic disproportion is most commonly manifest clinically as uterine dysfunction; however, most often, uterine dysfunction can be corrected with oxytocin and vaginal delivery can be safely accomplished ([Chap. 20, p. 474](#)). Indeed, according to the [American College of Obstetricians and Gynecologists \(1995a\)](#), the bony pelvis is not the factor, with rare exceptions, that limits vaginal delivery. Such a statement was not possible in the early decades of

the 20th century when *rickets* was prevalent and deformed pelves were common—up to 15 percent of women were diagnosed to have *rachitic* pelves at the Johns Hopkins Hospital in 1924 ([Williams, 1936](#)).

Given the complex interrelationship between uterine dysfunction and fetopelvic disproportion, and in the absence of objective means of precisely distinguishing these two causes of labor failure, clinicians must rely on a *trial of labor* to determine if labor can be successful in effecting vaginal delivery. Defining the adequacy of a trial of labor is a priority, in our opinion, in moderating the primary cesarean delivery rate for dystocia in the United States.

UTERINE DYSFUNCTION

Propulsion and expulsion of the fetus is brought about by contractions of the uterus, reinforced during the second stage by voluntary or involuntary muscular action of the abdominal wall—"pushing." Either of these factors may be lacking in intensity and result in delayed or interrupted labor. The frequency and intensity of uterine contractions are informative. Uterine dysfunction, characterized by infrequent low-intensity contractions, is common with significant disproportion because the uterus does not often self-destruct when faced with mechanical obstruction. This cervical response to labor has great prognostic significance. In general, orderly spontaneous progression to full dilatation indicates that vaginal delivery most likely will be successful.

As described earlier, latent phase (*prodromal*) labor is usually several hours duration, during which time the cervix undergoes softening and effacement but only slight dilatation. This phase is characterized by uterine contractions of mild intensity, short duration, and variable frequency. The active phase, or phase of rapid dilatation, follows. During this time, in what has long been called simply labor, the cervix dilates more rapidly and there is descent of the presenting part through the birth canal ([Fig. 18-3](#)).

Descent normally begins well before the cervix reaches full dilatation and progresses until the presenting part reaches the perineum. **This pattern is highly variable.** The presenting part in nulliparous women may be at the +1 or even +2 station before the onset of labor, whereas in parous women, descent of the presenting part may not begin until the cervix nearly is dilated fully.

Uterine dysfunction in any phase of cervical dilatation is characterized by lack of progress, for one of the prime characteristics of normal labor is its progression. The diagnosis of uterine dysfunction in the latent phase is difficult and sometimes can be made only in retrospect. One of the most common errors is to treat women for uterine dysfunction who are not yet in active labor.

There have been three significant advances in the treatment of uterine dysfunction:

1. Realization that undue prolongation of labor may contribute to perinatal morbidity and mortality.
2. Use of dilute intravenous infusion of oxytocin in the treatment of certain types of uterine dysfunction.
3. More frequent use of cesarean delivery rather than difficult midforceps delivery when oxytocin fails or its use is inappropriate.

TYPES OF UTERINE DYSFUNCTION. [Reynolds and co-workers \(1948\)](#) emphasized that uterine contractions of normal labor are characterized by a gradient of myometrial activity, being greatest and lasting longest at the fundus (fundal dominance) and diminishing toward the cervix. [Caldeyro-Barcia and colleagues \(1950\)](#) from Montevideo inserted small balloons into the myometrium at various levels ([Chap. 14, p. 355](#)). With the balloons attached to strain-gauge transducers, they reported that in addition to a gradient of activity, there was a time differential in the onset of the contractions in the fundus, midzone, and lower uterine segments. [Larks \(1960\)](#) described the stimulus as starting in one cornu and then several milliseconds later in the other, the excitation waves then joining and sweeping over the fundus and down the uterus.

The Montevideo group also ascertained that the lower limit of contraction pressure required to dilate the cervix is 15 mm Hg. This figure is in agreement with the findings of [Hendricks and co-workers \(1959\)](#), who reported that normal spontaneous contractions often exert pressures of about 60 mm Hg. From these observations, it is possible to define two types of uterine dysfunction. In the more common **hypotonic uterine dysfunction**, there is no basal hypertonus and uterine contractions have a normal gradient pattern (synchronous), but the slight rise in pressure during a contraction is insufficient to dilate the cervix. In the other, **hypertonic uterine dysfunction** or **incoordinate uterine dysfunction**, either basal tone is elevated appreciably or the pressure gradient is distorted, perhaps by contraction of the midsegment of the uterus with more force than the fundus or by complete asynchronism of the impulses originating in each cornu, or a combination of these two.

REPORTED CAUSES OF UTERINE DYSFUNCTION. A variety of labor interventions have been implicated as causes of uterine dysfunction.

EPIDURAL ANALGESIA. It is important to emphasize that epidural analgesia can slow labor ([Sharma and Leveno, 2000](#)). For example, and as shown in [Table 18-4](#), epidural analgesia has been associated with lengthening of both first- and second-stage labor as well as slowing of the rate of fetal descent.

CHORIOAMNIONITIS. Because of the association of prolonged labor with maternal intrapartum infection, some clinicians have suggested that infection itself plays a role in the development of abnormal uterine activity. [Satin and co-workers \(1992\)](#) studied the effects of chorioamnionitis on labor stimulation with oxytocin in 266 pregnancies. Chorioamnionitis diagnosed late in labor was found to be a marker of cesarean delivery for dystocia whereas this was not observed in women diagnosed as having chorioamnionitis early in labor. Specifically, 40 percent of women developing chorioamnionitis after requiring oxytocin for dysfunctional labor later required cesarean delivery for dystocia. It is likely that uterine infection in this clinical setting is a consequence of dysfunctional and therefore prolonged labor rather than a cause of dystocia.

MATERNAL POSITION DURING LABOR. In the first edition of this textbook, [Williams \(1903\)](#) stated, "During the first stage of labour the patient usually prefers to move about her room, and frequently is more comfortable when occupying a sitting position. During this period, therefore, she should not be compelled to take to her bed unless she feels so inclined." Those early observations gave way to the opinion that recumbency should be the norm. This opinion, however, has been challenged on the grounds that recumbency impaired labor. Conversely, walking during labor has also been reported to shorten labor, decrease the need for augmentation with oxytocin, decrease the need for analgesia, and lower the frequency of instrumental vaginal delivery ([Flynn and co-authors, 1978](#); [Read and colleagues, 1981](#)).

According to [Miller \(1983\)](#), uterine contractions occur more frequently but with less intensity with the mother in the supine position compared with lying on her side. Conversely, contraction frequency and intensity have been reported to increase with sitting or standing. [Lupe and Gross \(1986\)](#) concluded, however, that there is no conclusive evidence that upright maternal posture or ambulation improves labor. Without perturbations, women preferred to lie on their side or sit in bed. Few chose to walk, fewer to squat, and none wanted the knee-chest position. They tended to assume fetal positions in later labor. Most women enthusiastic about ambulating return to bed when active labor begins ([Carlson and associates, 1986](#); [Williams and co-workers, 1980](#)).

[Bloom and colleagues \(1998\)](#) conducted a randomized trial to study the effects of walking during first-stage labor. In 1067 women with uncomplicated term pregnancies delivered at Parkland Hospital, they reported that ambulation neither improved nor delayed labor in nulliparous or parous women ([Table 18-5](#)). Walking during labor did not reduce the need for analgesia, nor was it harmful to the fetus-infant. Since these results provided no evidence for or against walking during labor, we now give women without complications the option of electing either recumbency or supervised ambulation during labor.

BIRTHING POSITION IN SECOND-STAGE LABOR. Considerable interest has been shown in alternative second-stage labor birth positions that might affect labor. [Gupta and co-workers \(1991\)](#) reported that several randomized controlled trials, with and without the use of specific birthing aids, have produced conflicting results and are confounded by observer bias. One reported advantage from avoiding the traditional lithotomy position is an increase in the dimensions of the pelvic outlet. Specifically, [Russell \(1969\)](#) described a 20 to 30 percent increase in the area of the pelvic outlet with squatting compared with the supine position. [Gupta and co-workers \(1991\)](#) compared the usual Western delivery position—recumbent with the head and shoulders up 30 degrees—with the squatting position and found no significant change in the dimensions of either the pelvic inlet or outlet. [Crowley and associates \(1991\)](#) randomized 634 women to deliver in an obstetrical birth chair and compared these with 596 women delivered in bed. There were no advantages with use of the birthing chair, but hemorrhage was increased in this group.

[De Jong and co-workers \(1997\)](#), in a randomized trial of 517 South African women, found no increase in hemorrhage with the sitting position. Obstetrical outcomes were not improved by enforcing the upright position for second-stage labor. The main benefits reported were less maternal pain and enhanced maternal satisfaction with the birthing experience. [Babayer and co-authors \(1998\)](#) cautioned that prolonged sitting or squatting during the second stage may cause peroneal neuropathy.

IMMERSION IN WATER. This has been advocated as a means of relaxation that may contribute to more efficient labor ([Odent, 1983](#)). [Schorn and colleagues \(1993\)](#)

randomized 96 women at term to immersion in a hot tub with air jets or to their prevailing labor management. The women were permitted to stay in the tub as long as they desired, and most stayed 30 to 45 minutes. Water immersion did not alter the rate of cervical dilation, length of labor, route of delivery, or analgesia use.

[Robertson and associates \(1998\)](#) reported that immersion was not associated with chorioamnionitis or endometritis. [Kwee and co-workers \(2000\)](#) studied the effects of immersion in 20 women and reported that maternal blood pressure decreased while fetal heart rate was unaffected.

FETOPELVIC DISPROPORTION

This arises from either diminished pelvic size, excessive fetal size, or more usually, a combination of both.

PELVIC CAPACITY. Any contraction of the pelvic diameters that diminishes the capacity of the pelvis can create dystocia during labor. There may be contractions of the pelvic inlet, the midpelvis, the pelvic outlet, or a generally contracted pelvis caused by combinations of these.

CONTRACTED PELVIC INLET. The pelvic inlet is usually considered to be contracted if its shortest anteroposterior diameter is less than 10.0 cm or if the greatest transverse diameter is less than 12.0 cm. The anteroposterior diameter of the pelvic inlet is commonly approximated by manually measuring the diagonal conjugate, which is about 1.5 cm greater. Therefore, inlet contraction is usually defined as a diagonal conjugate of less than 11.5 cm. The errors inherent in the use of this clinical measurement are discussed in [Chapter 3 \(p. 58\)](#).

Using clinical and, at times, imaging pelvimetry, it is important to identify the shortest anteroposterior diameter through which the fetal head must pass. Occasionally, the body of the first sacral vertebra is displaced forward so that the shortest distance may actually be between this false, or abnormal, sacral promontory and the symphysis pubis.

Prior to labor, the fetal biparietal diameter has been shown to average from 9.5 to as much as 9.8 cm. Therefore, it might prove difficult or even impossible for some fetuses to pass through an inlet with an anteroposterior diameter of less than 10 cm. [Mengert \(1948\)](#) and [Kaltreider \(1952\)](#), employing x-ray pelvimetry, demonstrated that the incidence of difficult deliveries is increased to a similar degree when either the anteroposterior diameter of the inlet is less than 10 cm or the transverse diameter is less than 12 cm. When both diameters are contracted, dystocia is much greater than when only one is contracted. The configuration of the pelvic inlet is also an important determinant of the adequacy of any pelvis, independent of actual measurements of these diameters and of calculated "areas" (see [Fig. 3-28](#), and Caldwell-Moloy Classification, [Chap. 3, p. 57](#)).

A small woman is likely to have a small pelvis, but she is also likely to have a small infant. [Thoms \(1937\)](#) studied 362 nulliparas and found the mean birthweight of their offspring was significantly lower (280 g) in women with small pelvises than in those with medium or large pelvises. In veterinary obstetrics, it has frequently been observed that in most species maternal size rather than paternal size is the important determinant of fetal size.

Normally, cervical dilatation is facilitated by hydrostatic action of the unruptured membranes or, after their rupture, by direct application of the presenting part against the cervix. In contracted pelvises, however, when the head is arrested in the pelvic inlet, the entire force exerted by the uterus acts directly upon the portion of membranes that overlie the dilating cervix. Consequently, early spontaneous rupture of the membranes is more likely to result.

After membrane rupture, the absence of pressure by the head against the cervix and lower uterine segment predisposes to less effective contractions. Hence, further dilatation may proceed very slowly or not at all. [Cibils and Hendricks \(1965\)](#) reported that the mechanical adaptation of the fetal passenger to the bony passage plays an important part in determining the efficiency of contractions. The better the adaptation, the more efficient are the contractions. Because adaptation is poor in the presence of a contracted pelvis, prolongation of labor often results. With degrees of pelvic contractions incompatible with vaginal delivery, the cervix seldom dilates satisfactorily. Thus, cervical response to labor provides a prognostic view of the outcome of labor in women with inlet contraction.

A contracted inlet plays an important part in the production of abnormal presentations. In normal nulliparas, the presenting part at term commonly descends into the pelvic cavity before the onset of labor. When the inlet is contracted considerably, however, descent usually does not take place until after the onset of labor, if at all. Cephalic presentations still predominate, but because the head floats freely over the pelvic inlet or rests more laterally in one of the iliac fossae, very slight influences may cause the fetus to assume other presentations. **In women with contracted pelvises, face and shoulder presentations are encountered three times more frequently, and cord prolapse occurs four to six times more frequently.** [Critchlow and colleagues \(1994\)](#) have quantified the magnitude of risk for cord prolapse in women with cephalopelvic disproportion.

CONTRACTED MIDPELVIS. This is more common than inlet contraction. It is frequently a cause of transverse arrest of the fetal head, which can potentially lead to difficult midforceps operation or to cesarean delivery.

The obstetrical plane of the midpelvis extends from the inferior margin of the symphysis pubis, through the ischial spines, and touches the sacrum near the junction of the fourth and fifth vertebrae. A transverse line theoretically connecting the ischial spines divides the midpelvis into anterior and posterior portions. The former is bounded anteriorly by the lower border of the symphysis pubis and laterally by the ischiopubic rami. The posterior portion is bounded dorsally by the sacrum and laterally by the sacrospinous ligaments, forming the lower limits of the sacrosciatic notch.

Average midpelvis measurements are as follows: transverse (interspinous), 10.5 cm; anteroposterior (from the lower border of the symphysis pubis to the junction of the fourth and fifth sacral vertebrae), 11.5 cm; and posterior sagittal (from the midpoint of the interspinous line to the same point on the sacrum), 5 cm. Although the definition of midpelvic contractions has not been established with the same precision possible for inlet contractions, the midpelvis is likely contracted when the sum of the interischial spinous and posterior sagittal diameters of the midpelvis (normal, 10.5 plus 5 cm, or 15.5 cm) falls to 13.5 cm or below. This concept has been emphasized by [Chen and Huang \(1982\)](#) in evaluating possible midpelvic contraction. There is reason to suspect midpelvic contraction whenever the interischial spinous diameter is less than 10 cm. When it is smaller than 8 cm, the midpelvis is contracted.

The preceding definitions of midpelvic contraction do not imply that dystocia always develops in such a pelvis, but simply that it more likely will develop. Development of dystocia also depends upon the size and shape of the forepelvis and the size of the fetal head, as well as on the overall degree of midpelvic contraction.

Although there is no precise manual method of measuring midpelvic dimensions, a suggestion of contraction can sometimes be inferred if the spines are prominent, the pelvic sidewalls converge, or the sacrosciatic notch is narrow. Moreover, [Eller and Mengert \(1947\)](#) pointed out that the relationship between the intertuberos and interspinous diameters of the ischium is sufficiently constant that narrowing of the interspinous diameter can be anticipated when the intertuberos diameter is narrow. A normal intertuberos diameter, however, does not always exclude a narrow interspinous diameter.

CONTRACTED PELVIC OUTLET. This is usually defined as diminution of the interischial tuberos diameter to 8 cm or less. The pelvic outlet may be roughly likened to two triangles with the interischial tuberos diameter constituting the base of both. The sides of the anterior triangle are the pubic rami, and its apex the inferior posterior surface of the symphysis pubis. The posterior triangle has no bony sides but is limited at its apex by the tip of the last sacral vertebra (not the tip of the coccyx). [Floberg and associates \(1987\)](#) reported that outlet contractions were found in almost 1 percent of over 1400 unselected term nulliparas.

Diminution in the intertuberos diameter with consequent narrowing of the anterior triangle must inevitably force the fetal head posteriorly ([Fig. 18-7](#)). Whether delivery can take place therefore partly depends on the size of the posterior triangle, or more specifically on the interischial tuberos diameter and the posterior sagittal diameter of the outlet. A contracted outlet may cause dystocia not so much by itself as through the often associated midpelvic contraction. *Outlet contraction without concomitant midplane contraction is rare.*

Even when the disproportion between the fetal head and the pelvic outlet is not sufficiently great to give rise to severe dystocia, it may play an important part in the production of perineal tears. With increasing narrowing of the pubic arch, the occiput cannot emerge directly beneath the symphysis pubis but is forced increasingly farther down upon the ischiopubic rami. In extreme cases, the head must rotate around a line joining the ischial tuberosities. The perineum, consequently, must become increasingly distended and thus exposed to greater danger of disruption.

PELVIC FRACTURES AND RARE CONTRACTURES. [Speer and Peltier \(1972\)](#) reviewed experiences with pelvic fractures and pregnancy. Trauma from automobile collisions was the most common cause of pelvic fractures. With bilateral fractures of the pubic rami, compromise of birth canal capacity by callus formation or malunion was very common. A history of pelvic fracture warrants careful review of previous x-rays and possibly computed tomographic pelvimetry later in pregnancy. Descriptions and illustrations of rare pelvic contractions are discussed in the 10th through 17th editions of *Williams Obstetrics*.

ESTIMATION OF PELVIC CAPACITY. The techniques for clinical evaluation using digital examination of the bony pelvis during labor are described in detail in

[Chapter 3 \(p. 58\)](#). Briefly, the examiner attempts to judge the anteroposterior diameter of the inlet (diagonal conjugate), the interspinous diameter of the midpelvis, and the intertuberous distances of the pelvic outlet. A narrow pelvic arch, less than 90 degrees, can signify a narrow pelvis. An unengaged fetal head can indicate either excessive fetal head size or reduced pelvic inlet capacity.

X-RAY PELVIMETRY. The prognosis for successful vaginal delivery in any given pregnancy cannot be established on the basis of x-ray pelvimetry alone, because the pelvic capacity is but one of several factors that determine the outcome ([Mengert, 1948](#)). Thus, x-ray pelvimetry is considered to be of limited value in the management of labor with cephalic presentations ([American College of Obstetricians and Gynecologists, 1995b](#)). If vaginal delivery is anticipated for a fetus presenting as a breech, however, x-ray pelvimetry still is used in many medical centers ([Chap. 22, p. 512](#)).

COMPUTED TOMOGRAPHIC SCANNING. An advantage of computed tomographic pelvimetry such as that shown in [Figure 18-8](#) is a reduction in radiation exposure. The accuracy is greater than that of conventional x-ray pelvimetry, it is easier to perform, and costs are comparable. With either method, x-ray exposure is miniscule ([Chap. 42, p. 1147](#)). With conventional x-ray pelvimetry, the mean gonadal exposure is estimated to be 885 mrad by the Committee on Radiological Hazards to Patients ([Osborn, 1963](#)). Depending upon the machine and technique employed, fetal doses with computed tomography may range from 250 to 1500 mrad ([Moore and Shearer, 1989](#)).

MAGNETIC RESONANCE IMAGING (MRI). The advantages of [MRI](#)¹ include the lack of ionizing radiation, accurate pelvic measurements, complete fetal imaging, as well as the potential for evaluating reasons for soft tissue dystocia ([McCarthy, 1986](#); [Stark and co-workers, 1985](#)). Currently its use is limited because of expense, time involved for adequate imaging studies, and equipment availability.

[Sporri and co-workers \(1997\)](#) used magnetic resonance images postpartum to measure capacity at each level of the pelvis and ultrasound intrapartum to measure fetal head dimensions. In this study, "cephalic pelvic disproportion" was defined as arrest of labor for more than 4 hours in the presence of normal uterine contractions. "Failure to progress" was diagnosed when there was no labor progress and uterine activity was hypotonic. A fetal head volume exceeding measured pelvic capacity was a frequent finding in women with cephalopelvic disproportion, but not those with failure to progress. Clearly, use of [MRI](#)¹ to measure pelvic capacity is investigational.

EXCESSIVE FETAL SIZE. It is interesting to review statements in previous editions of *Williams Obstetrics* concerning excessive fetal size as a cause of dystocia:

1st Edition (1903): Provided the pelvis is not contracted, it is very exceptional for a normally formed child, weighing less than 5000 g (10 ¹/₂ lbs) to give rise to dystocia by its mere size.

7th Edition (1936): Provided the pelvis is not contracted, it is very exceptional for a normally formed child, weighing less than 4500 g (10 lbs) to give rise to dystocia by its mere size.

13th Edition (1966): Provided the pelvis is not contracted, it is unusual for a normally formed child weighing less than 4500 g (10 lbs) to give rise to dystocia on the basis of its size alone.

The theme of these statements, although the fetal weight threshold decreased from 5000 g to 4500 g, has been that fetal size seldom is a suitable explanation for failed labor. The greatest obstetrical concern expressed in these earlier editions was not that the fetal head might fail to traverse the pelvic passage, but, rather, that the shoulders might not fit through the pelvic inlet or outlet ([Chap. 19, p. 459](#)). Remarkably, this is also the theme of contemporary statements about excessive fetal development ([Chap. 29, p. 757](#)). For example, the [American College of Obstetricians and Gynecologists \(1997a\)](#) has concluded that planned cesarean delivery, in an attempt to forego shoulder dystocia, is only a reasonable strategy for diabetic women with estimated fetal weights exceeding 4250 to 4500 g. Selection of a fetal size threshold to predict fetopelvic disproportion and, therefore, prevent obstructed labor, is not possible because most cases of disproportion occur in fetuses whose weight is well within the range of the general obstetrical population. As shown in [Figure 18-9](#), two thirds of infants requiring cesarean delivery at Parkland Hospital after an attempt at forceps delivery failed, weighed less than 3700 g (8 lb 2 oz). Thus, fetopelvic disproportion usually is not associated with excessive fetal size.

ESTIMATION OF FETAL HEAD SIZE. Not only is there no definable fetal size threshold for predicting cephalopelvic disproportion, the methods for estimation of fetal head are also imprecise. Impression of the fetal head into the pelvis, as described by [Muller \(1880\)](#) and [Hillis \(1930\)](#), may provide useful information. In an occiput presentation, the brow and the suboccipital region are grasped through the abdominal wall with the fingers and firm pressure is directed downward in the axis of the inlet. Fundal pressure by an assistant usually is helpful. The effect of the forces on the descent of the head can be evaluated by concomitant vaginal examination. If no disproportion exists, the head readily enters the pelvis, and vaginal delivery can be predicted. Inability to push the head into the pelvis, however, does not necessarily indicate that vaginal delivery is impossible. A clear demonstration of a flexed fetal head that overrides the symphysis pubis, however, is presumptive evidence of disproportion. [Thorp and colleagues \(1993b\)](#) performed a prospective evaluation of the *Mueller-Hillis maneuver* and concluded that there was no relation between dystocia and failure of descent of the head.

Measurements of fetal head diameters using plain radiographic techniques are not used because of parallax distortions. The biparietal diameter and head circumference can be measured by ultrasonic means. There have been attempts to use ultrasonic measurements of the fetus in the management of dystocia. [Thurnau and colleagues \(1991\)](#) used the fetal-pelvic index to identify labor complications. Unfortunately, the sensitivity of such measurements to predict of cephalopelvic disproportion is poor ([Ferguson and associates, 1998](#)). We are of the view that there is no currently satisfactory method for accurate prediction of fetopelvic disproportion due to excessive fetal head size.

RUPTURED MEMBRANES WITHOUT LABOR

Membrane rupture without spontaneous uterine contractions occurs in about 8 percent of term pregnancies. Until recently, management generally included stimulation of contractions when labor did not begin after 6 to 12 hours. This intervention evolved about 40 years ago because of maternal and fetal complications due to amnionitis ([Calkins, 1952](#)). Such routine intervention was the accepted practice until challenged by [Kappy and co-workers \(1979\)](#), who reported excessive cesarean delivery in term pregnancies with ruptured membranes managed with labor stimulation compared with those managed by expectant observation. Further interest in observation was stimulated by a randomized trial reported by [Duff and colleagues \(1984\)](#). In this study, 134 women with ruptured membranes without labor at term were randomly treated with observation or oxytocin. The cesarean rate was significantly lower in those women managed by observation.

[Hannah and co-workers \(1996\)](#) and [Peleg and associates \(1999\)](#) performed an international randomized investigation of 5042 pregnancies with ruptured membranes at term. They measured the effects of induction versus expectant management and also compared induction with intravenous oxytocin to prostaglandin E₂ gel. There were approximately 1200 pregnancies in each of the four study arms. They concluded that labor induction with intravenous oxytocin was the preferred management. This was based on significantly fewer intrapartum and postpartum infections in women whose labor was induced. There were no significant differences in cesarean delivery rates. Subsequent analysis by [Hannah and colleagues \(2000\)](#) indicated increased adverse outcomes when expectant management at home was compared with in-hospital observation. Similar conclusions were reached by [Mozurkewich and Wolf \(1997\)](#) after meta-analysis of reported trials on management of ruptured membrane at term.

In another analysis by [Seaward and colleagues \(1998\)](#) of the international randomized trial described earlier, clinical chorioamnionitis and maternal colonization with group B streptococcus were the most important predictors of subsequent neonatal infection. At Parkland Hospital, labor is stimulated with oxytocin when ruptured membranes are diagnosed at term.

DIAGNOSIS OF INADEQUATE LABOR

ACTIVE-PHASE DISORDERS

According to the [American College of Obstetricians and Gynecologists \(1995a\)](#), neither failure to progress nor cephalopelvic disproportion are precise terms. They concluded that a more practical classification is to divide labor abnormalities into either slower-than-normal (protraction disorder) or complete cessation of progress (arrest disorder). The woman must be in the active phase of labor (cervix dilated 3 to 4 cm or more) to diagnose either of these.

[Handa and Laros \(1993\)](#) diagnosed active-phase arrest (no dilatation for 2 hours or more) in 5 percent of term nulliparas. Interestingly, this incidence has not changed since the 1950s ([Freidman, 1978](#)). Inadequate uterine contractions, defined as less than 180 Montevideo units ([Fig. 18-10](#)), were diagnosed in 80 percent of women with active-phase arrest. Protraction disorders are less well described, probably because the time interval necessary before diagnosing slow progress is undefined.

Said another way, how many hours must elapse before deciding that less than 1.2 cm/hr of cervical dilatation has occurred? The [World Health Organization \(1994\)](#) has proposed a labor management "partograph" in which protraction is defined as less than 1 cm/hr cervical dilatation for a *minimum of 4 hours*.

The current criteria recommended by the [American College of Obstetricians and Gynecologists \(1995a\)](#) for diagnosis of protraction and arrest disorders are shown in [Table 18-6](#). These criteria are adapted from those of [Cohen and Friedman \(1983\)](#) shown in [Table 18-2](#).

[Hauth and co-workers \(1986, 1991\)](#) reported that to effectively induce or augment labor with oxytocin, 90 percent of women achieve 200 to 225 Montevideo units, and 40 percent achieve at least 300 Montevideo units. These results suggest that there are certain minimums of uterine activity that should be achieved before performing cesarean delivery for dystocia. Accordingly, the [American College of Obstetricians and Gynecologists \(1989\)](#) has suggested that, before the diagnosis of arrest during first-stage labor is made, both of these criteria should be met:

1. The latent phase has been completed, with the cervix dilated 4 cm or more.
2. A uterine contraction pattern of 200 Montevideo units or more in a 10-minute period has been present for 2 hours without cervical change.

[Rouse and colleagues \(1999\)](#) have recently challenged the "2-hour rule" on the grounds that a longer time, i.e., at least 4 hours, is necessary before concluding that the active phase of labor has failed. We agree.

FETAL STATION AT ONSET OF ACTIVE LABOR

Descent of the fetal biparietal diameter to the level of the maternal pelvic ischial spines (0 station) is defined as engagement ([Chap. 13, p. 311](#)). [Friedman and Sachtleben \(1965\)](#) reported that there was a significant association between higher station at the onset of labor and subsequent dystocia. They described both protraction and arrest labor disorders in women with fetal head stations above +1 cm and that the higher the station at the onset of labor in nulliparas, the more prolonged the labor ([Friedman and Sachtleben, 1976](#)). [Handa and Laros \(1993\)](#) found that fetal station at the time of arrested labor was also a risk factor for dystocia. [Roshanfekr and associates \(1999\)](#) analyzed fetal station in 803 nulliparous delivered at term after active labor had been diagnosed. About 30 percent of these women presented to the hospital with the fetal head at or below 0 station, and the cesarean rate was 5 percent compared with 14 percent for those with higher fetal stations. The prognosis for dystocia, however, was not related to incrementally higher fetal head stations above the pelvic midplane (0 station). Importantly, 86 percent of nulliparous women without fetal head engagement at diagnosis of active labor delivered vaginally. Thus, lack of engagement at the onset of labor, although a statistical risk factor for dystocia, should not be assumed to necessarily predict fetopelvic disproportion. This is especially true for parous women because descent typically occurs relatively later in labor in these women.

SECOND-STAGE DISORDERS

With achievement of full cervical dilatation, the great majority of women cannot resist the urge to "bear down" or "push" each time the uterus contracts. Typically, the laboring woman inhales deeply, closes her glottis, and contracts her abdominal musculature repetitively with vigor to generate increased intra-abdominal pressure throughout the contractions. The combined force created by contractions of the uterus and abdominal musculature propels the fetus downward. Coaching women to push forcefully, compared with letting them follow their own urge to bear down, has been reported to offer no advantage ([Parnell and associates, 1993](#); [Vause and co-workers, 1998](#)).

CAUSES OF INADEQUATE EXPULSIVE FORCES

At times, the magnitude of the force created by contractions of abdominal musculature is compromised sufficiently to prevent spontaneous vaginal delivery. Heavy sedation or conduction analgesia—lumbar epidural, caudal, or intrathecal—are likely to reduce the reflex urge to push, and at the same time may impair ability to contract the abdominal muscles sufficiently. In some instances, the inherent urge to push is overridden by the intensification of pain that is created by bearing down.

Careful selection of the kind of analgesia and the timing of its administration are important to avoid compromise of voluntary expulsive efforts. With rare exception, intrathecal analgesia or general anesthesia should not be administered until all conditions for a safe outlet forceps delivery have been met ([Chap. 21, p. 490](#)). With continuous epidural analgesia, it may be necessary to allow the paralytic effects to wear off so that the woman can generate intra-abdominal pressure sufficient to move the fetal head into position appropriate for outlet forceps delivery. The alternatives—a possibly difficult midforceps delivery or cesarean delivery—are unsatisfactory choices in the absence of any evidence of fetal distress.

For the woman who cannot bear down appropriately with each contraction because of great discomfort, analgesia is likely to be of considerable benefit. Perhaps the safest choice for both fetus and mother is nitrous oxide, mixed with an equal volume of oxygen and provided during the time of each uterine contraction ([Chap. 15, p. 364](#)). At the same time, appropriate encouragement and instruction are most likely to be of benefit.

MATERNAL-FETAL EFFECTS OF DYSTOCIA

Although maternal and fetal effects resulting from dystocia are divided arbitrarily in the following discussion, dystocia may result in serious consequences to either or both simultaneously.

INTRAPARTUM INFECTION

Infection is a serious danger to which mother and fetus are exposed in labors complicated by prolonged labor, especially in the setting of ruptured membranes. Bacteria in amniotic fluid traverse the amnion and invade decidua and chorionic vessels, thus giving rise to maternal and fetal bacteremia and sepsis. Fetal pneumonia, caused by aspiration of infected amniotic fluid is another serious consequence. Digital cervical examinations introduce vaginal bacteria into the uterus ([Imseis and co-authors, 1999](#)). These should be limited during labor, especially when dystocia is suspected. Maternal and fetal infections are discussed in [Chapter 26](#) and [Chapters 56](#) and [57](#), respectively.

UTERINE RUPTURE

Abnormal thinning of the lower uterine segment creates a serious danger during prolonged labor, particularly in women of high parity and in those with prior cesarean deliveries ([Chap. 23, p. 542](#)). When the disproportion between fetal head and pelvis is so pronounced that there is no engagement and descent, the lower uterine segment becomes increasingly stretched, and rupture may follow. In such cases, a **pathological retraction ring** may develop and may be felt as a transverse or oblique ridge extending across the uterus somewhere between the symphysis and the umbilicus. Whenever this condition is noted, immediate abdominal delivery is indicated.

PATHOLOGICAL RETRACTION RING

Very rarely, localized rings or constrictions of the uterus develop in association with prolonged labors. The most common type is the *pathological retraction ring of Bandl*, an exaggeration of the normal retraction ring described in [Chapter 11 \(p. 255\)](#). It is often the result of obstructed labor, with marked stretching and thinning of the lower uterine segment. In such a situation, the ring may be seen clearly as an abdominal indentation and signifies impending rupture of the lower uterine segment (see [Fig. 19-7](#), p. 456). Localized uterine constrictions are rarely seen today because prolonged obstructed labor is unacceptable. These may still occur occasionally as hourglass constrictions of the uterus following birth of the first twin. In such a situation, they can sometimes be relaxed and delivery effected with appropriate general anesthesia, but occasionally prompt cesarean delivery offers a better prognosis for the second twin ([Chap. 30, p. 797](#)).

FISTULA FORMATION

When the presenting part is firmly weighed into the pelvic inlet but does not advance for a considerable time, portions of the birth canal lying between it and the pelvic wall may be subjected to excessive pressure. Because of impaired circulation, necrosis may result and become evident several days after delivery with the appearance of vesicovaginal, vesico-cervical, or rectovaginal fistulas. Most often, pressure necrosis follows a very prolonged second stage of labor. Formerly, when operative delivery was deferred as long as possible, such complications were frequent, but today they are rarely seen except in undeveloped countries ([Chap. 35, p. 923](#)).

PELVIC FLOOR INJURY

A long held belief is that injury to the pelvic floor muscles or to their nerve supply or to the interconnecting fascia is an inevitable consequence of vaginal delivery, particularly if the delivery is difficult. During childbirth the pelvic floor is exposed to direct compression from the fetal head as well as downward pressure from maternal expulsive efforts. These forces stretch and distend the pelvic floor resulting in functional and anatomical alterations in the muscles, nerves, and connective tissues. There is accumulating concern that such effects on the pelvic floor during childbirth lead to urinary and anal incontinence, and pelvic organ prolapse ([Leitch and Walker, 1998](#); [Sultan and Stanton, 1996](#)). Due to these concerns, in a recent poll of English female obstetricians, 30 percent expressed preference for an elective cesarean delivery rather than vaginal delivery, and cited avoidance of pelvic floor injury as the explanation for their choice ([Wagner, 2000](#)).

There is a long obstetrical history of interventions intended to prevent pelvic floor injury. For example, in 1920 DeLee advocated childbirth with *prophylactic forceps* to reduce the muscular and nerve strain of second-stage labor and to protect the pelvic floor and adjacent fascia from overstretching ([Chap. 21, p. 490](#)). Obstetrical accomplishments, however, in the 20th century were largely focused on improving the prognosis for newborn infants and preventing maternal morbidity and mortality due to preeclampsia, infection, and obstetrical hemorrhage. Indeed, [Brubaker \(1998\)](#) characterized this period by observing that "birth injury" is currently used in the context of injury to the fetus-neonate, while earlier in the 20th century, "birth injury" indicated maternal injuries that resulted in urogynecological disorders manifest later in the lives of women.

A classic example of such childbirth injury are anal sphincter tears occurring at vaginal delivery and discussed in [Chapter 13 \(p. 328\)](#). Such tears occur in 3 to 6 percent of deliveries and approximately half of these women report subsequent fecal or gas incontinence ([Zetterstrom and co-workers, 1999](#)). Although childbirth undoubtedly plays a significant role in pelvic floor injury, the incidence and types of injuries reported vary widely between studies. Currently, there is uncertainty regarding the incidence of childbirth-associated pelvic floor injury, and there is insufficient information as to the relative roles of specific obstetrical antecedents ([Samuëlsson and associates, 1999](#)).

FETAL EFFECTS

Prolonged labor itself may be deleterious. If the pelvis is contracted and there is associated prolonged membrane rupture and intrauterine infection, fetal and maternal risks are compounded. Intrapartum infection is not only a serious maternal complication but also an important cause of fetal and neonatal death. This obtains because bacteria in amniotic fluid traverse the amnion and invade decidua and chorionic vessels, thus giving rise to maternal and fetal bacteremia. Fetal pneumonia, caused by aspiration of infected amniotic fluid, is another serious consequence.

CAPUT SUCCEDANEUM. If the pelvis is contracted, during labor a large *caput succedaneum* frequently develops on the most dependent part of the fetal head. As shown in [Figure 18-11](#), this may assume considerable size and lead to serious diagnostic errors. **The caput may reach almost to the pelvic floor while the head is still not engaged. An inexperienced physician may make premature and unwise attempts at forceps delivery.** Typically, even a large caput disappears within a few days after birth.

FETAL HEAD MOLDING. Under the pressure of strong uterine contractions, cranial plates overlap one another at the major sutures, a process referred to as *molding* ([Fig. 18-11](#), see also [Figs. 39-16](#) and [39-17](#), pp. 1074, 1075). As a rule, the median margin of the parietal bone that is in contact with the sacral promontory is overlapped by that of its fellow; the same result occurs with the frontal bones. The occipital bone, however, is pushed under the parietal bones. These changes are frequently accomplished without obvious detriment. Alternatively, when the distortion is marked, molding may lead to tentorial tears, laceration of fetal blood vessels, and fatal intracranial hemorrhage.

[Sorbe and Dahlgren \(1983\)](#) measured fetal head diameters at birth and compared these with measurements obtained 3 days later. Molding was greatest in the suboccipitobregmatic dimension and averaged 0.3 cm with a range up to 1.5 cm. The biparietal diameter was not affected by fetal head molding. Factors associated with molding included nulliparity, oxytocin labor stimulation, and delivery with a vacuum extractor. [Carlan and colleagues \(1991\)](#) described a locking mechanism by which the free edges of cranial bones are forced into one another, preventing further molding and presumably providing protection for the fetal brain. They also observed that severe fetal head molding could develop before labor. [Holland \(1922\)](#) observed that severe molding could lead to fatal subdural hemorrhage due to tears involving the dura mater septa, especially the tentorium cerebelli. Such tears were observed in both normal and complicated deliveries.

Coincidental with molding, the parietal bone, which was in contact with the promontory, may show signs of being subjected to marked pressure, sometimes even becoming flattened. Accommodation more readily occurs when the bones of the head are imperfectly ossified. This important process may provide one explanation for the differences observed in the course of labor in two apparently similar cases in which the pelvis and the head present identical measurements. In one case, the head is softer and more readily molded, and spontaneous delivery results. In the other, the more ossified head retains its original shape and dystocia develops.

Characteristic pressure marks may form upon the scalp, covering the portion of the head that passes over the promontory of the sacrum. From their location, it is frequently possible to ascertain the movements that the head has undergone in passing through the inlet. Rarely, similar marks appear on the portion of the head that has been in contact with the symphysis pubis. Such marks usually disappear within a few days.

Skull fractures are occasionally encountered, usually following forcible attempts at delivery. As discussed in [Chapter 39 \(p. 1082\)](#), such fractures also may occur with spontaneous delivery or even with cesarean delivery ([Skajaa and associates, 1987](#)). The fractures are either a shallow groove or a spoon-shaped depression just posterior to the coronal suture ([Fig. 18-12](#)). The former is relatively common, but because it involves only the external bone plate, it is not very dangerous. The latter, however, if not surgically corrected, may lead to neonatal death, because it extends through the entire thickness of the skull and gives rise to inner surface projections that exert injurious pressure upon the brain. In these cases, it usually is advisable to elevate or remove the depressed portion of the skull.

LABOR MANAGEMENT PROTOCOLS

[O'Driscoll and colleagues \(1984\)](#) at the National Maternity Hospital in Dublin pioneered the concept that a disciplined, standardized labor management protocol reduced cesarean deliveries for dystocia. Their overall cesarean rate was 5 percent in the 1970s and 1980s with such management. The approach is now referred to as *active management of labor*. Its components, or at least two of them—amniotomy and oxytocin—have been widely used, especially in English-speaking countries outside the United States ([Thornton and Lilford, 1994](#)). Recently, [Impey and Boylan \(1999\)](#) observed that active management was never intended to reduce the cesarean rate and that the rate had in fact been low (about 5 percent) at the National Maternity Hospital prior to implementation of active management. In their view, active management did serve, however, to prevent the escalation of cesarean deliveries in Dublin that occurred in the United States and elsewhere. More recently, however, the cesarean rate for nulliparous women delivered at the National Maternity Hospital in 1997 has more than doubled to 11.6 percent. This increase was attributed to induction of labor, cesarean delivery for breech presentation, and changing maternal attitudes.

ACTIVE MANAGEMENT OF LABOR. This phrase describes a codified approach to labor diagnosis and management only in nulliparous women. Labor is diagnosed when painful contractions are accompanied by complete cervical effacement, bloody "show," or ruptured membranes. Women with such findings are committed to delivery within 12 hours. Pelvic examination is performed each hour for the next 3 hours, and thereafter at 2-hour intervals. Progress is assessed for the first time 1 hour after admission. When dilatation has not increased by at least 1 cm, amniotomy is performed. Progress is again assessed at 2 hours and high-dose oxytocin infusion, described in [Chapter 20 \(p. 474\)](#), is started unless significant progress of 1 cm/hr is documented. Women are constantly attended by midwives.

If membranes rupture prior to admission, oxytocin is begun for no progress at the 1-hour mark. No special equipment is used, either to dispense oxytocin or monitor its effects, and electronic uterine contraction monitoring is not used. Oxytocin is dispensed by gravity regulated by a personal nurse. The solution contains 10 units of oxytocin in 1 liter of dextrose and water; the total dose may not exceed 10 units and the infusion rate may not exceed 60 drops/min or 30 to 40 mU/min (15 to 20 drops = 1 mL). In the Irish protocol, scalp blood sampling was used as the definitive test for fetal distress.

[Lopez-Zeno and colleagues \(1992\)](#) prospectively compared active management with the "traditional" approach to labor management practiced at Northwestern Memorial Hospital in Chicago. They randomized, in an unblinded fashion, 705 uncomplicated nulliparas in spontaneous labor at term. The cesarean rate was 10.5 percent with active management and 14.1 percent with the "traditional" approach. [Frigoletto and co-workers \(1995\)](#) also reported a randomized trial of active management in 1934 nulliparous women delivered at Brigham and Women's Hospital in Boston. Although they found that such management somewhat shortened labor, it did not affect the cesarean rate. Similar results were reported by [Rogers and colleagues \(1997\)](#).

WORLD HEALTH ORGANIZATION PARTOGRAPH. A *partogram* was designed for use in developing countries ([Dujardin and co-workers, 1992](#)). Labor is divided into a latent phase, which should last no longer than 8 hours, and an active phase starting at 3 cm dilatation, the rate of which should be no slower than 1 cm/hr. A 4-hour wait (lag time) is recommended before intervention when the active phase is slow. Labor is graphed and analysis includes use of *alert* and *action* lines. The

protocol has been found to be beneficial in Southeast Asia ([World Health Organization, 1994](#)) and in Liverpool, England ([Lavender and associates, 1998](#)).

PARKLAND HOSPITAL LABOR MANAGEMENT PROTOCOL. During the 1980s, the obstetrical volume at Parkland Hospital doubled to approximately 15,000 births per year. In response, a second delivery unit designed for women with uncomplicated term pregnancies was developed. This provided a unique opportunity to implement and evaluate a standardized protocol for labor management. Its design was based upon the labor management approach that had evolved at our hospital up to that time, and which emphasized the implementation of specific, sequential interventions when abnormal labor was suspected. This approach is currently used in both complicated and uncomplicated pregnancies.

Women at term are admitted when active labor—defined as cervical dilatation of 3 to 4 cm or more in the presence of uterine contractions—is diagnosed or ruptured membranes confirmed. Management guidelines summarized in [Figure 18-13](#) stipulate that pelvic examinations be performed approximately every 2 hours. Ineffective labor is suspected when the cervix does not dilate within about 2 hours of admission. Amniotomy is then performed and labor progress evaluated at the next 2-hour evaluation. In women whose labors do not progress, an intrauterine pressure catheter is placed to evaluate uterine function. Hypotonic contractions and no cervical progress after an additional 2 to 3 hours result in stimulation of labor using the high-dose oxytocin regimen described in [Chapter 20 \(p. 474\)](#). Uterine activity of 200 to 250 Montevideo units is expected for 2 to 4 hours before dystocia is diagnosed.

Dilatation rates of 1 to 2 cm/hr are accepted as evidence of progress after satisfactory uterine activity has been established with oxytocin. As shown in [Figure 18-13](#), this can require up to 8 hours or more before cesarean delivery is performed for dystocia. Probably the cumulative time required to effect this stepwise management approach permits many women the time necessary to establish effective labor. This management protocol has been evaluated in more than 20,000 women with uncomplicated pregnancies. Cesarean delivery rates in nulliparous and parous women were 8.7 and 1.5 percent, respectively. Importantly, these labor interventions and the relatively infrequent use of cesarean delivery did not jeopardize the fetus-newborn infant.

PRECIPITATE LABOR AND DELIVERY

Not only can labor be too slow as described in this chapter, labor can also be abnormally rapid. Precipitate—that is, extremely rapid—labor and delivery may result from an abnormally low resistance of the soft parts of the birth canal, from abnormally strong uterine and abdominal contractions, or *very rarely*, from the absence of painful sensations and thus a lack of awareness of vigorous labor.

DEFINITION. According to [Hughes \(1972\)](#), precipitate labor terminates in expulsion of the fetus in less than 3 hours. Using this definition, 79,933 live births (2 percent) were complicated by precipitate labor in the United States during 1998 ([Ventura and co-workers, 2000](#)). Although so-defined precipitate labor is not rare, very little published information exists on its maternal and fetal effects. [Mahon and colleagues \(1994\)](#) described 99 pregnancies delivered within 3 hours of commencement of regular contractions. Short labors, defined as a rate of cervical dilatation of 5 cm/hr or faster for nulliparas and 10 cm/hr for multiparas, were associated with abruption (20 percent), meconium, postpartum hemorrhage, cocaine abuse, and low Apgar scores. Most (93 percent) of the women were multiparas and typically had uterine contractions more often than every 2 minutes.

MATERNAL EFFECTS. Precipitate labor and delivery are seldom accompanied by serious maternal complications if the cervix is effaced appreciably and easily dilated, the vagina has been stretched previously, and the perineum is relaxed. Conversely, vigorous uterine contractions combined with a long, firm cervix and a birth canal that resists stretch may lead to uterine rupture or extensive lacerations of the cervix, vagina, vulva, or perineum. It is in these latter circumstances that the rare condition of *amniotic fluid embolism* most likely develops ([Chap. 25, p. 660](#)). **The uterus that contracts with unusual vigor before delivery is likely to be hypotonic after delivery, with hemorrhage from the placental implantation site as the consequence.** Postpartum hemorrhage from uterine atony is discussed in [Chapter 25 \(p. 637\)](#).

EFFECTS ON FETUS AND NEONATE. Perinatal mortality and morbidity from precipitate labor may be increased considerably for several reasons. The tumultuous uterine contractions, often with negligible intervals of relaxation, prevent appropriate uterine blood flow and fetal oxygenation. Another reason is that the resistance of the birth canal to expulsion of the head may cause intracranial trauma, although this must be rare. [Acker and colleagues \(1988\)](#) reported that Erb-Duchenne palsy was associated with such labors in a third of cases. Finally, during an unattended birth, the infant may fall to the floor and be injured or may need resuscitation that is not immediately available.

TREATMENT. Unusually forceful spontaneous uterine contractions are not likely to be modified to a significant degree by analgesia. The use of tocolytic agents such as magnesium sulfate is unproven in these circumstances. Use of general anesthesia with agents that impair uterine contractility, such as halothane and isoflurane, is often excessively heroic. Certainly, any oxytocin agents being administered should be stopped immediately.

TABLE 18-2. Abnormal Labor Patterns, Diagnostic Criteria, and Methods of Treatment
Diagnostic Criteria

Labor Pattern	Nulliparas	Multiparas	Preferred Treatment	Exceptional Treatment
Prolongation Disorder (Prolonged latent phase)	> 20 hr	> 14 hr	Bed rest	Oxytocin or cesarean delivery for urgent problems
Protraction Disorders				
1. Protracted active phase dilatation	< 1.2 cm/hr	< 1.5 cm/hr	Expectant and support	Cesarean delivery for CPD
2. Protracted descent	< 1.0 cm/hr	< 2 cm/hr		
Arrest Disorders				
1. Prolonged deceleration phase	> 3 hr	> 1 hr	Oxytocin without CPD	Rest if exhausted
2. Secondary arrest of dilatation	> 2 hr	> 2 hr	Cesarean with CPD	Cesarean delivery
3. Arrest of descent	> 1 hr	> 1 hr		
4. Failure of descent	No descent in deceleration phase or second stage			

CPD = cephalopelvic disproportion.

Modified from Cohen and Friedman (1983).

19. Dystocia Abnormal Presentation, Position, and Development of the Fetus

In nearly 97 percent of pregnancies, at the time of delivery, the fetus is entering the pelvis as a cephalic presentation ([Table 19-1](#)). In about 3 percent there is a breech presenting, and this is discussed in [Chapter 22](#). In the remaining 0.5 percent, the fetus presents with the long axis either transverse or oblique, or the head may be extended to present the fetal face or brow.

FACE PRESENTATION

With a face presentation, the head is hyperextended so that the occiput is in contact with the fetal back and the chin (mentum) is presenting. The fetal face may present with the chin (mentum) anterior or posterior, relative to the maternal symphysis pubis. In term-size fetuses, labor progression is usually impeded with mentum posterior face presentations because the fetal brow (bregma) is compressed against the maternal symphysis pubis. This position precludes flexion of the fetal head necessary to negotiate the birth canal. In contrast, flexion of the head and vaginal delivery is typical with mentum anterior presentations. Many mentum posterior presentations convert spontaneously to anterior even in late labor ([Duff, 1981](#)).

INCIDENCE. [Cruikshank and White \(1973\)](#) reported an incidence of 1 in 600, or 0.17 percent. Among more than 70,000 singleton infants delivered at Parkland Hospital from 1995 through 1999, 36—or about 1 in 2000—were face presentations at delivery ([Table 19-1](#)).

DIAGNOSIS. Face presentation is diagnosed by vaginal examination and palpation of the distinctive facial features of the mouth and nose, malar bones, and particularly the orbital ridges. As discussed in [Chapter 22 \(p. 511\)](#), it is possible to mistake a breech for a face presentation, because the anus may be mistaken for the mouth and the ischial tuberosities for the malar prominences. The radiographic demonstration of the hyperextended head with the facial bones at or below the pelvic inlet is quite characteristic ([Fig. 19-1](#)).

ETIOLOGY. Causes of face presentations are numerous, generally stemming from any factor that favors extension or prevents head flexion. In exceptional instances, marked enlargement of the neck or coils of cord about the neck may cause extension. Anencephalic fetuses naturally present by the face. Extended positions occur more frequently when the pelvis is contracted, or the fetus is very large. In a series of 141 face presentations studied by [Hellman and co-workers \(1950\)](#), the incidence of inlet contraction was 40 percent. This high incidence of pelvic contraction, as well as large infants, must be kept in mind when considering management.

In multiparous women, a pendulous abdomen may predispose to face presentation. It permits the back of the fetus to sag forward to laterally, often in the same direction in which the occiput points, thus promoting extension of the cervical and thoracic spine. High parity itself is a predisposing factor ([Fuchs and colleagues, 1985](#)).

MECHANISM. Face presentations are rarely observed above the pelvic inlet. The brow generally presents, and it is usually converted into a face presentation after further extension of the head during descent. The mechanism of labor in these cases consists of the cardinal movements of descent, internal rotation, and flexion, and the accessory movements of extension and external rotation ([Fig. 19-2](#)). Descent is brought about by the same factors as in cephalic presentations. Extension results from the relation of the fetal body to the deflected head, which is converted into a two-armed lever, the longer arm of which extends from the occipital condyles to the occiput. When resistance is encountered, the occiput must be pushed toward the back of the fetus while the chin descends ([Fig. 19-3](#)).

The objective of internal rotation of the face is to bring the chin under the symphysis pubis. Only in this way can the neck subtend the posterior surface of the symphysis pubis. If the chin rotates directly posteriorly, the relatively short neck cannot span the anterior surface of the sacrum, which measures about 12 cm in length ([Fig. 19-3](#)). Hence, the birth of the head is impossible unless the shoulders enter the pelvis at the same time, an event that is impossible except when the fetus is extremely small or macerated. Internal rotation results from the same factors as in vertex presentations.

After anterior rotation and descent, the chin and mouth appear at the vulva, the undersurface of the chin presses against the symphysis, and the head is delivered by flexion ([Fig. 19-2](#)). The nose, eyes, brow (bregma), and occiput then appear in succession over the anterior margin of the perineum. After birth of the head, the occiput sags backward toward the anus. Next, the chin rotates externally to the side toward which it was originally directed, and the shoulders are born as in cephalic presentations.

Edema may sometimes significantly distort the face ([Fig. 19-4](#)). At the same time, the skull undergoes considerable molding, manifested by an increase in length of the occipitofrontal diameter of the head ([Fig. 19-3](#)).

MANAGEMENT

In the absence of a contracted pelvis, and with effective labor, successful vaginal delivery will usually follow. Fetal heart rate monitoring is probably better done with external devices to avoid damage to the face and eyes. Because face presentations among term-size fetuses are more common when there is some degree of pelvic inlet contraction, cesarean delivery is frequently indicated.

Attempts to convert a face manually into a vertex presentation, manual or forceps rotation of a persistently posterior chin to a mentum anterior position, and internal podalic version and extraction are dangerous and not attempted. [Neuman and colleagues \(1994\)](#) have described intrapartum bimanual conversion of mentoposterior to occipitoanterior presentations in 11 women who refused cesarean delivery.

BROW PRESENTATION

This is the rarest presentation ([Table 19-1](#)), and is diagnosed when that portion of the fetal head between the orbital ridge and the anterior fontanel presents at the pelvic inlet. As shown in [Figure 19-5](#), the fetal head thus occupies a position midway between full flexion (occiput) and extension (mentum or face). Except when the fetal head is small or the pelvis is unusually large, engagement of the fetal head and subsequent delivery cannot take place as long as the brow presentation persists.

ETIOLOGY. The causes of persistent brow presentation are the same as those for face presentation. A brow presentation is commonly unstable and often converts to a face or an occiput presentation ([Cruikshank and White, 1973](#)).

DIAGNOSIS. The presentation may be recognized by abdominal palpation when both the occiput and chin can be palpated easily, but vaginal examination is usually necessary. The frontal sutures, large anterior fontanel, orbital ridges, eyes, and root of the nose can be felt on vaginal examination. Neither mouth nor chin is within reach, however ([Fig. 19-5](#)).

MECHANISM OF LABOR. With a very small fetus and a large pelvis, labor is generally easy. With a larger fetus, however, it is usually very difficult, because engagement is impossible until there is marked molding that shortens the occipitofrontal diameter or, more commonly, until there is either flexion to an occiput presentation or extension to a face presentation. The considerable molding essential for vaginal delivery of a persistent brow characteristically deforms the head. The caput succedaneum is over the forehead, and it may be so extensive that identification of the brow by palpation is impossible. In these instances, the forehead is prominent and squared, and the occipitofrontal diameter is diminished.

PROGNOSIS. In transient brow presentations, the prognosis depends upon the ultimate presentation. If the brow persists, prognosis is poor for vaginal delivery unless the fetus is small or the birth canal is huge.

MANAGEMENT

Principles are much the same as those for a face presentation. If, by chance, spontaneous labor is progressing without any evidence of distress in the closely monitored fetus, and without unduly vigorous uterine contractions, no interference is necessary.

TRANSVERSE LIE

This occurs when the long axis of the fetus is approximately perpendicular to that of the mother. When the long axis forms an acute angle, an **oblique lie** results. The latter is usually only transitory, because either a longitudinal or transverse lie commonly results when labor supervenes. For this reason, the oblique lie is called an

unstable lie in Great Britain.

In transverse lies, the shoulder is usually over the pelvic inlet, with the head lying in one iliac fossa and the breech in the other. In such a **shoulder presentation**, the side of the mother toward which the acromion is directed determines the designation of the lie as right or left acromial. Moreover, because in either position the back may be directed anteriorly or posteriorly, superiorly or inferiorly, it is customary to distinguish varieties as dorsoanterior and dorsoposterior ([Fig. 19-6](#)).

INCIDENCE. Transverse lie occurred once in 322 singleton deliveries (0.3 percent) at both the Mayo Clinic and the University of Iowa Hospital ([Cruikshank and White, 1973](#); [Johnson 1964](#)). At Parkland Hospital, transverse lie was encountered in about 1 in 335 singleton fetuses delivered over a 4-year period ([Table 19-1](#)).

ETIOLOGY. The common causes of transverse lie are:

1. Unusual relaxation of the abdominal wall resulting from high parity.
2. Preterm fetus.
3. Placenta previa.
4. Abnormal uterus.
5. Excessive amniotic fluid.
6. Contracted pelvis.

Women with four or more deliveries have a tenfold incidence of transverse lie compared with nulliparous women. Relaxation of the abdominal wall with a pendulous abdomen allows the uterus to fall forward, deflecting the long axis of the fetus away from the axis of the birth canal into an oblique or transverse position. Placenta previa and pelvic contraction act similarly. A transverse or oblique lie occasionally develops in labor from an initial longitudinal position.

DIAGNOSIS. This is usually made easily, often by inspection alone. The abdomen is unusually wide, whereas the uterine fundus extends to only slightly above the umbilicus. No fetal pole is detected in the fundus, and the ballotable head is found in one iliac fossa and the breech in the other. At the same time, the position of the back is readily identified. When the back is anterior ([Fig. 19-6](#)), a hard resistance plane extends across the front of the abdomen; when it is posterior, irregular nodulations representing the small parts are felt in the same location.

On vaginal examination, in the early stages of labor, the side of the thorax, if it can be reached, may be recognized by the "gridiron" feel of the ribs. When dilatation is further advanced, the scapula and the clavicle are distinguished on opposite sides of the thorax. The position of the axilla indicates the side of the mother toward which the shoulder is directed. Later in labor, the shoulder will become tightly wedged in the pelvic canal, and a hand and arm frequently prolapse into the vagina and through the vulva ([Fig. 19-7](#)).

COURSE OF LABOR. Spontaneous delivery of a fully developed infant is impossible with a persistent transverse lie. After rupture of the membranes, if labor continues, the fetal shoulder is forced into the pelvis, and the corresponding arm frequently prolapses ([Fig. 19-7](#)). After some descent, the shoulder is arrested by the margins of the pelvic inlet, with the head in one iliac fossa and the breech in the other. As labor continues, the shoulder is impacted firmly in the upper part of the pelvis. The uterus then contracts vigorously in an unsuccessful attempt to overcome the obstacle. After a time, a retraction ring rises increasingly higher and becomes more marked. The situation is referred to as a *neglected transverse lie*. If not promptly managed, the uterus eventually ruptures, and the mother and fetus die.

If the fetus is quite small (usually less than 800 g) and the pelvis is large, spontaneous delivery is possible despite persistence of the abnormal lie. The fetus is compressed with the head forced against the abdomen. A portion of the thoracic wall below the shoulder thus becomes the most dependent part, appearing at the vulva. The head and thorax then pass through the pelvic cavity at the same time, and the fetus, which is doubled upon itself (*conduplicato corpore*), is expelled.

PROGNOSIS. Labor with a shoulder presentation increases maternal risk and adds tremendously to fetal hazards. Most maternal deaths from neglected cases are from spontaneous or traumatic uterine rupture consequent upon late and ill-advised version and extraction. Even with the best of care, morbidity is increased because of the frequent association with placenta previa, increased likelihood of cord prolapse, and necessity for major operative interferences.

MANAGEMENT

In general, the onset of active labor in a woman with a transverse lie is an indication for cesarean delivery. Once labor is well established, attempts at conversion to a longitudinal lie by abdominal manipulation will likely not be successful. Before labor or early in labor, with the membranes intact, attempts at external version are worthy of a trial in the absence of other complications that indicate cesarean delivery. [Phelan and co-workers \(1986\)](#) recommend such an attempt only after 39 weeks because of the high (83 percent) spontaneous conversion to a longitudinal lie. If during early labor, the fetal head can be maneuvered by abdominal manipulation into the pelvis, it should be held there during the next several contractions in an attempt to fix the head in the pelvis. If these measures fail, cesarean delivery is performed.

Because neither the feet nor the head of the fetus occupy the lower uterine segment, a low transverse incision into the uterus may lead to difficulty in extraction of a fetus entrapped in the body of the uterus above the level of incision. Therefore, a vertical incision is likely to be indicated ([Chap. 23, p. 550](#)).

COMPOUND PRESENTATION

In a compound presentation, an extremity prolapses alongside the presenting part, with both presenting in the pelvis simultaneously ([Fig. 19-8](#)).

INCIDENCE AND ETIOLOGY. [Goplerud and Eastman \(1953\)](#) identified a hand or arm prolapsed alongside the head once in every 700 deliveries. Much less common was prolapse of one or both lower extremities alongside a cephalic presentation or a hand alongside a breech. We identified compound presentations in only 68 of more than 70,000 singleton fetuses delivered from 1995 through 1999, for an incidence of about 1 in 1000 ([Table 19-1](#)). Causes of compound presentations are conditions that prevent complete occlusion of the pelvic inlet by the fetal head, including preterm birth ([Goplerud and Eastman, 1953](#)).

PROGNOSIS AND MANAGEMENT

Perinatal loss is increased due to preterm delivery, prolapsed cord, and traumatic obstetrical procedures. In most cases, the prolapsed part should be left alone, because most often it will not interfere with labor. [Goplerud and Eastman \(1953\)](#) described 50 cases not associated with a prolapsed cord; in almost half, normal delivery ensued with loss of only one infant. If the arm is prolapsed alongside the head, the condition should be closely observed to ascertain whether the arm rises out of the way with descent of the presenting part. If it fails to do so and if it appears to prevent descent of the head, the prolapsed arm should be gently pushed upward and the head simultaneously downward by fundal pressure. [Tebes and co-authors \(1999\)](#) described a tragic outcome in an infant delivered spontaneously with the hand alongside the head. The child developed ischemic necrosis of the presenting forearm which required amputation.

PERSISTENT OCCIPUT POSTERIOR POSITION

Most often, occiput posterior positions undergo spontaneous anterior rotation followed by uncomplicated delivery. Although the precise reasons for failure of spontaneous rotation are not known, transverse narrowing of the midpelvis is undoubtedly a contributing factor. [Gardberg and associates \(1998\)](#) used ultrasonography to record the position of the fetal head in 408 term pregnancies at entry into labor ([Fig. 19-9](#)). Early in labor, about 15 percent of the fetuses were occiput posterior and 5 percent were in this position at delivery. Importantly, two thirds of occiput posterior deliveries were in those who were occiput anterior at the beginning of labor. Thus, most occiput posterior presentations at delivery are the result of malrotation of occiput anterior position during labor and most (87 percent) of occiput posterior presentations at the outset of labor spontaneously rotate anteriorly. Induction of labor and epidural analgesia were not factors linked to occiput posterior presentations in this study.

Labor and delivery need not differ remarkably from that with the occiput anterior. Progress may be ascertained by assessing cervical dilatation and descent of the head. In most instances, delivery can usually be accomplished without great difficulty once the head reaches the perineum. The possibilities for vaginal delivery are:

1. Await spontaneous delivery.
2. Forceps delivery with the occiput directly posterior.
3. Forceps rotation of the occiput to the anterior position and delivery.
4. Manual rotation to the anterior position followed by spontaneous or forceps delivery.

SPONTANEOUS DELIVERY

If the pelvic outlet is roomy and the vaginal outlet and perineum are somewhat relaxed from previous vaginal deliveries, rapid spontaneous delivery will often take place. If the vaginal outlet is resistant to stretch and the perineum is firm, late first stage or the second stage of labor, or both, may be appreciably prolonged. During each expulsive effort, with the occiput posterior, the head is driven against the perineum to a much greater degree than when anterior. Therefore, forceps delivery is often indicated. A generous episiotomy is usually needed.

FORCEPS DELIVERY AS AN OCCIPUT POSTERIOR

The need for more traction compared with forceps deliveries from the occiput anterior position can be minimized by making a larger episiotomy. The use of forceps and a large episiotomy warrant more complete analgesia than may be achieved with pudendal block and local perineal infiltration. The forceps are applied bilaterally along the occipitomenal diameter, as described in [Chapter 21 \(p. 496\)](#).

It is important to identify the infrequent case in which protrusion of fetal scalp through the introitus is the consequence of marked elongation of the fetal head from molding combined with formation of a large caput. In this circumstance, the head may not even be engaged—that is, the biparietal diameter may not have passed through the pelvic inlet. Labor has characteristically been long in such a case and, in turn, descent of the head has been slow. Careful palpation above the symphysis may disclose the fetal head to be above the pelvic inlet. Prompt cesarean delivery is appropriate in such cases.

MANUAL ROTATION

The requirements for forceps rotation must be met before doing a manual rotation. When the hand is introduced to locate the posterior ear and thus confirm the posterior position, the occiput often rotates toward the anterior position. The head may be grasped with the fingers over the posterior ear and the thumb over the anterior ear and an attempt made to rotate the occiput to the anterior position ([Chap. 21, p. 495](#)).

FORCEPS ROTATION

If the head is engaged, the cervix fully dilated, and the pelvis adequate, forceps rotation may be attempted if the operator is sufficiently skilled. These circumstances are most likely to prevail when expulsive efforts of the mother during the second stage are ineffective, such as with continuous regional analgesia. Rotation with forceps is described in [Chapter 21 \(p. 497\)](#).

[Menticoglou and co-workers \(1995\)](#) reviewed the obstetrical features of 15 infants with birth-related high cervical spinal cord injuries in 13 Canadian hospitals between 1982 and 1994. All of these infants had in common cephalic delivery with forceps rotation of 90 degrees or more from occipitoposterior or occipitotransverse positions. They could not determine whether these serious—albeit rare—fetal injuries occurred as a result of mismanagement or as an intrinsic risk of properly performed forceps rotation. They estimated that this complication developed in less than 1 per 1000 forceps rotations.

OUTCOME

There are notable differences when persistent occiput posterior position is compared with the occiput anterior. [Phillips and Freeman \(1974\)](#) reported that labor was prolonged on the average 1 hour in parous women and 2 hours in nulliparous women. Episiotomy extension was increased appreciably. [Gardberg and Tuppurainen \(1994\)](#) later observed that both first- and second-stage labor were longer in persistent occiput posterior and that 65 percent required operative interventions. [Johanson and co-workers \(1993\)](#) found that both forceps and vacuum-assisted deliveries for occiput posterior positions more often failed compared with anterior presentations (24 versus 7 percent). With vaginal delivery, especially instrumental, accompanying severe perineal lacerations are associated with long-term morbidity, as discussed in [Chapter 13 \(p. 325\)](#).

At Parkland Hospital, either manual rotation to the anterior position followed by forceps delivery, or forceps delivery from the occiput posterior position, is used to effect delivery. When neither can be done with relative ease, cesarean delivery is performed.

PERSISTENT OCCIPUT TRANSVERSE POSITION

In the absence of a pelvic architecture abnormality, the occiput transverse position is most likely a transitory one as the occiput rotates to the anterior position. If hypotonic uterine dysfunction, either spontaneous or the consequence of regional analgesia, does not develop, spontaneous rotation is usually completed rapidly, thus allowing the choice of spontaneous delivery or delivery with outlet forceps.

DELIVERY

If rotation ceases because of lack of uterine action and in the absence of pelvic contraction, vaginal delivery can usually be accomplished readily in a number of ways. The occiput may be manually rotated anteriorly or posteriorly and forceps delivery carried out from either the anterior or posterior position. Another approach recommended by some is to apply forceps of the Kielland type to the head in the occiput transverse position ([Chap. 21, p. 497](#)), rotate the occiput to the anterior position, and then deliver the head with either the same forceps or with standard forceps. If failure of spontaneous rotation is caused by hypotonic uterine dysfunction *without cephalopelvic disproportion*, oxytocin may be infused with close monitoring.

The genesis of the occiput transverse position is not always so simple, or the treatment so benign. With the platypelloid (anteroposteriorly flat configuration) and the android (heart-shaped) pelvis, there may not be adequate room for rotation of the occiput to either the anterior or the posterior position. With the android pelvis, the head may not even be engaged, yet the scalp may be visible through the vaginal introitus as the consequence of considerable molding and caput formation. This situation is fraught with danger to both the fetus and mother. If forceps are tried for delivery, it is imperative that undue force not be applied but, instead, cesarean delivery be accomplished.

SHOULDER DYSTOCIA

The incidence of shoulder dystocia varies greatly depending on the criteria used for diagnosis. For example, [Gross and co-authors \(1987\)](#) identified that 0.9 percent of almost 11,000 vaginal deliveries were coded for shoulder dystocia at the Toronto General Hospital. True shoulder dystocia, however, diagnosed because maneuvers were required to deliver the shoulders in addition to downward traction and episiotomy, was identified in only 24 births (0.2 percent). Significant infant trauma was observed only in shoulder dystocias requiring a maneuver to effect delivery. Current reports, where the diagnosis of shoulder dystocia is limited to those deliveries requiring a maneuver, cite an incidence that varies between 0.6 percent and 1.4 percent ([American College of Obstetricians and Gynecologists, 2000](#); [Baskett and Allen, 1995](#); [McFarland and co-workers, 1995](#); [Nocon and co-workers, 1993](#)).

There is some evidence that the incidence of shoulder dystocia increased from 1960 to 1980 ([Hopwood, 1982](#)). This is likely due to increasing birthweight. [Modanlou and co-workers \(1982\)](#) showed that neonates experiencing shoulder dystocia had significantly greater shoulder-to-head and chest-to-head disproportions compared with equally macrosomic infants delivered without dystocia. It is also likely that the increased incidence of shoulder dystocia is due in part to increased attention to its appropriate documentation ([Nocon and co-workers, 1993](#)).

Use of maneuvers to define shoulder dystocia has been criticized ([Beall and associates, 1998](#); [Spong and colleagues, 1995](#)). In deliveries in which shoulder dystocia is anticipated, one or more maneuvers may be used prophylactically, but no diagnosis of shoulder dystocia is recorded. In other cases, one or two maneuvers may be used with rapid resolution of shoulder dystocia and excellent outcome, and the diagnosis is not identified. [Spong and colleagues \(1995\)](#) attempted to more objectively

define shoulder dystocia by witnessing 250 unselected deliveries and timing intervals from delivery of the head, to delivery of the shoulders, and to completion of the birth. The incidence defined by the use of obstetrical maneuvers was higher than previously reported (11 percent); however, only about half of these were diagnosed by the clinicians. The mean head-to-body delivery time in normal births was 24 seconds compared with 79 seconds in those with shoulder dystocia. They proposed that a head-to-body delivery time exceeding 60 seconds be used to define shoulder dystocia.

MATERNAL CONSEQUENCES

Postpartum hemorrhage, usually from uterine atony, but also from vaginal and cervical lacerations, is the major maternal risk ([Benedetti and Gabbe, 1978](#); [Parks and Ziel, 1978](#)). Puerperal infection following cesarean delivery also remains a problem.

FETAL CONSEQUENCES

Shoulder dystocia may be associated with significant fetal morbidity and even mortality. [Gherman and co-workers \(1998\)](#) reviewed 285 cases of shoulder dystocia and 25 percent were associated with fetal injuries. Transient brachial plexus palsies were the most common injury, accounting for two thirds; 38 percent had clavicular fractures, and 17 percent sustained humeral fractures. There was one neonatal death, and four infants had persistent brachial plexus injuries. In this series, almost half of the cases of shoulder dystocia required a direct fetal manipulation such as the Woods maneuver, in addition to the McRoberts procedure, to effect release of the impacted shoulders. Direct fetal manipulation, however, when compared with use of the McRoberts procedure alone, was not associated with an increased rate of fetal injury.

BRACHIAL PLEXUS INJURY. Injury to the brachial plexus may be localized to the upper or lower part of the plexus ([Chap. 39, p. 1080](#)). It usually results from downward traction on the brachial plexus during delivery of the anterior shoulder. *Erb palsy* results from injury to the spinal nerves C₅₋₆ and sometimes C₇. It consists of a paralysis of shoulder and arm muscles resulting in a hanging upper arm that may be extended at the elbow. Involvement of the lower spinal nerves (C_{7-T1}) always includes injury of the upper nerves and results in a palsy including the hand, which can cause a clawhand deformity. [Hardy \(1981\)](#) studied the prognosis of 36 infants with brachial plexus injuries. Interestingly, shoulder dystocia had been reported in only 10 of these, and two had been delivered abdominally. Nearly 80 percent of these children had complete recovery by 13 months, and none with residual defects had severe sensory or motor deficits in the hand. [Jennett and associates \(1992\)](#) and [Gherman and colleagues \(1999\)](#) have presented evidence that brachial plexus injuries may precede the delivery itself and may occur even prior to labor.

CLAVICULAR FRACTURE. Fractured clavicles are relatively common and have been diagnosed in 0.4 percent of infants delivered vaginally at Parkland Hospital ([Roberts and co-workers, 1995](#)). Such fractures, although at times associated with shoulder dystocia, often occur without any clinical events to suspect them. Investigators have concluded that isolated fractured clavicles are unavoidable, unpredictable, and are of no clinical consequence ([Chez and co-authors, 1994](#); [Roberts and co-workers, 1995](#)).

PREDICTION AND PREVENTION OF SHOULDER DYSTOCIA

There has been considerable evolution in obstetrical thinking about the preventability of shoulder dystocia in the past two decades ([Chap. 29, p. 758](#)). During the 1970s, when the use of cesarean delivery was escalating rapidly, it was hoped that certain pregnancy risk factors could be used to identify women in whom cesarean delivery would avoid shoulder dystocia. During the 1980s it became apparent, however, that the rate of cesarean delivery was likely excessive. It also became obvious that predicting, and therefore preventing, shoulder dystocia was not simple. Although there are clearly several risk factors associated with shoulder dystocia, actual identification of individual instances before the fact has proven to be impossible.

RISK FACTORS. A variety of maternal, intrapartum, and fetal characteristics have been implicated in the development of shoulder dystocia ([Baskett and Allen, 1995](#); [Nesbitt and associates, 1998](#); [Nocon and co-authors, 1993](#)). Several maternal risk factors, including obesity, multiparity, and diabetes, all exert their effects because of associated increased birthweight. For example, [Keller and co-workers \(1991\)](#) identified shoulder dystocia in 7 percent of pregnancies complicated by gestational diabetes. Similarly, the association of postterm pregnancy with shoulder dystocia is likely because many fetuses continue to grow after 42 weeks ([Chap. 28, p. 738](#)).

Intrapartum complications associated with shoulder dystocia include midforceps delivery and prolonged first- and second-stage labor ([Baskett and Allen, 1995](#); [Nocon and co-authors, 1993](#)). [McFarland and co-workers \(1995\)](#), however, using matched controls, found that first- and second-stage labor abnormalities were not useful clinical predictors of shoulder dystocia.

The common thread running through all current reports on risk factors for shoulder dystocia is increased birthweight (Nesbitt and colleagues, 1998). [Table 19-2](#) gives the incidence of shoulder dystocia related to birthweight groupings at Parkland Hospital during 1994. Clearly, shoulder dystocia increases with greater birthweight; however, almost half of the births with shoulder dystocia weighed less than 4000 g. Indeed, [Nocon and co-workers \(1993\)](#) described shoulder dystocia with birth of a 2260-g infant. Despite this, some authors ([O'Leary, 1992](#)) advocate identification of macrosomia with ultrasound and liberal use of cesarean delivery to shoulder dystocia. Others have disputed the concept that cesarean delivery is indicated for identified large fetuses, even those estimated to weigh in excess of 4500 g. [Rouse and Owen \(1999\)](#) concluded that a prophylactic cesarean policy for macrosomic infants would require more than 1000 cesarean deliveries and millions of dollars to avert a single permanent brachial plexus injury. The [American College of Obstetricians and Gynecologists \(2000\)](#) has concluded that performing cesarean deliveries for all women suspected of carrying a macrosomic fetus is not appropriate, except possibly for estimated fetal weights over 5000 g in nondiabetic women and over 4500 g in those with diabetes.

PRIOR SHOULDER DYSTOCIA. [Smith and colleagues \(1994\)](#) identified recurrent shoulder dystocia in 5 of 42 (12 percent) women. Seven of these women had heavier infants in their subsequent pregnancy, but only two experienced recurrent shoulder dystocia. In contrast, [Baskett and Allen \(1995\)](#) found a much lower risk (1 to 2 percent) of recurrent shoulder dystocia.

SUMMARY. The [American College of Obstetricians and Gynecologists \(1997, 2000\)](#) reviewed studies classified according to the evidence-based methods outlined by the United States Preventive Services Task Force. It concluded that the preponderance of current evidence is consistent with the view that:

1. Most cases of shoulder dystocia cannot be predicted or prevented because there are no accurate methods to identify which fetuses will develop this complication.
2. Ultrasonic measurements to estimate macrosomia have limited accuracy.
3. Planned cesarean delivery based on suspected macrosomia is not a reasonable strategy.
4. Planned cesarean delivery may be reasonable for the nondiabetic with an estimated fetal weight exceeding 5000 g or the diabetic whose fetus is estimated over 4500 g.

MANAGEMENT

Because shoulder dystocia cannot be predicted, the practitioner of obstetrics *must* be well versed in the management principles of this occasionally devastating complication. Reduction in the interval of time from delivery of the head to delivery of the body is of great importance to survival. An initial gentle attempt at traction, assisted by maternal expulsive efforts is recommended. Overly vigorous traction on the head or neck, or excessive rotation of the body, may cause serious damage to the infant.

Some have advocated performing a large episiotomy, and adequate analgesia is certainly ideal. The next step is to clear the infant's mouth and nose. Having completed these steps, a variety of techniques have been described to free the anterior shoulder from its impacted position beneath the maternal symphysis pubis:

1. Moderate **suprapubic pressure** is applied by an assistant while downward traction is applied to the fetal head.
2. The **McRoberts maneuver** was described by [Gonik and associates \(1983\)](#) and named for William A. McRoberts, Jr., who popularized its use at the University of Texas at Houston. The maneuver consists of removing the legs from the stirrups and sharply flexing them upon the abdomen ([Fig. 19-10](#)). [Gherman and colleagues \(2000\)](#) analyzed the McRoberts maneuver using x-ray pelvimetry. They found that the procedure caused straightening of the sacrum relative to the lumbar vertebrae, along with accompanying rotation of the symphysis pubis toward the maternal head and a decrease in the angle of pelvic inclination. While this does not increase pelvic dimensions, pelvic rotation cephalad tends to free the impacted anterior shoulder. [Gonik and co-workers \(1989\)](#) tested the McRoberts position objectively with

laboratory models and found that the maneuver reduced fetal shoulder extraction forces.

3. [Woods \(1943\)](#) reported that, by progressively rotating the posterior shoulder 180 degrees in a corkscrew fashion, the impacted anterior shoulder could be released. This is frequently referred to as the **Woods corkscrew maneuver** ([Fig. 19-11](#)).

4. **Delivery of the posterior shoulder** consists of carefully sweeping the posterior arm of the fetus across the chest, followed by delivery of the arm. The shoulder girdle is then rotated into one of the oblique diameters of the pelvis with subsequent delivery of the anterior shoulder ([Fig. 19-12](#)).

5. [Rubin \(1964\)](#) recommended two maneuvers. First, the fetal shoulders are rocked from side to side by applying force to the abdomen. If this is not successful, the pelvic hand reaches the most easily accessible fetal shoulder, which is pushed toward the anterior surface of the chest. This most often results in abduction of both shoulders. This in turn produces a smaller shoulder-to-shoulder diameter and displacement of the anterior shoulder from behind the symphysis pubis ([Fig. 19-13](#)).

6. [Hibbard \(1982\)](#) recommended that pressure be applied to the fetal jaw and neck in the direction of the maternal rectum, with strong fundal pressure applied by an assistant as the anterior shoulder is freed. Strong fundal pressure applied at the wrong time may result in even further impaction of the anterior shoulder. [Gross and associates \(1987\)](#) reported that fundal pressure in the absence of other maneuvers " **resulted in a 77 percent complication rate and was strongly associated with (fetal) orthopedic and neurologic damage.**"

7. [Sandberg \(1985\)](#) reported the **Zavanelli maneuver** for cephalic replacement into the pelvis and then cesarean delivery. The first part of the maneuver consists of returning the head to the occiput anterior or occiput posterior position if the head has rotated from either position. The second step is to flex the head and slowly push it back into the vagina, following which cesarean delivery is performed. Terbutaline (250 ug subcutaneously) is given to produce uterine relaxation. [Sandberg \(1999\)](#) has subsequently reviewed 103 reported cases in which the Zavanelli maneuver was used. This maneuver was successful in 91 percent of cephalic cases and in all cases of breech head entrapments. Fetal injuries were common in the desperate circumstances under which the Zavanelli maneuver was used; there were eight neonatal deaths, six stillbirths, and 10 neonates suffered brain damage. Uterine rupture was also reported.

8. Deliberate **fracture of the clavicle** by pressing the anterior clavicle against the ramus of the pubis can be done to free the shoulder impaction. In practice, however, it is difficult to deliberately fracture the clavicle of a large infant. The fracture will heal rapidly, and is not nearly as serious as a brachial nerve injury, asphyxia, or death.

9. **Cleidotomy** consists of cutting the clavicle with scissors or other sharp instruments, and is usually used on a dead fetus ([Schramm, 1983](#)).

∴ **Symphysiotomy** also has been applied successfully as described by [Hartfield \(1986\)](#). [Goodwin and colleagues \(1997\)](#) reported three cases in which symphysiotomy was performed after the Zavanelli maneuver had failed—all three infants died and maternal morbidity was significant due to urinary tract injury.

[Hernandez and Wendel \(1990\)](#) suggested use of a *shoulder dystocia drill* to better organize emergency management of an impacted shoulder. The drill is a set of maneuvers performed sequentially as needed to complete vaginal delivery. The [American College of Obstetricians and Gynecologists \(1991\)](#) recommends the following steps—their sequence will depend on the experience and preference of the individual operator:

1. Call for help—mobilize assistants, an anesthesiologist, and a pediatrician. At this time, an initial gentle attempt at traction is made. Drain the bladder if it is distended.
2. A generous episiotomy (mediolateral or episiotomy) may afford room posteriorly.
3. Suprapubic pressure is used initially by most practitioners because it has the advantage of simplicity. Only one assistant is needed to provide suprapubic pressure while normal downward traction is applied to the fetal head.
4. The McRoberts maneuver requires two assistants. Each assistant grasps a leg and sharply flexes the maternal thigh against the abdomen.

These maneuvers will resolve most cases of shoulder dystocia. If they fail, however, the following steps may be attempted:

5. The Woods screw maneuver.
6. Delivery of the posterior arm is attempted, but if it is in a fully extended position, this is usually difficult to accomplish.
7. Other techniques generally should be reserved for cases in which all other maneuvers have failed. These include intentional fracture of the anterior clavicle or humerus and the Zavanelli maneuver.

HYDROCEPHALUS AS A CAUSE OF DYSTOCIA

Hydrocephalus is an excessive accumulation of cerebrospinal fluid with consequent cranial enlargement. For a number of reasons, discussed in [Chapter 41 \(p. 1119\)](#), it is uncommon with births at term. Associated defects are common, especially neural-tube defects. Normal fetal head circumference at term ranges between 32 and 38 cm. With hydrocephalus, the circumference not infrequently exceeds 50 cm, and sometimes it reaches 80 cm. Fluid volume is usually between 500 and 1500 mL, but as much as 5 L may accumulate. Breech presentation is found in at least a third of cases. Whatever the presentation, gross cephalopelvic disproportion is the rule, with serious dystocia the usual consequence ([Figs. 19-14 and 19-15](#)).

Hydrocephalus is somewhat more difficult to diagnose radiographically with a breech presentation, because the outline of a normal fetal head often appears enlarged to a degree suggestive of hydrocephalus. The difficulties inherent in radiological diagnosis are obviated by the use of sonography to compare the diameter of the lateral ventricles to the biparietal diameter of the head, and to evaluate the thickness of the cerebral cortex, as well as to compare the size of the head to that of the thorax and abdomen ([Clark and associates, 1985](#)).

MANAGEMENT

Most often, the size of the hydrocephalic head must be reduced if the head is to pass through the birth canal. Even with cesarean delivery, it may be desirable to remove cerebrospinal fluid just before incising the uterus in order to circumvent dangerous extensions of a low transverse or vertical incision and to avoid deliberately creating a very long vertical uterine incision. Removal of fluid by *cephalocentesis* was a mainstay in the historical management of fetal hydrocephalus with macrocephaly, but has come under considerable scrutiny in recent years. [Chervenak and colleagues \(1985\)](#) described results of cephalocentesis in 11 fetuses where the procedure was used to permit vaginal or cesarean delivery. Ten of these fetuses died either in utero or within 3 hours of delivery, and seven had intracranial bleeding at autopsy. [Chervenak and McCullough \(1986\)](#) advocate that use of cephalocentesis be limited to fetuses with severe associated abnormalities. They recommended that all others be delivered abdominally. Such management requires precise knowledge of the extent of fetal malformations, which is not always possible.

TECHNIQUE OF CEPHALOCENTESIS. This varies depending on fetal presentation. With cephalic presentation, as soon as the cervix is dilated 3 to 4 cm, the ventricles may be tapped transvaginally with a needle. An 8-inch, 17-gauge needle is satisfactory for promptly removing appreciable volumes of cerebrospinal fluid. With a breech presentation, labor can be allowed to progress and the breech and trunk delivered. With the head over the inlet and the face toward the maternal back, the needle is inserted transvaginally just below the anterior vaginal wall and into the aftercoming head through the widened suture line. To protect the birth canal from the needle as it is passed toward the head, the more distal part of the needle, including the point, may be covered with a segment of sterile plastic tubing about 6 inches long cut from an intravenous infusion set. Alternatively, fluid may be withdrawn through a needle inserted via the maternal abdomen into the fetal head. After the bladder is emptied and the skin is cleansed, the needle is inserted in the midline somewhat below the maternal umbilicus and inferior to the top of the fetal skull. The transabdominal approach to remove cerebrospinal fluid can also be used in the event of a cephalic presentation before trying to stimulate labor with oxytocin. The transabdominal approach has also been successfully applied in the breech fetus using ultrasound to guide the needle ([Osathanondh and associates, 1980](#)).

FETAL ABDOMEN AS A CAUSE OF DYSTOCIA

Enlargement of the fetal abdomen sufficient to cause dystocia is usually the result of a *greatly distended bladder* ([Fig. 19-16](#)), *ascites*, or *enlargement of the kidneys*

or liver. Occasionally, the edematous fetal abdomen may attain such proportions that spontaneous delivery is impossible. Enlargement of the fetal abdomen may escape detection until fruitless attempts at delivery have demonstrated an obstruction. An enlarged abdomen and intra-abdominal accumulation of fluid can usually be diagnosed by ultrasound. If the diagnosis is made before delivery, the decision must be made whether or not to perform an abdominal delivery ([Clark and associates, 1985](#)). In general, prognosis is very poor, regardless of the method of delivery.

TABLE 19-2. Incidence of Shoulder Dystocia According to Birthweight Grouping in Singleton Infants Delivered Vaginally in 1994 at Parkland Hospital

Birthweight Group	Births	Shoulder Dystocia (Percent)
= 3000 g	2953	0
3001-3500 g	4309	14 (0.3)
3501-4000 g	2839	28 (1.0)
4001-4500 g	704	38 (5.4)
> 4500 g	91	17 (19.0)
All weights	10,896	97 (0.9)
