Infrequently, the vagina may be obstructed by a congenital *annular stricture* or band. These strictures are unlikely to interfere seriously with delivery because they usually soften during pregnancy and yield before the oncoming head. An incision rarely is required.

Sometimes the upper vagina is separated from the rest of the canal by a *transverse septum* with a small opening, as shown in [Figure 35-1](#). Some of these are associated with in utero exposure to diethylstilbestrol (p. 918). Such a stricture is occasionally mistaken for the upper limit of the vaginal vault, and at the time of labor, the opening in the septum is erroneously considered to be an undilated external os. After the external os has dilated completely, the head impinges upon the septum and causes it to bulge downward. If the septum does not yield, slight pressure upon its opening usually will lead to further dilatation, but occasionally cruciate incisions may be required to permit delivery.

A communicating transverse vaginal septum as illustrated in [Figure 35-1](#) is better corrected prior to pregnancy. Such a lesion in pregnancy may lead to significant vaginal lacerations or to a cesarean delivery. The surgical correction should follow an attempt to identify the extent of the lesion. As illustrated in [Figure 35-1](#), a Foley catheter is inserted through the communicating tract. Normal saline is used to flush the area before filling the distal vagina. With saline filling the distal vagina, a vaginal probe sonogram is used to map the distal vaginal area and outline any additional cervical abnormalities. Following this mapping procedure and under the same anesthetic, a Z-plasty removal of the septum should be performed. Patency of the distal vagina must be maintained using a vaginal stent for several months, even in sexually active women.

ATRESIA. Complete congenital *vaginal atresia*, unless corrected operatively, forms an effective bar to pregnancy ([Chakravarty and colleagues, 2000](#)). Incomplete atresia can be a manifestation of faulty development as shown in [Figure 35-2A, C, and D](#), or it results from accidents such as scarring from injury or inflammation (p. 923). In most cases of partial atresia, because of pregnancy-induced tissue softening, obstructions are gradually overcome by pressure exerted by the presenting part. Less often, manual or hydrostatic dilatation or incisions or even cesarean delivery are necessary.

CERVICAL AND UTERINE ABNORMALITIES

TYPES OF CERVICES. As with development there are a number of cervical anomalies that are encountered.

1. *Single.* The normal cervix.
2. *Septate.* Cervix consisting of a single muscular ring partitioned by a septum. The septum may be confined to the cervix, or more often, it may be the downward continuation of a uterine septum or the upward extension of a vaginal septum.
3. *Double.* Two distinct cervixes, each resulting from separate müllerian duct maturation. Both septate and true double cervixes are frequently associated with a longitudinal vaginal septum. Unfortunately, many septate cervixes are erroneously classified as double.
4. *Single hemicervix.* This arises from a unilateral müllerian maturation.

DIAGNOSIS OF CERVICAL AND UTERINE MALFORMATIONS. Some of these are discovered by simple inspection or during bimanual examination. Frequently they are discovered at cesarean delivery or during manual exploration of the uterine cavity after delivery. Fundal notching, palpated abdominally, is most often indicative of a malformed uterus. Ultrasonic screening for uterine anomalies, although 98 percent specific, has only a 43 percent sensitivity ([Nicolin and associates, 1987](#)). It is difficult to distinguish a septate from bicornuate uterus without radiological examination, high-resolution sonography, direct visualization of the uterine cavity, and often laparoscopic examination. *Hysteroscopic examination* and *hystero-graphy* are of value in ascertaining the configuration of the uterine cavity. When combined with a laparoscopic confirmation of the absence or presence of an external division of the uterus and the presence or absence of a rudimentary uterine horn, virtually all uterine abnormalities can be described and classified accurately as subsequently described.

INCIDENCE. Accurate figures are not available for these anomalies. [Green and Harris \(1976\)](#) identified 80 uterine developmental anomalies during the course of 31,836 deliveries (1 in 400). They emphasized that detection was greatest during a period when one especially interested staff member espoused uterine exploration at delivery, and when an anomaly was suspected, hysterosalpingography was performed 6 to 8 weeks postpartum.

Sonography may be used to identify abnormal uterine development, although it lacks the precision of diagnosis provided by hysteroscopy and hysterosalpingography. During actual or suspected pregnancy, however, ultrasonic evaluation can be quite informative ([Raga and co-workers, 1996](#); [Salle and associates, 1998](#)). *Magnetic resonance imaging* may be more specific ([Kelley and associates, 1990](#)).

UROLOGICAL EVALUATION. When asymmetrical development of the reproductive tract is found, urological evaluation is indicated because of the frequent association of urinary tract anomalies. When there is uterine atresia on one side or when one side of a double vagina terminates blindly, an ipsilateral urological anomaly is common ([Fedele and associates, 1987](#); [Heinonen, 1983, 1984](#); [Wiersma and colleagues, 1976](#)).

AUDITORY EVALUATION. Up to a third of women with müllerian defects have been reported to have auditory defects ([Letterie and Vauss, 1991](#)). These are characterized as mild to severe sensorineural hearing defects in the high-frequency range.

UTERINE ANOMALIES IN WILMS TUMOR SURVIVORS. Survivors of this rare malignancy appear to have an increased incidence of urinary and reproductive tract anomalies ([Nicholson and colleagues, 1996](#)). The authors suggest that this observation might partially explain infertility noted in female survivors.

OBSTETRICAL SIGNIFICANCE OF CERVICAL ABNORMALITIES. Complete atresia of the cervix is incompatible with conception ([Chakravarty and associates, 2000](#)). Cicatricial *cervical stenosis* may follow various forms of cervical trauma (p. 924). Because there usually is tissue softening during pregnancy, cervical stenosis gradually yields during labor. In rare instances, stenosis may be so pronounced that dilatation appears improbable and cesarean delivery is necessary.

OBSTETRICAL SIGNIFICANCE OF UTERINE HYPOPLASIA OR AGENESIS BUTTRAM AND GIBBONS CLASS I. The range of anomalies seen with müllerian agenesis is shown in [Figure 35-2](#). As discussed, vaginal hypoplasia or agenesis renders pregnancy virtually impossible, and even in rare cases in which a uterus is reattached surgically to a neovagina, successful pregnancy is unusual. The various types of vaginal septa can be dilated, displaced, or surgically divided. The septate cervix functions remarkably well, but during labor there is possible danger of rupture and hemorrhage.

BUTTRAM AND GIBBONS CLASSES II THROUGH V. Major obstetrical difficulties arise from uterine anomalies ([Raga and co-workers, 1997](#)). Uterine defects that result from development of only one müllerian duct, or from lack of fusion, often give rise to a hemiuterus that fails to dilate and hypertrophy appropriately. This may result in a number of possible difficulties, including miscarriage, ectopic pregnancy, rudimentary horn pregnancy, preterm delivery, fetal growth restriction, abnormal fetal lie, uterine dysfunction, and uterine rupture ([Ben-Rafael and associates, 1991](#); [Michalas, 1991](#)). Surprisingly, even in conditions where only a uterine septum is present, miscarriage is increased ([Buttram and Gibbons, 1979](#); [Buttram, 1983](#)). Because of these obstetrical problems, each uterine defect is discussed within the classification outlined in [Table 35-1](#).

REPRODUCTIVE PERFORMANCE OF WOMEN WITH UNICORNUATE UTERUS (BUTTRAM AND GIBBONS CLASS II). Developmental anomalies that result in a unicornuate uterus are shown in [Figure 35-3](#). Its incidence in a series of 1160 uterine anomalies was 14 percent ([Zanetti and associates, 1978](#)). This was likely an underestimate, because the major diagnostic technique used was hysterosalpingography, which cannot identify noncommunicating rudimentary horns. [O'Leary and O'Leary \(1963\)](#) estimated that in 90 percent of unicornuate uteri with rudimentary horns there was no communication between the horns. The increased incidence of infertility, endometriosis, and dysmenorrhea in such cases is certainly more easily understood ([Fedele and associates, 1987, 1995](#); [Heinonen, 1983](#)).

As shown in [Table 35-2](#), pregnancy outcome is poor, and fetal wastage is over 40 percent. This likely is due to anatomical defects, and increased pregnancy loss may be partially explained by smaller uterine size or implantation of the zygote in a communicating rudimentary horn. The smaller hemiuterine size is almost certainly an explanation for the increased rates of preterm delivery, fetal growth restriction, breech presentation, dysfunctional labor, and increased cesarean delivery ([Andrews and Jones, 1982](#); [Fedele and associates, 1995](#); [Heinonen, 1983, 1997](#)).

Tubal pregnancies and pregnancies in the noncommunicating rudimentary horn are special problems. [Rolen and associates \(1966\)](#) reported that in 70 pregnancies with implantation in rudimentary horns, uterine rupture usually occurred prior to 20 weeks. Intraperitoneal hemorrhage in such cases may be massive and life-threatening, but rare cases of fetal survival have been reported ([Akhtar, 1988](#); [Heinonen and Aro, 1988](#)). In one case, surviving twins were delivered 8 days apart ([Nahum, 1997](#)). In another, pregnancy in a rudimentary noncommunicating horn was mistaken for uterine incarceration with sacculation ([Nwosu and Thatcher, 1993](#)). The more liberal use of magnetic resonance imaging may result in an earlier diagnosis of such problems in pregnancy ([Lawhon and associates, 1998](#)).

Pregnancy in a rudimentary uterine horn at 15 weeks is shown in [Figure 35-4](#). There was no connection between the rudimentary horn and the opposite horn or the vagina. Sperm had to migrate out the oviduct of the patent horn and cross transperitoneally to enter the oviduct attached to the rudimentary horn. At 15 weeks, the woman complained of sudden, severe, cramping lower abdominal pain. A tender mass was felt to the left of a somewhat enlarged uterus. Fetal heart motion was identified in this mass. At laparotomy, about 200 mL of blood was found free in the peritoneal cavity. A total hysterectomy and left salpingo-oophorectomy were performed. Her three previous pregnancies, all breech presentations, resulted in infants who weighed 750 g (expired), 1220 g (lived), and 2815 g (lived).

REPRODUCTIVE PERFORMANCE IN WOMEN WITH UTERINE DIDELPHYS (BUTTRAM AND GIBBONS CLASS III). Uterine didelphys is distinguished from bicornuate and septate uteri by the presence of complete reduplication of cervixes and hemiuterine cavities ([Fig. 35-5](#)). In a series of 26 such women, [Heinonen \(1984\)](#) reported that all had a longitudinal vaginal septum as well. Except for ectopic and rudimentary horn pregnancies, problems associated with uterine didelphys are similar to those seen with a unicornuate uterus. [Heinonen \(1984\)](#) reported an overall successful pregnancy outcome of 70 percent. In addition to 30 percent miscarriages, there was preterm delivery in 20 percent, fetal growth restriction in 10 percent, breech presentation in 43 percent, and the cesarean delivery rate was 82 percent. Subsequent trial of labor results in a higher uterine rupture rate ([Ravasia and colleagues, 1999](#)). The case shown in [Figure 35-6](#) is illustrative of these complications.

Multifetal gestation is unusual but not rare in women with uterine didelphys ([Heinonen, 1984](#); [Hochner-Celnikier and colleagues, 1983](#)). [Mashiach and associates](#)

(1981) reported a case of triplets with a delivery interval of 72 days!

REPRODUCTIVE PERFORMANCE IN WOMEN WITH BICORNUATE AND SEPTATE UTERI (BUTTRAM AND GIBBONS CLASSES IV AND V). In both classes IV and V (Figs. 35-7 and 35-8), there is a marked increase in spontaneous miscarriage. This is likely due to the abundant muscular tissue in the septum ([Dabirashrafi and colleagues, 1995](#)). The exception is for the arcuate uterus, which is merely a slight deviation from normal. Pregnancy losses in the first 20 weeks were observed by [Buttram and Gibbons \(1979\)](#) to be 70 percent for bicornuate and 88 percent for septate uteri. This extraordinarily high pregnancy wastage likely is due to partial or complete implantation on the largely avascular septum ([Fedele and co-workers, 1989](#); [Gast and Martin, 1992](#)). In 255 women with uterine malformations, three with a septate uterus had newborns with limb reduction defects ([Heinonen, 1999](#)). [Leible and associates \(1998\)](#) showed that two-thirds of women with lateral placental mullerian anomalies had implantation and that the nonplacental uterine artery in these cases had an abnormally high systolic/diastolic ratio. Once pregnancy is well established, overall outcome is associated with an increased incidence of preterm delivery, abnormal fetal lie, and cesarean delivery. Subsequent trials of labor have a high uterine rupture rate ([Ravasia and associates, 1999](#)).

A hysterosalpingogram usually cannot be used alone to differentiate the septate and bicornuate uterus, but transvaginal hysterosonography markedly improves the diagnostic accuracy ([Salle and associates, 1998](#)). Three-dimensional ultrasound also has been reported to improve diagnostic accuracy, but like hysterosonography, is not 100 percent accurate ([Raga and co-workers, 1996](#)). [Buttram and Gibbons \(1979\)](#) stressed the necessity of laparoscopy to establish the presence of an external uterine division. This diagnosis now can be established in a noninvasive manner using magnetic resonance imaging techniques ([Kelley and associates, 1990](#)). Subsequent trials of labor have a high uterine rupture rate ([Ravasia and associates, 1999](#)).

MANAGEMENT OF UTERINE ANOMALIES. Abnormal fetal presentations are commonly seen with an abnormal uterus. Attempts at external podalic version are less likely to be successful and may prove dangerous. If uterine dysfunction develops, it seems unwise to stimulate these defective uteri with oxytocin. Cesarean delivery is safer, but unfortunately the diagnosis is often unexpected.

CERCLAGE. Therapeutic and prophylactic cervical cerclages may be indicated in women with uterine didelphys and unicornuate or bicornuate uteri ([Golan and Caspi, 1992](#); [Golan and associates, 1990b, 1992](#); [Maneschi and colleagues, 1988](#); [Seidman and co-workers, 1991](#)). Transabdominal cerclage offers the best hope of successful pregnancy outcome in women with partial cervical atresia or cervical hypoplasia ([Hampton and colleagues, 1990](#); [Welker and associates, 1988](#)). [Caspi and associates \(1990\)](#) have described a modified Shirodkar cerclage that closes the internal os without resorting to an abdominal procedure. This technique is performed by making a small transverse incision at the anterior vaginal-bladder junction and advancing the bladder up to the level of the internal os. A large round needle is used to insert a monofilament suture around either side of the cervix under the vaginal mucosa. The suture is brought out from under the vaginal mucosa in the cul-de-sac and ligated. This procedure was performed in women with short or lacerated cervixes and in women with previous McDonald cerclage failures. The results obtained were similar to those achieved with a Shirodkar cerclage, but operative time and blood loss were less. Transvaginal cervical cerclage has been used successfully in DES-exposed women with cervical hypoplasia ([Ludmir and co-workers, 1991](#)). The question of whether to place a suture in both cervixes of a uterine didelphys is unresolved ([Heinonen, 1984](#)). There appears to be no reason for cerclage with an arcuate uterus. Cerclage should not be needed after successful resection of a uterine septum, but probably should still be used following abdominal metroplasties for uterine didelphys and bicornuate uteri. If active labor supervenes, procrastination in severing a cerclage ligature must be avoided because of the increased risk of uterine rupture.

METROPLASTY. Women with septate or bicornuate anomalies and poor reproductive outcomes are likely to benefit from uterine repair ([Ayhan, 1992](#); [Khalifa, 1993](#); [Musich, 1978](#); [Teti, 1991](#); [Zorlu, 1996](#), and all their co-workers).

Repair of a bicornuate uterus (classes IV-A and IV-B, [Fig. 35-7](#)) is by transabdominal metroplasty involving septal resection and recombination of the fundi ([Candiani and associates, 1990](#); [Gitsch and colleagues, 1990](#); [Kessler and co-workers, 1986](#)). Following repair, uterine activity is normal if anatomically symmetrical uterine horns have been conjoined ([Oliva and associates, 1992](#)).

Repair of a septate uterus (class V, [Fig. 35-8](#)) is best done by hysteroscopic resection of the septum ([Daly, 1989](#); [Grigoris, 1998](#); [Hassiakos, 1990](#); [Israel, 1984](#); [Jourdain, 1998](#), and all their co-workers). Excessive infusion of dextran during these hysteroscopic procedures can result in life-threatening pulmonary edema and induce a severe coagulopathy ([Vercellini and colleagues, 1992](#)). Laser septal resection apparently only adds time and expense to the procedure ([Candiani and associates, 1991](#)). Postoperative intrauterine device insertion and hormonal therapy are not necessary to prevent septal fusion ([Vercellini and associates, 1989](#)).

[Fedele and associates \(1988\)](#) reported improved pregnancy outcomes following abdominal metroplasty to correct uterine didelphys (class III, [Fig. 35-5](#)). Cerclage was used only once following uterine repair.

DIETHYLSTILBESTROL-INDUCED REPRODUCTIVE TRACT ABNORMALITIES

For nearly a quarter of a century, until the early 1970s, diethylstilbestrol (DES), a synthetic, nonsteroidal estrogen, was prescribed for an estimated 3 million pregnant women in the United States. Early uncontrolled reports claimed the drug was useful in treating abortion, preeclampsia, diabetes, and preterm labor. Other than its lack of effectiveness, the first serious problem to be linked to its use was identification of vaginal clear-cell adenocarcinoma in some daughters who were exposed in utero ([Herbst and co-workers, 1971](#)). It has been established that the risk of malignancy is from 0.14 to 1.4 per 1000 exposed daughters observed through the age of 24 years. Subsequently, it was established that these women also had an increased risk of developing small-cell cervical carcinoma ([Herbst, 2000](#)). Cervical intraepithelial neoplasia may also be more common ([Fowler and associates, 1981](#)).

Several non-neoplastic abnormalities of the vagina and cervix have been reported. The most frequent of these are vaginal adenosis and cervical ectropion. Major structural abnormalities of the vagina, cervix, uterus, and fallopian tubes have also been reported, and these are associated with an increased incidence of poor reproductive outcome ([Goldberg and Falcone, 1999](#); [Kaufman and colleagues, 2000](#); [Managan and associates, 1982](#); [Senekjian and co-workers, 1988](#)).

STRUCTURAL ABNORMALITIES. From a fourth to a half of women exposed to DES in utero have identifiable structural variations in the cervix and vagina. These include transverse septa, circumferential ridges involving the vagina and cervix, and cervical collars. Uterine cavity anomalies are evident on hystero-graphy in perhaps two thirds of exposed women ([Kaufman and associates, 1980](#)). Significantly smaller uterine cavities, shortened upper uterine segments, and T-shaped cavities have also been described ([Figs. 35-9 and 35-10](#)). About half of women with uterine defects also have cervical defects, especially a hypoplastic cervix. Finally, a variety of abnormalities of the oviduct have been described, including shortening, narrowing, and absence of fimbriae. [Kipersztok and colleagues \(1996\)](#) believe that hysterosalpingography remains the procedure of choice when compared with magnetic resonance imaging and transvaginal ultrasonography in identifying these anomalies.

REPRODUCTIVE PERFORMANCE. Lower conception rates are reported for women exposed to DES in utero ([Goldberg and Falcone, 1999](#); [Senekjian and co-workers, 1988](#)). Of those who conceive, spontaneous miscarriage, ectopic pregnancies, and preterm births are increased ([Herbst and co-workers, 1981, 1989](#); [Kaufman and associates, 1984, 2000](#)). The risk is greatest for women with demonstrated structural abnormalities.

ECTOPIC PREGNANCY. The incidence of ectopic pregnancy was reported to be 7 percent compared with none for controls ([Herbst and colleagues, 1989, 2000](#)). The etiology is likely due to tubal anomalies, but decreased uterine size may also be a factor ([Kaufman and associates, 1980, 1984](#)).

MISCARRIAGE AND PRETERM LABOR. The incidence of preterm labor is increased, likely due to uterine and cervical anomalies ([de Haas and associates, 1991](#)). Spontaneous abortion is increased, but the mechanism responsible for early abortion is not well understood. Cervical incompetence appears to be responsible for the increased incidence of midpregnancy losses and preterm labor ([Ayers and associates, 1988](#); [Ludmir and colleagues, 1987](#)). This was shown graphically by [Michaels and co-workers \(1989\)](#) in their serial prospective ultrasonic study of DES-exposed women. In 5 of 21 pregnancies, preterm cervical effacement and dilatation were identified using serial sonographic evaluation of the lower uterine segment, cervix, and vagina. A cerclage was applied in each of the five cases, and all continued to at least 36 weeks.

[Michaels and co-workers \(1989\)](#) advise these women that they are at risk for preterm labor. They are followed weekly with serial ultrasound surveillance of the lower uterine-cervicovaginal area, beginning at 14 weeks and continuing through 27 weeks. If there is progressive cervical effacement and dilatation, cerclage is performed. [Ayers and associates \(1988\)](#) and [Ludmir and co-workers \(1987, 1991\)](#) recommend cervical cerclage in most of these women, but especially those with cervical hypoplasia. [Hampton and colleagues \(1990\)](#) recommend abdominal cerclage for women with partial atresia or hypoplasia of the cervix.

INFERTILITY. Reduced fertility in these women is poorly understood but is associated with cervical hypoplasia and atresia. Surgical correction with vaginal and cervical reanastomosis has been accomplished ([Welker and co-workers, 1988](#)). Successful pregnancies have been achieved using a variety of different zygote intrafallopian transfer techniques ([Thijssen and associates, 1990](#)).

TREATMENT. Treatment of DES-exposed women consists of continued surveillance for development of clear-cell carcinoma of the vagina and cervix ([American College of Obstetricians and Gynecologists, 1996](#)). Annual examinations are adequate for most women, but they should be done twice yearly in women with extensive vaginal adenosis. Women with cervical or vaginal atypia should be examined as often as indicated. No specific therapy is recommended for adenosis in the absence of cellular atypia. The treatment of clear-cell carcinoma of the vagina involves irradiation or radical extirpation.

Surgical management of structural anomalies has been reported to improve reproductive performance. [Garbin and associates \(1998\)](#) recommend hysteroscopic metroplasty using a monopolar hook to resect the lateral spurs of the upper interior uterine walls of a T-shaped uterus. They also resect the arcuate fundus of the uterine cavity to further increase uterine volume. They reported a decrease in abortions from 88 to 13 percent and an increase in term deliveries from 3 to 88 percent. [Nagel and Malo \(1993\)](#) and [Katz and colleagues \(1996\)](#) reported improved pregnancy outcomes with hysteroscopic uterine resection using scissors, electrocoagulation, and a cutting electrode.

ACQUIRED REPRODUCTIVE TRACT ABNORMALITIES

VULVAR ABNORMALITIES

EDEMA. In women with the nephrotic syndrome and hypoproteinemia, troublesome vulvar edema may be problematic even by midpregnancy. Sometimes in normal women and especially those with severe preeclampsia, the vulva may become edematous during labor. Venous thromboses and hematomas may also cause edema and significant pain and make an episiotomy difficult to perform.

INFLAMMATORY LESIONS. Extensive perineal inflammation and scarring from *hidradenitis suppurativa*, *lymphogranuloma venereum*, or Crohn disease may create difficulty with vaginal delivery, episiotomy, and repair. A mediolateral episiotomy may prevent some of these difficulties and rectal lacerations.

BARTHOLIN ABSCESS. Drainage must be established whenever an abscess develops during pregnancy. In some cases, local analgesia will suffice but with large abscesses with cellulitis, drainage is best performed in the operating room. After incision and drainage, the cut edges of the abscess cavity, if actively bleeding, are sutured with fine chromic catgut. A gauze drain should be inserted to keep the ostium open until granulation is complete. Both aerobic and anaerobic bacteria can be identified in pus from such abscesses, but *Neisseria gonorrhoeae* has been identified in less than 10 percent. A broad-spectrum antibiotic should be administered until cellulitis resolves.

BARTHOLIN CYSTS. Because of pregnancy-induced hyperemia, treatment of asymptomatic cysts is best postponed until after delivery. Rarely is a labial cyst of sufficient size to cause difficulty at delivery. If so, needle aspiration will suffice as a temporary measure.

URETHRAL AND BLADDER LESIONS. Trauma to the urethra or infection of its glands may result in periurethral abscesses, cysts, and diverticulae. Abscesses usually resolve spontaneously, with asymptomatic cyst formation as a sequela. A urethral diverticulum may fill with debris that intermittently empties through the urethra to give rise to proteinuria of obscure etiology. In general, surgical excision of cysts or diverticulae should not be done during pregnancy.

Obstruction of labor by bladder stones resulting in cesarean delivery has been reported by [Rai and Ramesh \(1998\)](#) and by [Penning and associates \(1997\)](#). [Hendry \(1997\)](#) reviewed the literature concerning bladder tumors and concluded that cesarean delivery was required in some cases of bladder cancer.

CONDYLOMA ACUMINATA. Genital infection with the human papillomavirus results in condyloma acuminata, often called *venereal warts*. Treatment of these sexually transmitted lesions is discussed in [Chapter 57 \(p. 1505\)](#). In some cases, genital condyloma may be so extensive that vaginal delivery is undesirable.

FEMALE GENITAL MUTILATION. Inaccurately called female circumcision, female genital mutilation refers to medically unnecessary modification. Currently, such female mutilation is practiced in countries throughout Africa and the Middle East and in Muslim populations of Indonesia and Malaysia. It affects 80 to 110 million women worldwide. According to the [World Health Organization \(1992\)](#), female circumcision is significantly associated with poverty, illiteracy, and low status of women. Increasing numbers of such patients are seen by physicians in the United States. [Jones and colleagues \(1997\)](#) estimated that nearly 170,000 such women live in this country.

There are different kinds of surgical modifications to female genitalia. The [World Health Organization \(1997\)](#) classifies female genital mutilation into four types as listed in [Table 35-3](#). Others have described three forms. *Sunna* is the only type of female genital procedure that could properly be called circumcision. It is the least extreme form and consists of a subtotal clitoridectomy, the degree of which varies. When performed under sterile conditions—which is often not the case—long-term adverse physical consequences are rare ([Toubia, 1994](#)). The second type is known as *excision*. It consists of clitoridectomy and sometimes the removal of part or all of the labia minora. More severe medical consequences of this procedure can ensue.

The third and most extreme form is known as *infibulation* or *pharaonic circumcision* ([Fig. 35-11](#)). It consists of the removal of the entire clitoris, the whole labia minora, and at least two thirds of the labia majora. The two sides of the vulva are then stitched together by silk or catgut or are held together by thorns. A small opening is left—usually made by the insertion of a matchstick—for the passage of menstrual blood and urine. The legs of the girl are then bound from hip to ankle for up to 40 days so that scar tissue will form. Infibulation has the most severe medical consequences. [Knight and co-workers \(1999\)](#) reported that almost 80 percent of "circumcised" women who presented to the Royal Women's Hospital in Melbourne had undergone infibulation.

The procedure is typically performed at the age of 7 years, though it is known to be practiced on girls any time between infancy and puberty. The surgery is usually performed without anesthesia by a midwife or village woman. The instruments most commonly used to perform female genital mutilation are razor blades, kitchen knives, scissors, glass, and in some regions, the teeth of the midwife.

The most immediate danger of female genital mutilation is exsanguination. Severe infections may develop within a few days. A common problem with infibulated women is urinary retention due to wound pain and a narrowly sewn introitus. Long-term complications include chronic vaginal and uterine infections, which can lead to sterility, urinary infections and increasingly difficult urination, dysmenorrhea, dyspareunia, and apareunia ([Knight and colleagues, 1999](#); [Nour, 2000](#)). It may predispose to human immunodeficiency virus infection ([Kun, 1997](#)).

These women experience a number of obstetrical complications due to birth canal obstruction by scar tissue. For many reasons, they do not desire deinfibulation until pregnant. [Nour \(2000\)](#) recommends that this be done at midpregnancy under spinal anesthesia. If not, the scar must usually be cut open at delivery by anterior episiotomy. Failure to do so will result in severe vaginal tearing and can obstruct labor. If the circumcision scar is cut early enough, a conventional episiotomy may not be needed ([Baker and colleagues, 1993](#)). These women also suffer the consequences of anterior episiotomy such as vesicovaginal and rectovaginal fistulas.

The [American College of Obstetricians and Gynecologists \(1995\)](#) has long been opposed to female genital mutilation. In 1999, the College made available to its fellows a slide lecture kit containing materials that include photographs, illustrations, and case studies which address the following issues:

1. How to care for these women including during pregnancy.
2. How to discuss this procedure with such women in a culturally sensitive manner.
3. How to manage complication(s) due to these procedures.
4. How and when to refer these women for emotional and social needs.

Copies of this kit are available by calling the ACOG Distribution Center at 800-762-2264. Additional information about the ACOG Task Force on Female Circumcisions/Female Genital Mutilation can be obtained at 800-673-8444.

[The Council on Scientific Affairs of the American Medical Association \(1995\)](#) recommends support of legislation to eliminate the performance of female genital mutilation in the United States and to protect girls and women at risk of undergoing the procedure. The [American Academy of Pediatrics \(1998\)](#) similarly opposes all forms of female genital mutilation and encourages development of community educational programs for immigrant populations. We agree with [Barstow \(1999\)](#) that female genital mutilation is the penultimate form of gender abuse. Fortunately, albeit slowly, even in countries where this procedure has been routinely performed, laws are being enacted to prohibit such mutilation ([Ciment, 1999](#); [Eke and Nkanginieme, 1999](#)).

VAGINAL ABNORMALITIES

PARTIAL ATRESIA. Incomplete atresia may result from scarring from injury or inflammation. Following an infection in which much of the lining of the vagina sloughs, the vaginal lumen may be obliterated almost entirely during the healing process. Injuries that lead to extensive scarring, such as trauma during rape of a child, also may cause vaginal atresia.

During labor, partial atresias are usually overcome by pressure exerted by the presenting part. Less often, manual or hydrostatic dilatation or incisions are necessary. If the structure is so resistant that spontaneous dilatation appears improbable, cesarean delivery is performed early in labor.

GARTNER DUCT CYST. These cysts may protrude into the vagina and even through the introitus to such a degree that they may be confused with a *cystocele*. During labor, cystocele may be managed successfully by bladder catheterization and upward manual pressure on the prolapsed anterior vaginal wall. A Gartner duct cyst may slip above the presenting part; if it does not, the cyst may be aspirated.

GENITAL TRACT FISTULAS FROM PARTURITION. In obstructed labor, the tissues of various parts of the genital tract may be compressed between the fetal head and the bony pelvis. If the pressure is brief, it is without significance; but if it is prolonged, necrosis results and is followed in a few days by sloughing and perforation. In most cases, the perforation develops between the vagina and the bladder, giving rise to a *vesicovaginal fistula*. Miklos and colleagues (1995) described a *vesicouterine fistula* that developed following vaginal delivery after a prior low-transverse cesarean delivery. In other rare cases, the anterior cervical lip is compressed against the symphysis pubis, and an abnormal communication eventually is established between the cervical canal and the bladder, a *vesicocervical fistula*. If the woman has no infection, the fistula may heal spontaneously. More often it persists, requiring subsequent repair.

CERVICAL ABNORMALITIES

STENOSIS. Cicatricial *cervical stenosis* may follow extensive cauterization or difficult labor associated with infection and considerable tissue destruction (Cardwell, 1988; Melody, 1957). Of the 10 cases of severe cervical dystocia following cervical treatment reported by Gibbs and Moore (1968), previous conization was responsible in six. Cryotherapy and laser therapy are less likely to produce stenosis (Spitzer and colleagues, 1995). Likewise, large-loop excision of the transformation zone (LLETZ) with diathermy loop does not seem to impair subsequent pregnancy outcome (Cruickshank and associates, 1995). Amputation of the cervix, with suturing to effect hemostasis and promote reepithelialization, may lead to stenosis, although cervical incompetence is much more likely.

Due to cervical effacement with labor, a *conglutinated cervix* may undergo complete obliteration, but the cervical os may not dilate. Thus, the presenting part is often separated from the vagina by only a thin layer of cervical tissue. Ordinarily, complete dilatation promptly follows pressure with a fingertip, although in rare instances manual dilatation or cruciate incisions may be required. Cervical stenosis almost always yields during labor.

CARCINOMA OF THE CERVIX. Dystocia may be caused by extensive cervical infiltration by carcinoma because dilatation is inadequate even with uterine contractions. Carcinoma of the cervix complicating pregnancy is discussed in Chapter 55 (p. 1450).

UTERINE DISPLACEMENT

ANTEFLEXION. Exaggerated degrees of antelexion frequently observed in early pregnancy are without significance. In later months, particularly when the abdominal wall is very lax, the uterus may fall forward. The sagging occasionally is so exaggerated that the fundus lies considerably below the lower margin of the symphysis pubis. Marked antelexion of the enlarging pregnant uterus usually is associated with *diastasis recti* and a pendulous abdomen. When the abnormal uterine position prevents the proper transmission of uterine contractions to the cervix, cervical dilatation, as well as engagement of the presenting part, is impeded. Marked improvement may follow maintenance of the uterus in an approximately normal position by means of a properly fitting abdominal binder.

RETROFLEXION. The retroflexed uterus is not a pathological finding in itself. Treatment is seldom needed during pregnancy, and an exception is in the rare circumstance in which the growing retroflexed uterus remains incarcerated in the hollow of the sacrum (Fig. 35-12). Women with a retroflexed uterus should be evaluated frequently early in the second trimester to ensure that the uterus is not incarcerated.

Symptoms from an incarcerated uterus usually include abdominal discomfort and inability to void. Acute urinary retention may also occur (Myers and Scotti, 1995). As pressure from the full bladder increases, small amounts of urine are passed involuntarily, but the bladder never empties entirely— *paradoxical incontinence*. Urinary obstruction can be so severe as to cause azotemia. With relief of obstruction, there may be a marked diuresis. After bladder catheterization, the uterus can usually be pushed out of the pelvis when the woman is placed in the knee-chest position. Occasionally spinal analgesia or general anesthesia will be necessary to effect repositioning. Seubert and associates (1999) used colonoscopy to dislodge an incarcerated uterus in five women. When passed above the level of the fundus, the endoscope causes anterior pressure to dislodge the uterus. A catheter is left in place until bladder tone returns. Insertion of a soft pessary usually will prevent reincarceration. Lettieri and colleagues (1994) described seven cases of uterine incarceration of which three were not relieved by these simple procedures. In two women, laparoscopy was used at 13 to 14 weeks to displace the uterus out of the pelvis using the round ligaments for traction.

SACCUATION OF THE UTERUS. Persistent entrapment of the pregnant uterus in the pelvis may result in an anterior uterine sacculation. Friedman and associates (1986) reported a posterior uterine sacculation following aggressive treatment for intrauterine adhesions (Asherman syndrome).

Rarely, the persistently entrapped uterus produces few symptoms, and yet extensive dilatation of the lower portion of the body of the uterus takes place to accommodate the fetus (Jackson and associates, 1988; Lettieri and co-workers, 1994). In one case at Parkland Hospital, at the time of cesarean delivery, the Foley catheter bulb lay just above the urethra in the bladder at the level of the umbilicus. The cervix was at an equally high level. Most of the 2500-g living fetus, amniotic fluid, and fetal membranes were contained in a remarkably thin sacculation of the anterior wall of the lower segment. The fetal head was entrapped in the most superior part of the sacculation, along with three loops of cord, by a constricting ring of myometrium. The fundus of the uterus and the placenta were contained in the true pelvis beneath a sharp sacral promontory. After delivery, the uterus soon contracted and retracted to assume a more normal shape.

Spearing (1978) stressed the importance of describing the distorted anatomy. He suggested that the finding of an elongated vagina passing above the level of a fetal head deeply placed into the pelvis is suggestive of a sacculation or an abdominal pregnancy. He also recommended extension of the abdominal incision to above the umbilicus and delivery of the entire gravid uterus from the abdomen before an attempt was made to incise it. **This simple procedure will restore anatomy to the correct relationships and prevent inadvertent incisions into and through the vagina and bladder.**

Engel and Rushovich (1984) reported a true uterine diverticulum confused with sacculation. Finally, uterine retroversion can be mistaken for uterine sacculations (Hill and associates, 1993).

PROLAPSE OF THE PREGNANT UTERUS. The cervix, and occasionally a portion of the body of the uterus, may protrude to a variable extent from the vulva during the early months of pregnancy. As pregnancy progresses, however, the body of the uterus usually rises above the pelvis, and may draw the cervix up with it. If the uterus persists in its prolapsed position, symptoms of incarceration may develop during the third or fourth month.

Early in pregnancy, the uterus should be replaced and held in position with a suitable pessary. If, however, the pelvic floor is too relaxed to permit retention of the pessary, the woman should be kept recumbent as long as possible until after the fourth month. If much of the cervix persists outside the vulva and cannot be replaced, the pregnancy should be terminated. Successful pregnancies and even vaginal deliveries have been reported following sacrospinous uterosacral fixation of the uterus to correct severe uterine prolapse (Kovac and Cruickshank, 1993).

CYSTOCELE AND RECTOCELE. Attenuation of fascial support that normally is interposed between the vagina and the bladder leads to prolapse of the bladder into the vagina, or cystocele. Attenuation of fascia between the vagina and the rectum results in a rectocele. Urinary stasis associated with a large cystocele predisposes to infection. A large rectocele may fill with feces that, at times, can only be evacuated manually. During labor, both lesions can block normal fetal descent unless they are emptied and pushed out of the way. A cystocele often is associated with *urinary stress incontinence* due to loss of the posterior urethrovesical angle. This may be made worse during pregnancy by the enlarging uterus and increased intra-abdominal pressure. These women have low urethral closing pressures that do not increase sufficiently to compensate for the progressive increase in bladder pressure induced by the enlarging uterus (Iosif and Ulmsten, 1981).

ENTEROCELE. In rare instances, an enterocele of considerable size filled with loops of intestine may complicate pregnancy. If symptomatic, the protrusion should be replaced and the woman kept in a recumbent position. If the mass interferes with delivery, it should be pushed up or held out of the way.

Surgical repair of uterine prolapse, cystocele, rectocele, and enterocele should not be attempted during the antepartum or intrapartum periods. Definitive repair, often with vaginal hysterectomy for associated uterine prolapse and sterilization, should be carried out after pregnancy-induced pelvic hyperemia has subsided completely.

TORSION OF THE PREGNANT UTERUS. Rotation of the pregnant uterus, most often to the right, is common during pregnancy. Torsion of sufficient degree to arrest uterine circulation and produce an acute abdominal catastrophe, however, is rare. [Bakos and Axelsson \(1987\)](#) reported a case of severe levotorsion associated with repeated fetal heart rate decelerations that prompted cesarean delivery. As a consequence of the extreme uterine torsion, the incision inadvertently was made in the posterior side of the uterus! As emphasized by [Spearing \(1978\)](#), the uterus should be removed from the abdomen prior to making the uterine incision. [Sherer and colleagues \(1994\)](#) stress the fact that this condition can be confused with an abdominal pregnancy ([Chap. 34, p. 900](#)). The accuracy of an antepartum diagnosis may be improved with magnetic resonance imaging and the identification of the "X" sign ([Dietz and co-workers, 1998](#); [Nicholson and associates, 1995](#)). This sign is based upon the fact that the vagina is normally seen on magnetic resonance imaging as an H-shaped structure; but with torsion of the uterus and upper vagina, the vagina appears as an X-shaped structure. An extensive review of this subject has been provided by [Jensen \(1992\)](#).

UTERINE LEIOMYOMAS

Uterine leiomyomas or myomas, which are also erroneously called "fibroids," commonly are found during pregnancy. [Rice and colleagues \(1989\)](#) found that 1.4 percent of over 6700 pregnancies were complicated by myomas. [Katz and associates \(1989\)](#) reported that 1 in 500 pregnant women were admitted for a complication related to a myoma.

Uterine myomas may be located immediately beneath the endometrial or decidual surface of the uterine cavity (*submucous*), immediately beneath the uterine serosa (*subserous*), or may be confined to the myometrium (*intramural*). An intramural myoma, as it grows, may develop a significant subserous or submucous component, or both. Submucous and subserous myomas may at times be attached to the uterus by only a stalk (*pedunculated*). These may undergo torsion with necrosis to the extent that the myoma is detached from the uterus. At times, a subserous myoma may become *parasitic*, and much or all of its blood is supplied through a highly vascularized omentum.

Myomas during pregnancy or the puerperium occasionally undergo "red" or "carneous" degeneration that is caused by *hemorrhagic infarction*. The symptoms and signs are focal pain, with tenderness on palpation and sometimes low-grade fever. Moderate leukocytosis is common. On occasion, the parietal peritoneum overlying the infarcted myoma becomes inflamed and a peritoneal friction rub develops. Red degeneration is difficult to differentiate at times from appendicitis, placental abruption, ureteral stone, or pyelonephritis, but the imaging techniques discussed later will likely prove helpful ([Kawakami and associates, 1994](#)). Treatment consists of analgesia such as codeine. Most often, signs and symptoms abate within a few days, but inflammation may stimulate labor.

Myomas may become infected during the course of puerperal metritis or septic abortion. They are especially likely to do so if the myoma is located immediately adjacent to the placental implantation site or if an instrument, such as a sound or curette, perforates the myoma. If the myoma is infarcted, the risk of infection is increased, and the likelihood of cure of the infection, except by hysterectomy, is reduced.

EFFECTS OF PREGNANCY. The stimulatory effects of pregnancy on uterine myoma growth have been noted clinically for many years. These actions were later assumed to be via estrogen and progesterone receptors that have been identified in normal uterine tissue and myomas ([Soules and McCarty, 1982](#)). Actually, the normal rapid uterine expansion that occurs during pregnancy is likely a more complex mechanism mediated in part by estrogen, progesterone, and some growth factors, especially *platelet-derived growth factor* ([Mendoza and co-workers, 1990](#)).

Estrogen receptors are reduced in number in normal myometrium during the secretory phase of the menstrual cycle and during pregnancy ([Benassayag and colleagues, 1999](#)). In myomas, estrogen receptors are present throughout the menstrual cycle, but they are suppressed during pregnancy. Progesterone receptors are present in both myometrium and myomas throughout the menstrual cycle and pregnancy. The Ki-67 cell proliferation-associated antigen is more abundant in myometrial cells during pregnancy, but it is even higher in myomas throughout the menstrual cycle and pregnancy ([Kawaguchi and associates, 1991](#)). Thus, factors that stimulate normal uterine growth during pregnancy appear to be estrogen, progesterone, various growth factors, and an increase in cells with Ki-67 antigen.

Stimulatory effects of uterine myomas in the nonpregnant woman appear to be from increased estrogen and estrogen receptors, progesterone and progesterone receptors, Ki-67 cells, and *epidermal growth factor* (EGF) ([Ichimura and co-workers, 1998](#); [Lumsden and associates, 1988](#)). It is likely that EGF^1 is stimulated by estrogen.

These observations support the concept that the same or similar hormonal and growth factors that normally cause uterine growth during pregnancy, also stimulate growth of leiomyomas early in pregnancy. This may serve to explain the paradoxical observations that large myomas remain unchanged or decrease in size late in pregnancy. It is likely that during pregnancy, myoma estrogen receptors are downregulated due to massive amounts of estrogen. Without effective estrogen receptors, and thus estrogen action in the myomas, epidermal growth factor binding is also decreased.

[Lev-Toaff and co-workers \(1987\)](#), using serial ultrasonic monitoring, observed that only half of myomas changed significantly in size during pregnancy ([Table 35-4](#)). Specifically, during the first trimester, myomas of all sizes either remained unchanged or increased in size (early response due to increased estrogen). During the second trimester, smaller myomas (2 to 6 cm) usually remained unchanged or *increased* in size, whereas larger myomas become smaller (start of downregulation of estrogen receptors). Regardless of *initial* myoma size, during the third trimester, myomas usually remained unchanged or decreased in size (estrogen receptors downregulated). The importance of these observations is that an accurate prediction of myoma growth in pregnancy cannot be made.

EFFECTS OF MYOMA SIZE, LOCATION, AND NUMBER ON PREGNANCY. Several investigators have attempted to assess the effects on pregnancy of myoma size, location, and number ([Tables 35-5](#) and [35-6](#)). With respect to size alone, [Rice and associates \(1989\)](#) concluded that women with myomas greater than 3 cm had significantly increased rates of preterm labor, placental abruption, pelvic pain, and cesarean delivery. Tumors less than 3 cm were not clinically significant. [Lev-Toaff and colleagues \(1987\)](#) noted that as both size and number of myomas increased, there was a significantly higher frequency of retained placenta, fetal malpresentation, and preterm contractions. [Hasan and co-workers \(1990\)](#) found no association with respect to myoma size except for an increased likelihood of obstructed labor when myoma size was more than 6 cm. [Davis and associates \(1990\)](#) as well as [Roberts and co-workers \(1999\)](#) observed no relationship of complications with myoma size, location, or number.

[Coronado and co-workers \(2000\)](#) reviewed pregnancy outcomes in 2065 women with leiomyoma who were ascertained from Washington state birth certificates. Placental abruption and breech presentation were increased fourfold, first-trimester bleeding and dysfunctional labor twofold, and cesarean delivery sixfold. The likelihood of placental abruption appears to be increased if the placenta is in contact with or covers a uterine myoma ([Table 35-6](#)). Abortion and postpartum hemorrhage were not increased unless the placenta was adjacent to or implanted over a myoma. Although the *incidence* of postpartum hemorrhage was not increased, if hemorrhage did occur, it was massive, unrelenting, and often corrected only by hysterectomy ([Hasan and associates, 1990](#)). [Lev-Toaff and colleagues \(1987\)](#) found an increased incidence of retained placenta in cases with lower uterine segment myomas.

Several conclusions can be derived from these reports:

1. Growth of myomas during pregnancy cannot be predicted.
2. Placental implantation over or in contact with a myoma increases the likelihood of placental abruption, abortion, preterm labor, and postpartum hemorrhage.
3. Multiple myomas are associated with an increased incidence of fetal malposition and preterm labor.
4. Degeneration of myomas may be associated with a characteristic sonographic pattern.
5. The incidence of cesarean delivery is increased ([Vergani and colleagues, 1994](#)).

Serial ultrasonic examinations should be considered throughout pregnancy in women with uterine myomas.

CERVICAL MYOMAS. Myomas in the cervix or lower uterine segment may obstruct labor and may be confused with the fetal head. Sonograms from such a case early in pregnancy are shown in [Figure 35-13](#). At term, cesarean hysterectomy was necessary ([Fig. 35-14](#)). Myomas that lie within or contiguous to the birth canal earlier in pregnancy may be carried upward as the uterus enlarges, with relief of obstruction to vaginal delivery. A decision regarding the method of delivery should usually not

be made before the onset of labor.

IMAGING OF MYOMAS. The critical issue to be resolved after the detection of an abdominopelvic mass is its etiology. Ultrasound has helped tremendously not only in correctly identifying such masses but also in following the progression, regression, and response to therapy. Limitations of sonography in evaluating pelvic masses have been established ([Exacoustos and Rosati, 1993](#); [Kier and co-workers, 1990](#); [Strobel and associates, 1994](#)). Ovarian masses (both benign and malignant), molar pregnancies, ectopic pregnancies, missed abortions, bowel abnormalities, and even fetal heads have all been confused with uterine myomas. In some cases the use of color Doppler imaging has been recommended ([Kessler and colleagues, 1993](#); [Locci and associates, 1993](#)).

To improve accuracy, some clinicians recommend that magnetic resonance imaging supersede, or at least serve as an adjunct to ultrasound ([Hricak and associates, 1992](#); [Karasick and colleagues, 1992](#); [Kier and co-workers, 1990](#)). Comparisons of ultrasound with magnetic resonance imaging have been made in the same women, and magnetic resonance imaging was found superior to ultrasound, especially in correctly identifying uterine myomas ([Weinreb and associates, 1990](#); [Zawin and colleagues, 1990](#)). Even with magnetic resonance imaging, however, errors are made in diagnosing uterine myomas ([Brown and associates, 1990](#)). This emphasizes again the importance and the difficulty in establishing a noninvasive diagnosis for an abdominopelvic mass during pregnancy. Several investigators have described techniques using magnetic resonance imaging which markedly improve the reliability of identifying uterine myomas when compared with other pelvic structures ([Mayer and Shipilov, 1995](#); [Schwartz and associates, 1998](#); [Torashima and colleagues, 1998](#)).

MYOMECTOMY DURING PREGNANCY. Myomectomy during pregnancy should be limited to myomas with a discrete pedicle that can be clamped and easily ligated ([Burton and associates, 1989](#)). Myomas should not be dissected from the uterus during pregnancy or at the time of delivery, because bleeding may be profuse and, at times, hysterectomy may be required. Although [Glavind and associates \(1990\)](#) maintain that a more aggressive approach will not increase pregnancy losses compared with nonsurgical controls; this remains to be confirmed. Typically, myomas will undergo remarkable involution after delivery; therefore, myomectomy should be deferred until involution has occurred.

MYOMECTOMY BEFORE PREGNANCY. Removal of an intramural leiomyoma is especially hazardous for subsequent pregnancy. **After myomectomy there is a significant risk of uterine rupture during a subsequent pregnancy.** Furthermore, rupture may occur early in gestation at a time remote from labor ([Golan and associates, 1990a](#)). When a myomectomy results in a defect through or immediately adjacent to the endometrium, subsequent pregnancies should be delivered before active labor begins. Arterial embolization of uterine myomas recently has been performed in nonpregnant women ([Katsumori and colleagues, 1999](#)). The outcome and complications in pregnancies following this procedure is unknown.

ENDOMETRIOSIS

Severe, active endometriosis is an uncommon complication of pregnancy. Bizarre and vexing clinical symptoms may be caused by rupture of an endometrial cyst. There may be clinical features suggestive of pyelonephritis, acute appendicitis, or tubal pregnancy ([Rossman and associates, 1983](#)). Rarely, an enlarging pelvic endometrioma may cause dystocia; but most women with endometriosis go through pregnancy and labor without complications.

ADENOMYOSIS

[Azziz \(1986\)](#) reviewed the literature from the prior 80 years and reported that adenomyosis and pregnancy coexisted in 17 percent of women over age 35. Fortunately, it was rarely associated with obstetrical or surgical problems. When complications occurred, however, they were serious and included uterine rupture, ectopic pregnancy, uterine atony, and placenta previa. Live births may follow treatment of adenomyosis with gonadotropin-releasing hormone agonists ([Hirata and co-workers, 1993](#); [Silva and colleagues, 1994](#)). The accurate, noninvasive diagnosis of adenomyosis is now possible using magnetic resonance imaging techniques ([Kataoka and co-workers, 1998](#); [Lipson and Hricak, 1996](#); [Troiano and colleagues, 1998](#)).

OVARIAN MASSES

Any type of ovarian mass may complicate pregnancy. The incidence of tumors and cysts varies with age groups studied, as well as the use of routine sonography during pregnancy. From their review, [Katz and colleagues \(1993\)](#) found an average incidence of adnexal masses of 1 in 200 pregnancies. [Whitecar and associates \(1999\)](#) reported an incidence of 1 in 1300 pregnancies of masses that required laparotomy. [Koonings and co-workers \(1988\)](#) reported finding one adnexal neoplasm for every 197 cesarean deliveries.

The most common ovarian tumors are cystic ([Fig. 35-15](#)). [Whitecar and associates \(1999\)](#) described 130 adnexal masses diagnosed during pregnancy; 30 percent were cystic teratomas, 28 percent were serous or mucinous cystadenomas, 13 percent were corpus luteal cysts, and 7 percent other benign cysts. Of the 130 masses, 5 percent were malignant. Half of malignancies were serous carcinomas of low-malignant potential. Similar observations were reported by [Sunoo and colleagues \(1990\)](#). [Hopkins and Duchon \(1986\)](#) found that benign cystic teratomas and corpus luteum cysts each accounted for about a third of adnexal masses. In a report by [Comerci and associates \(1994\)](#), half of 27 mature cystic teratomas in pregnancy were found at cesarean delivery.

The most frequent and most serious complication of benign ovarian cysts during pregnancy is torsion. This complicated 5 percent of the 130 adnexal masses reported by [Whitecar and colleagues \(1999\)](#). Torsion is most common in the first trimester, and may result in cyst rupture into the peritoneal cavity. Cyst rupture may also occur during labor or during surgical removal. When a tumor blocks the pelvis, it may lead to uterine rupture.

MANAGEMENT. Early in pregnancy, an ovary may be enlarged, creating a suspicion of neoplasm. Ovaries less than 6 cm in diameter usually are the consequence of corpus luteum formation. [Thornton and Wells \(1987\)](#) reported that with the advent of high-resolution sonography, a conservative approach to management of ovarian cysts might be adopted based upon their sonographic characteristics. They recommend resection of all cysts suspected of rupture, torsion, or obstruction of labor, and those over 10 cm in diameter because of the increased risk of cancer in large cysts. Cysts 5 cm or less could be left alone. Cysts between 5 and 10 cm in diameter also could be managed expectantly if they had a simple cystic appearance. [Whitecar and co-workers \(1999\)](#) caution against this approach because half of 41 women with a simple cyst on sonography had a neoplasm. Of these 20, there were two who had a serous tumor of low malignant potential. Most agree that if the 5- to 10-cm cysts contain septae or nodules, or if there are solid components, then the cysts should be resected.

[Fleischer and associates \(1990\)](#) recommend observation in asymptomatic women with masses less than 5 cm. If a mass increases in size, become symptomatic, or has sonographic characteristics that are suspicious, then malignancy should be strongly considered. Some of these changes include irregular septae, papillary excrescences, or large solid areas. [Caspi and co-workers \(2000\)](#) provided support for these recommendations. They described 49 women with ultrasonically diagnosed ovarian cystic teratomas that were less than 6 cm. Excluding abortions, there were 63 pregnancies during which no torsion, rupture, or labor obstruction developed.

[Hess and colleagues \(1988\)](#) recommend elective resection of any ovarian mass 6 cm or larger that persists after 16 weeks. They reported better perinatal outcome in such women compared with those in whom an emergency procedure was required for resection of a ruptured, twisted, or infarcted cyst. [Platek and colleagues \(1995\)](#) described such management of *persistent* adnexal masses that were 6 cm or greater—including those that were simple or complex. They cited an incidence of this complication as 1 in 1400 in over 43,000 women after 16 weeks. The study was retrospective and multi-institutional; thus management varied. Of 31 women with a persistent mass, 60 percent had operative intervention. Most of these (13 of 19) were benign cysts, and 6 of 19 were benign cystic teratomas. Of 12 women managed conservatively, five became symptomatic and benign ovarian cysts were drained percutaneously and had negative cytological findings. In another retrospective study, [Parker and co-workers \(1996\)](#) described laparoscopy between 9 and 17 weeks to remove a benign cystic teratoma in 12 women. Although 10 of 12 of these tumors—5 to 13 cm—ruptured intraoperatively, there was no evidence of peritonitis.

The major questions to be answered once a pelvic mass is discovered include the following:

1. What is the mass and is it malignant?
2. Is there a good likelihood that the mass will regress?
3. Will the mass result in dystocia and/or torsion and possible rupture?

Only time, serial ultrasonic surveillance, and labor will provide answers to the last two questions. As for the first question, [Kier and associates \(1990\)](#) reported that magnetic resonance imaging correctly identified the origin of unknown pelvic masses in 17 of 17 cases versus 12 of 17 cases (70 percent) using sonography. They concluded that magnetic resonance imaging was a valuable complement to sonography for preoperative evaluation. [Kurjak and Zalud \(1990\)](#) claim that transvaginal

color Doppler assessment of tumor vascularity can be used for better characterization of adnexal tumors and may potentially be useful as a screening test for ovarian malignancy. Most clinicians recommend exploratory laparotomy if a reasonable doubt exists as to the possibility of malignancy.

TUMOR MARKERS. Measurement of serum ovarian tumor markers are rarely helpful during pregnancy. [Frederiksen and associates \(1991\)](#) and [Montz and co-workers \(1989\)](#) reported that elevated serum alpha-fetoprotein values obtained during routine screening for neural-tube defects led to the diagnosis of an immature ovarian teratoma in two women. A similar discovery of an ovarian endodermal sinus tumor was reported ([van der Zee and associates, 1991](#)). The role of tumor markers CA54/61, CASA, CA15-3, inhibin, macrophage colony-stimulating factor, and CA125 remains unproven even for management of nonpregnant women with ovarian malignancies. Thus, use of these markers during pregnancy is even more problematical ([Devine and associates, 1994](#); [Spitzer and colleagues, 1998](#)).

CARCINOMA OF THE OVARY. Malignant ovarian neoplasms are unusual during pregnancy, but their incidence is probably increasing due to the recognition of borderline tumors of low malignant potential and the widespread use of ultrasound. The diagnosis and treatment of ovarian malignancies are discussed in [Chapter 55 \(p. 1452\)](#).

TABLE 35-2. Pregnancy Outcomes in Women with a Unicornuate Uterus

Outcome	Heinonen (1983)	Moutos et al. (1992)	Acien (1993)	Fedele et al. (1995)	Total
Patients	15	20	24	26	85
Pregnancies	35	36 ^a	55	57	183
Spontaneous abortions (%) ^b	4 (11)	13 (36)	12 (22)	33 (58)	62 (34)
Ectopic pregnancies (%) ^b	4 (11)	1 (2.8)	1 (1.8)	3 (5.2) ^c	9 (5)
Deliveries (%) ^b	27 (77)	22 (61)	42 (76)	21 (37)	112 (61)
Breech presentations ^d	9 (33)	—	13 (31)	—	—
Cesarean deliveries ^d	8 (30)	8 (36)	—	—	—
Preterm deliveries ^d	4 (15)	3 (14)	9 (21) ^e	5 (24)	21 (19)
Term deliveries ^d	23 (85)	19 (86)	33 (79)	16 (76)	91 (21)
Fetal survival ^b	25 (71)	21 (58)	39 (71)	20 (35)	105 (57)

^aThis number excludes four elective abortions.

^bOf all pregnancies.

^cThis number includes one blind horn pregnancy.

^dOf deliveries, this number excludes abortions and ectopic pregnancies.

^eThis number includes one preterm infant who did not survive.

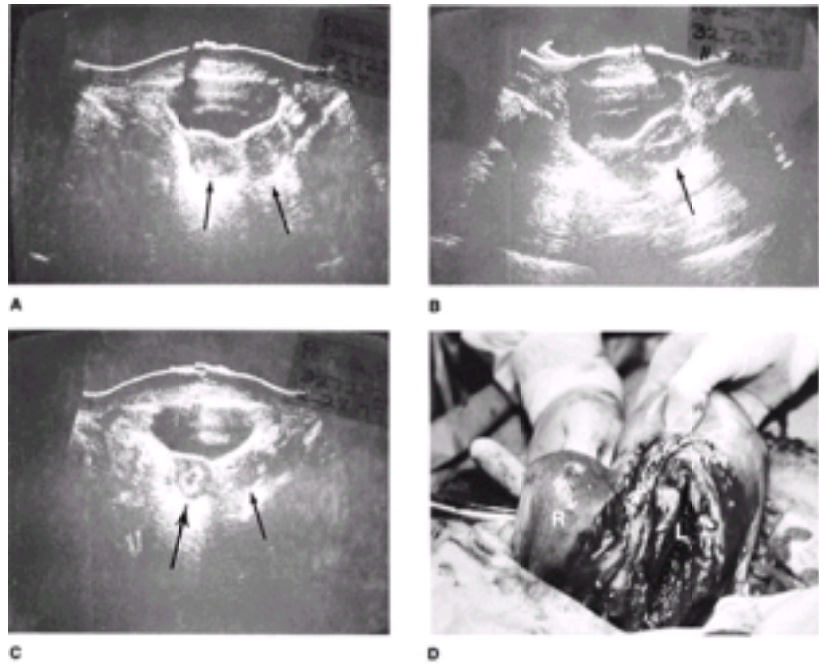

FIGURE 35-6.

Woman with uterine didelphys who had experienced seven consecutive abortions. In this eighth pregnancy, as illustrated in transverse sonogram **A**, two uterine cavities are apparent above the arrows. In sonogram **B**, a pregnancy ring, probably abnormal, is seen in the left uterine cavity above the arrow. In sonogram **C**, 90 days later, a normal pregnancy ring is seen in the right uterine cavity above the larger arrow but not in the left uterine cavity above the smaller arrow. A 2900-g healthy infant was delivered from the right uterus as a double footling breech by cesarean at 38 weeks' gestation. The left kidney was absent. Necrotic placental villi from the missed abortion were expelled from the left uterus 2 days postpartum. **D**. The same woman in **C** conceived again 3 years later in the left uterus (L). A growth-restricted fetus who thrived after cesarean birth was delivered at 37 weeks through a vertical uterine incision. The small right uterus (R) is larger than when nonpregnant.

SECTION X - FETAL ABNORMALITIES: INHERITED AND ACQUIRED DISORDERS

36. Genetics

Simply put, genetics is the study of biological variation. Medical genetics is the investigation of individual variation in the incidence of and susceptibility to disease, as well as disease mechanisms, response to therapy, and results of genetic tests. The genetic basis of normal biological variation as well as that of many common diseases is rapidly being elucidated, and soon will be incorporated into the daily practice of medicine.

Between 2 and 3 percent of children are born with a congenital birth defect. By age 18, approximately 8 percent are discovered to have one or more anomalies. While correct, these figures comprise only a small portion of genetic disease. Both susceptibility to most common diseases as well as the disease itself have a genetic basis. Finally, most cancers develop as the result of cumulative mutations. Thus, two thirds of the population will experience a disease with a genetic component in their lifetime, and if cancers are included, 91 percent will be affected ([Rimoin and colleagues, 1997](#)). The types and estimated frequencies of all categories of genetic conditions by age at diagnosis are listed in [Table 36-1](#).

The **Human Genome Project**, a joint venture of the United States Department of Energy and the National Institutes of Health, has as its goal the mapping of the complete human genome. As the result of unprecedented worldwide cooperation from both the private and public sectors, this enterprise was completed in 2000, and nearly 3 years ahead of schedule ([Collins, 1999](#)). It is hoped that mapping the approximately 80,000 genes that comprise the haploid human genome will facilitate further studies of normal and abnormal gene function, and will provide the basis for future diagnosis and therapy. Within a decade or so, consideration of genetic background and specific traits and susceptibilities may thus become part of routine patient care. If true, then knowledge of genetic principles will be essential for all practitioners.

ETIOLOGY OF BIRTH DEFECTS

Birth defects can arise in at least three ways ([Fig. 36-1](#)). In a **malformation** the fetus or structure is genetically abnormal and thus "programmed" to develop abnormally. An example is limb contractures resulting from diastrophic dysplasia. A **deformation** is when a genetically normal fetus develops in an abnormal uterine environment, causing structural changes. An example is oligohydramnios causing limb contractures. In a **disruption**, a genetically normal fetus suffers an insult resulting in disruption of normal development. An example is early amnion rupture causing limb deformities. These three examples illustrate that identical-appearing abnormalities, referred to as **phenocopies**, can have widely varying etiologies. It is apparent that phenocopies make the diagnosis of even relatively simple defects difficult.

Multiple structural defects or developmental abnormalities can also occur together in one individual. A cluster of several anomalies or defects can be a **syndrome**, meaning that all the abnormalities have the same cause—for example, trisomy 18; a **sequence**, meaning that all abnormalities occurred sequentially as the result of one initial insult—for example, oligohydramnios leading to pulmonary hypoplasia, limb contractures, and facial deformities; or an **association**, meaning that these particular anomalies occur together frequently, but do not seem to be linked etiologically—for example, *CHARGE association*, which is combination of coloboma, heart defects, atresia choanae, mental retardation, growth deficiency, and ear anomalies. Classification of anomalies can thus be challenging, and reclassification may be required as more is learned.

In this chapter the various known genetic causes of disease are considered, starting with the most obvious defects such as chromosomal abnormalities, and proceeding to the most obscure, illustrated by genetic imprinting. Descriptions of certain genetic diseases are provided for illustrative purposes only, with the caveat that these descriptions may be rendered incomplete or even inaccurate as understanding of the genetic basis of disease advances.

CHROMOSOMAL ABNORMALITIES

STANDARD NOMENCLATURE

By convention, karyotypes are reported using nomenclature agreed upon by the genetics community and codified in 1985 by the International System for Human Cytogenetic Nomenclature (ISCN). The total number of chromosomes is listed first, and corresponds to the number of *centromeres* present. This is followed by the sex chromosomes (XX or XY), and then by a description of any variation or abnormality detected. Specific abnormalities are indicated by standard abbreviations, such as *dup* (*duplicated*), *der* (*derivative*), *t* (*translocated*), and many more. The standard nomenclature for writing a karyotype is shown in [Table 36-2](#).

Chromosome abnormalities figure prominently in assessments of the impact of genetic disease, viz, 50 percent of embryonic deaths, 5 to 7 percent of fetal losses, 6 to 11 percent of stillbirths and neonatal deaths, and 0.9 percent of live-born children ([Hook, 1992](#); [Tolmie, 1995](#)).

ANEUPLOIDY

There are a total of 44 autosomes, arranged in pairs numbered from 1 to 22, and one pair of sex chromosomes. The most obvious or easily recognized chromosomal abnormalities are numerical. In these, the affected individual inherits an extra chromosome—**trisomy**; is missing a chromosome—**monosomy**; or has an abnormal number of haploid chromosome complements—**polyploidy**. The estimated incidence of aneuploidy and other chromosomal abnormalities among unselected newborns is shown in [Table 36-3](#). The incidence of chromosome abnormalities of 9 per 1000 is derived from data using high-resolution banding (350 to 550 bands), which allows accurate identification of deletions and rearrangements. While the pathophysiological basis of all aneuploidy is not completely understood, most trisomies and nonmosaic monosomies result from an abnormality in meiosis.

TRISOMY. Numerical abnormalities most often result from nondisjunction, in which the chromosomes pair up properly but then fail to separate. They can also occur after premature separation of the paired chromosomes, or from failure to pair up in the first place ([Gardner and Sutherland, 1996](#); [Sherman and colleagues, 1991](#)). The risk of nondisjunction increases with maternal age ([Table 36-4](#)). Oocytes are held suspended in midprophase of meiosis I from birth until ovulation, in some cases for 50 years! Aging is thought to break down chiasmata that keep paired chromosomes aligned. When meiosis is completed at the time of ovulation, nondisjunction leads to one daughter gamete receiving two copies of the chromosome in question, resulting in trisomy. The other gamete receives no copies, leading to monosomy if fertilized.

Although 3 to 4 percent of sperm and 10 to 20 percent of oocytes are aneuploid as the result of meiotic errors, these abnormal gametes are less likely to result in conception than normal gametes. If fertilization does occur, selection results in early loss of most aneuploid conceptions. Each of the 23 chromosome pairs is equally likely to be involved in a segregation error ([Kamiguchi and associates, 1993](#)). Despite this, only a few trisomies are typically identified because those causing the most severe abnormalities result in preimplantation or early loss. For example, trisomy 1 has never been reported even in the earliest abortus tissue. Trisomy 16 accounts for 16 percent of all first-trimester loss, but it is never seen later in pregnancy. Of the autosomal aneuploidies associated with survival past the first trimester, trisomies 13, 18, and 21 can result in term viable pregnancies in 57, 14, and 70 percent cases respectively ([Table 36-5](#)). In their review, [McIntosh and colleagues \(1995\)](#) confirmed that 32 percent of Down syndrome fetuses in women 35 years and older are lost in the interval between chorionic villus sampling at 10 weeks and amniocentesis at 16 weeks; half are lost by term.

MONOSOMY. Although non-dysfunction leads to both nullisomic and disomic gametes, there is no clinically recognized association between maternal age and monosomy. Most likely, monosomy is almost universally incompatible with life, and monosomic conceptions are lost prior to implantation ([Garber and co-workers, 1996](#)). As a rule, missing a portion of chromosomal material is much more devastating to the organism than having extra chromosome material. One exception is *monosomy X*, or *Turner syndrome*. Although it accounts for about 20 percent of first-trimester loss, a small proportion survive.

POLYPLOIDY. Abnormalities of ploidy account for about 20 percent of early losses and are rarely seen in late pregnancies. Two thirds of **triploidy** cases result from fertilization of one egg by two sperm. The remainder are caused by failure of one of the meiotic divisions, resulting in a diploid chromosome complement in the egg or more frequently, the sperm. If the extra set of chromosomes is paternal, the result is usually a partial hydatidiform mole, and no fetal structures are detected ([Chap. 32, p. 836](#)). Rarely, a fetus develops. In this situation, the origin of the extra chromosomes determines the phenotype. With an extra maternal haplotype (digynic), the fetus and placenta will be severely growth restricted. If the extra haplotype is paternal (diandric), the fetus may be relatively normal in size but the placenta will be abnormally large and cystic. Triploides of either kind can be dysmorphic. If a woman has a triploid pregnancy involving a fetus that survived past the first trimester, the recurrence risk is 1 to 1.5 percent, which justifies offering prenatal diagnosis in subsequent pregnancy ([Gardner and Sutherland, 1996](#)).

Tetraploids are always 96, XXXX or 92, XXYY, indicating that they result from postzygotic failure to complete an early cleavage division ([Thompson and colleagues, 1991](#)). The recurrence risk for tetraploidy is minimal.

PATERNAL EFFECTS

Unlike advanced maternal age, there is no association between aneuploidy and paternal age. This likely is because aneuploid sperm cannot fertilize an egg. Advanced paternal age does, however, logarithmically increase the risk of new mutations causing autosomal dominant diseases ([Friedman, 1981](#)). These new mutations may also be a factor in early pregnancy loss. The absolute frequency of new autosomal dominant mutations among newborns whose fathers are 40 years old is at least 0.3 percent. In one example, [Orioli and colleagues \(1995\)](#) compared nonfamilial cases of three diseases caused relatively frequently by new mutations—achondroplasia, thanatophoric dysplasia, and osteogenesis imperfecta—with matched controls. Half of neonates with achondroplasia and thanatophoric dwarfism, and a third of those with osteogenesis imperfecta, were born to fathers above age 35. Marfan syndrome is another example.

There is some evidence that paternal age may affect the incidence of isolated structural abnormalities ([McIntosh and colleagues, 1995](#)). Finally, paternal chromosome abnormalities are increased when conception is induced by **intracytoplasmic sperm injection (ICSI)**. These fetuses are at increased risk to have Y chromosome deletions ([In't Velt and colleagues, 1997](#)). They do not appear to be at risk for other chromosome abnormalities ([ESHRE Task Force, 1998](#); [Loft and associates, 1999](#)).

AUTOSOMAL TRISOMIES

TRISOMY 21. This is also called **Down syndrome** after J.L.H. Down who described it in 1866. A trisomy 21 karyotype is shown in [Figure 36-2](#). Its incidence is 1 in 800 to 1000 newborns. Because it is the most common nonlethal trisomy, this condition is the focus of most genetic screening and testing protocols. Almost 95 percent of Down syndrome is due to maternal nondisjunction of chromosome 21—75 percent during meiosis I and 25 percent in meiosis II. The remaining cases result from mosaicism or translocation. Affected children have marked hypotonia, tongue protrusion, and a small head, flattened occiput, flat nasal bridge, and epicanthal folds with up-slanting palpebral fissures ([Fig. 36-3](#)). There is frequently loose skin at the nape of the neck, short and stubby fingers, and a single palmar crease, and the fifth fingers are curved inward (clinodactyly) due to absence or hypoplasia of the middle phalanx. Associated major abnormalities include heart defects (particularly endocardial cushion defects) in 30 to 40 percent, gastrointestinal atresias, neonatal or childhood leukemia, and thyroid disease. The intelligence quotient (IQ) ranges from 25 to 50, with a few individuals testing higher, and most affected children have social skills averaging 3 to 4 years ahead of their mental age. The chromosome region responsible for the mental deficit is located at 22q 22.13 to 22.2.

RECURRENCE RISK. Once a woman has had a child with trisomy 21 resulting from nondisjunction, her risk to have another with any trisomy is 1 percent until her age-related risk exceeds this; then her age-related risk predominates. This justifies offering invasive prenatal diagnosis. Parental chromosome studies are not necessary unless the trisomy was due to a translocation (approximately 3 percent).

Females with Down syndrome are fertile, and approximately a third of their offspring will have Down syndrome ([Scharrer and colleagues, 1975](#)). Males are almost always sterile, and only one case of reproduction has been reported ([Simpson and associates, 1982](#)).

TRISOMY 18. This is known as **Edward syndrome** and occurs in 1 in 8000 newborns. The incidence is much higher in the first trimester, but 85 percent of fetuses with this syndrome are lost between 10 weeks and term ([Snijders and colleagues, 1995](#)).

Trisomy 18 fetuses and neonates are usually growth restricted with a mean birthweight of 2340 g. Striking facial features include prominent occiput, rotated and malformed auricles, short palpebral fissures, and a small mouth ([Jones, 1997](#)). Virtually every organ system can be affected by trisomy 18. Almost 95 percent have cardiac defects, most commonly ventricular or atrial septal defect or patent ductus arteriosus. Horseshoe kidney, radial aplasia, hemivertebrae, clinched hands with overlapping fingers, and syndactyly may be present. Hernias, diastasis, or imperforate anus may be evident. These infants are usually feeble, have frequent apneic spells, and half die in the first week. Another 45 percent die before one year and those who survive past 12 months are profoundly retarded. There are rare reports of individuals with trisomy 18 surviving to age 10 or more.

In view of the extremely poor outcome, prenatal diagnosis should prompt discussion of pregnancy termination. If not chosen, the mode of delivery must be discussed. Because it is extremely unlikely that cesarean delivery will change the outcome, it is reasonable to plan vaginal delivery regardless of whether the fetus tolerates labor, recognizing that intrapartum fetal demise may occur. Fetuses with trisomy 18 commonly have fetal heart rate abnormalities during labor. Schneider and colleagues (1989) reported that the primary cesarean delivery rate was 56 percent in 48 pregnancies—85 percent of these were performed for "fetal distress."

TRISOMY 13. Known as **Patau syndrome**, trisomy 13 occurs in approximately 1 in 20,000 births. Common abnormalities include cardiac defects in 80 to 90 percent and holoprosencephaly in 70 percent. Other abnormalities are moderate microcephaly, microphthalmia, cleft lip and/or cleft palate, abnormal ears, omphalocele, polycystic kidneys, and radial aplasia. The occurrence of *cutis aplasia* (localized punched-out appearing scalp defects) and *polydactyly* together strongly suggests either trisomy 13 or the usually lethal deletion 4p. The median survival for infants is about 3 days, and 90 percent die within the first month. The few surviving trisomy 13 individuals are profoundly retarded. Counseling is approached as previously described with trisomy 18.

OTHER TRISOMIES. It is rare to see live-born infants with other autosomal trisomies, although mosaicism involving a few other autosomal chromosomes has been reported. Information concerning characteristic malformation patterns and genetic counseling for these aneuploidies can be provided by a genetic counselor.

SEX CHROMOSOME ABNORMALITIES

XXX AND XXY. [Robinson and colleagues \(1991\)](#) used Barr-body analysis to screen 40,000 infants consecutively born at two Denver hospitals between 1964 and 1974. Karyotypes were performed on those who screened positive, and 43 (1 in 930) infants with sex chromosome aneuploidy were identified. These children were then followed prospectively with annual physical and psychometric evaluations until age 24. Females with 47, XXX and males with 46, XXY (also known as Klinefelter syndrome) had very similar phenotypes. Both tended to be tall, but had no striking phenotypic abnormalities. Pubertal development in females was usually normal, but XXY males did not virilize and required testosterone therapy. While XXX females had normal fertility, XXY males were more likely to be infertile from gonadal dysgenesis and to have gynecomastia and small testicles. Neither XXX or XXY was strongly associated with mental retardation, but there was a great deal of variability in intellectual function. The IQ¹ range was 71 to 122 and the mean IQ of XXY males was 95 while that of XXX females was 87—both within normal limits, but lower than controls. Most XXX and XXY study subjects have developmental problems, speech disabilities, and neuromotor and learning disabilities.

Females with more than three X chromosomes (48, XXXX; 49, XXXXX) are likely to have physical abnormalities that are apparent at birth, and to exhibit varying degrees of mental retardation. For both males and females, a drop in IQ¹ occurs with each additional X chromosome.

47, XYY. These males are tall but phenotypically normal. They generally have normal intelligence, although their IQ¹s may be lower than those of their siblings. They often have learning disabilities. The syndrome was once associated with criminal or violent behavior, and the XYY karyotype has even been used as a defense in several sensational murder trials ([Brogger, 1985](#)). Most early reports were biased, however, because prisoners or men with serious psychological dysfunction were tested preferentially. In their prospective study, [Robinson and colleagues \(1997\)](#) found only an increased risk of emotional difficulties, including mild depression, and increased hyperactivity and aggressiveness in XYY men.

Males with more than two extra Y chromosomes (48, XYYY) or with both additional X and Y chromosomes (48, XXYY; 49, XXXYY) have obvious physical abnormalities and significant mental retardation.

45, X. This is called **Turner syndrome** and it is the only monosomy compatible with life. It is the most common aneuploidy in abortuses and accounts for 20 percent of chromosomally abnormal first-trimester losses. Its prevalence in live-born infants is about 1 in 5000 births. There are three distinct phenotypes. The first comprises 98 percent of 45, X conceptuses which are so abnormal that they are spontaneously aborted. A second group survives until the second or third trimester, but then presents with cystic hygroma and other stigmata of Turner syndrome, or as a fetal demise. Incredibly, considering the outcomes for the majority, the third group has a phenotype mild enough to be compatible with life. Survivors usually have relatively minor problems and normal intellectual capacity.

The tremendous range of phenotypes of 45, X may be explained by the finding that 45, X abortuses and stillbirths are generally nonmosaic with only one population of 45, X cells identified. In contrast, 45, X survivors have a high incidence of mosaicism with two or more populations of cells identified; for example, some 45, X; some 46, XX or XY ([Held and colleagues, 1992](#); [Saenger, 1996](#)). It is likely that this nonlethal Turner syndrome does not occur as the result of maternal age-related meiotic nondisjunction, but rather as the result of a postzygotic mitotic error. This causes one population of cells in a zygote to lose an X chromosome during mitotic cleavage.

The missing X chromosome does not appear to be lost randomly, as the maternal X is retained in 80 percent of all surviving 45, X cases ([Cockwell and colleagues, 1991](#); [Hassold and associates, 1991](#)). If ultimately the majority of cells are 45, X, that individual will have the Turner phenotype, but modified by the presence of the other cell populations ([Koeberl and co-workers, 1995](#)). Several large studies have shown that up to half of surviving women with Turner syndrome are mosaics; the remainder may have mosaicism expressed only in tissues that are not routinely tested ([Fernandez, 1996](#); [Kim, 1999](#); [Nazarenko, 1999](#), and their colleagues).

Women with a 45, X or 45, X mosaic karyotype usually have a fairly specific phenotype. This includes short stature, broad chest with widely spaced nipples, congenital lymphedema with puffy fingers and toes, low hairline with webbed posterior neck, and minor bone and cartilage abnormalities. Ovarian dysgenesis and infertility are found in over 90 percent, who will require life-long hormone therapy beginning just before adolescence. Mosaicism can modify this phenotype, for example, a 46, XY cell line usually results in increased height. Some mosaic individuals with a normal 46, XX cell line may reproduce, although as a rule they have premature ovarian failure ([Saenger, 1996](#)). Between 30 and 50 percent have a major cardiac malformation, and most of these have aortic coarctation or bicuspid aortic valves and may develop subsequent aortic dissection. Intelligence is generally in the normal range, however, 45, X females have visual-spatial organization deficits and difficulty with nonverbal problem solving and interpretation of subtle social cues ([Jones, 1997](#)).

Deletions of portions of the X chromosome can also produce features of Turner syndrome. Deletion or complete absence of the short arm of the X chromosome results in short stature, while loss of the long arm results in streak ovaries and amenorrhea. As discussed later, the same phenotypes are found with isochromosomes consisting of either the long or short arms of X.

CHROMOSOMAL DELETIONS

A deletion refers to a portion of a chromosome that is missing. These are usually described by the location of the two chromosomal break points or, if the deletion is common, by an eponym—for example, **del 5p** is also called **cri du chat syndrome**. Most deletions occur during meiosis and result from malalignment or mismatching during pairing of homologous chromosomes. If the two chromosomes are not aligned properly, the unaligned loop may be deleted ([Fig. 36-4](#)). If the mismatch remains and the two chromosomes recombine, the result may be a deletion in one and a duplication in the other. If a deletion is identified, the parents should be tested to find if it is associated with a familial translocation that would have a recurrence risk.

CHROMOSOMAL BANDING. Recognition of a deletion during cytogenetic analysis is facilitated by various staining methods used to create light and dark chromosome bands. These banding patterns are unique and allow identification of each chromosome as well as recognition of missing segments. Recently, several genetic conditions have been identified that are caused by **microdeletions**—deletions too small to be detected by older methods. These may be recognized with high-resolution banding and molecular techniques, or by fluorescence in situ hybridization using a probe for the deleted region ([Driscoll and colleagues, 1993](#); [Korf, 2000](#)).

The genes in a deleted chromosome segment often control individual traits. **Contiguous gene deletion syndromes** usually involve serious but unrelated phenotypic and functional abnormalities. Although deletions can occur in any area of any chromosome, some now discussed are found more frequently than expected by chance alone. This is probably because certain regions are predisposed to breakage.

DELETION 4p. Known as **Wolf-Hirschhorn syndrome**, this is deletion of material from the short arm of chromosome number 4. There is marked fetal growth restriction, hypotonia, characteristic facial appearance, severe mental deficiency, and posterior midline scalp defects (cutis aplasia). Children often have severe seizures and seldom survive childhood. Approximately 85 percent of deletions occur de novo, and in 80 percent the deleted chromosome is paternal.

DELETION 5p. The partial deletion of the short arm of chromosome 5 causes the **cri du chat syndrome**. Affected infants are growth restricted, hypotonic, and severely retarded. They are sometimes identified by their mewling, high-pitched, catlike cry, attributed to abnormal laryngeal development.

SHPRINTZEN SYNDROME AND DIGEORGE SEQUENCE. These both result from the same 22q11.2 microdeletion ([Driscoll and colleagues, 1993](#)). Shprintzen syndrome is also called **velo-cardio-facial syndrome**. Individuals with this deletion have cleft palate, velopharyngeal incompetence, prominent nose, a long face with retruded mandible, cardiac defects, learning difficulties, and short stature. By contrast, the DiGeorge sequence is characterized by thymus hypo- or aplasia, parathyroid hypo- or aplasia, and aortic arch malformations. Typical facies includes short palpebral fissures, micrognathia with a short philtrum, and ear anomalies. Mental development and heights are usually normal.

It has been hypothesized that DiGeorge and Shprintzen syndromes represent two extremes of a spectrum of abnormalities associated with the identical deletion. It is also possible that each condition represents a separate contiguous gene deletion syndrome of genes located at 22q11.2, but that current cytogenetic methods cannot distinguish differences between the two.

CHROMOSOMAL TRANSLOCATIONS

RECIPROCAL TRANSLOCATIONS. A reciprocal or double-segment translocation is a rearrangement of chromosomal material in which breaks occur in two different chromosomes. The fragments are exchanged before the breaks are repaired. The rearranged chromosome is called a **derivative (der) chromosome**. If no chromosomal material is gained or lost in this process, it is a *balanced translocation*. Although the transposition of chromosome segments can cause abnormalities due to repositioning of specific genes, in most cases genetic function in the balanced carrier is not affected. Offspring who inherit either the two normal chromosomes or the two translocated chromosomes are also usually normal. Despite this, [Fryns and associates \(1992\)](#) reported a 6.4 percent total risk (including background) for anomalies with a balanced translocation.

Carriers of a balanced translocation can produce unbalanced gametes that result in abnormal offspring. As shown in [Figure 36-5](#), if one of the translocated chromosomes and one of the normal co-chromosomes are included in the oocyte or sperm, the result is monosomy for part of one chromosome and trisomy for part of another. The observed risk for each translocation can be provided by a genetic counselor, but in general, translocation carriers identified after the birth of an abnormal child have a 5 to 30 percent risk of having unbalanced offspring. Carriers identified for other reasons, for example, during an infertility workup, have up to 5 percent risk, probably because their conceptions with unbalanced chromosome segments are nonviable.

ROBERTSONIAN TRANSLOCATIONS. These result from the centric fusion of two acrocentric chromosomes, which are 13, 14, 15, 21, and 22 ([Fig. 36-2](#)). Robertsonian translocations are common. Their incidence in newborns is approximately 1 in 1000, which is equal to all other translocations combined. Almost all translocations involve chromosome 14, with material translocated to 13, 14, or 15 most commonly ([Levitan, 1988](#)). Fusion at the centromeres results in the loss of one centromere and the *satellite regions* on the short arms. These regions contain only genes coding for ribosomal RNA, which are also present in multiple copies on other acrocentric chromosomes. As long as the fused q arms are intact, the translocation carrier is usually phenotypically normal. The normal carrier of a robertsonian translocation will have only 45 chromosomes because the number of centromeres determines the chromosome count.

Robertsonian carriers have reproductive difficulties. If the fused chromosomes are homologous, for example, made up of both copies of chromosome 21, the carrier makes only unbalanced gametes. Each egg or sperm contains either two copies of the translocated chromosome which would result in trisomy if fertilized, or no copy, which results in monosomy.

The fused chromosomes may be nonhomologous. While the most common translocation involves 14 and 21, any acrocentric chromosomes can be involved. Gametes produced in this situation could have any of six potential chromosome combinations, of which four would result in abnormal offspring. In general, the recurrence risk is 15 percent if carried by the mother, and 2 percent if carried by the father because several possible gametes would be nonviable. Robertsonian translocations are not a major cause of miscarriage and occur in less than 5 percent of couples with recurrent pregnancy loss ([Smith and Gaha, 1990](#)). Still, identification of these translocations has tremendous impact on reproductive plans, and may have implications for other family members. Chromosome studies should be obtained on both parents if their offspring is found to have a translocation trisomy. When robertsonian translocations occur spontaneously, neither parent is a carrier and the recurrence risk is low.

ISOCHROMOSOMES. These are composed of either two q (long) arms or two p (short) arms of one chromosome fused together. Isochromosomes are thought to arise when the centromere breaks transversely instead of longitudinally during meiosis II or mitosis. They also may result from a meiotic error in a chromosome with a robertsonian translocation. Robertsonian 21/21 translocation is a kind of isochromosome. An isochromosome made up of an acrocentric chromosome (q arms only) behaves like a homologous robertsonian translocation in that no important genetic material is lost. In these cases, the carrier is usually phenotypically normal but produces only abnormal gametes. Conversely, when an isochromosome involves nonacrocentric chromosomes that have p arms containing functional genetic material, the carrier is usually phenotypically abnormal and produces abnormal gametes. One of these isochromosomes is frequently lost during cell division. Thus, all the genes located on the lost chromosome will be deleted, and phenotypic abnormalities specific to that gene deletion result. An example is *isochromosome X*. The

carrier has an isochromosome with two q arms but is missing all the genes from the p arm. This causes the full Turner syndrome phenotype including streak gonads. An individual with an X isochromosome composed of only the two p arms has streak gonads, but not the short stature or any other characteristic features of the 45, X phenotype.

CHROMOSOMAL INVERSIONS

These inversions result when two breaks occur in the same chromosome, and the intervening genetic material is inverted before the breaks are repaired. Although no genetic material is lost or duplicated, the rearrangement may alter gene function. **Paracentric inversions** are those in which the inverted material is from only one arm, and the centromere is not within the inverted segment ([Fig. 36-6](#)). The carrier has either normal (balanced) gametes, or gametes that are so abnormal as to preclude fertilization. Thus, although infertility may be a problem, the risk of abnormal offspring is extremely low.

Pericentric inversions occur when the breaks are in each arm, and the inversion includes the centromere. Because of problems in alignment during meiosis, the carrier is at high risk to produce abnormal offspring. The risk can be calculated individually for each unique inversion. In general, however, the observed risk is 5 to 10 percent if ascertainment occurred after the birth of an abnormal child, and 1 to 3 percent if ascertainment occurred by some other means ([Gardner and Sutherland, 1996](#)).

RING CHROMOSOMES

When there are deletions from both ends of a chromosome, the ends may unite, forming a ring chromosome. If the deletions are substantial, the carrier is phenotypically abnormal. If only the telomeres are lost, all important genetic material is retained and the carrier is essentially balanced. However, the ring disrupts cell division during meiosis. This causes abnormal growth of many tissues with small stature, borderline to moderate mental deficiency, and minor dysmorphisms ([Gardner and Sutherland, 1996](#)).

A ring chromosome may occur de novo or may be inherited from a carrier. In all cases of parent-to-child transmission, the mother is the carrier. This may be because a ring chromosome somehow compromises spermatogenesis. The clinical significance of a ring chromosome depends on the amount and function of the lost genetic material. *Ring X chromosome* is associated with Turner syndrome. The ring configuration may interfere with normal chromosomal segregation and production of abnormal gametes and pregnancy loss.

CHROMOSOMAL MOSAICISM

This is defined as two or more cytogenetically distinct cell lines in the same individual. In many cases, mosaicism is a cell-culture artifact that must be differentiated from true mosaicism ([Claussen and co-workers, 1984](#)). While true mosaicism is rarely encountered either in a fetus or in amniocytes, *placental mosaicism* is relatively common. Chorionic villus sampling has shown that 2 percent of placentas are mosaic, although the associated fetus is usually normal ([Henderson and associates, 1996](#)). Such *confined placental mosaicism* likely results from nondisjunction during early mitotic divisions in one or more cells destined to become the placenta. Another mechanism is that the conceptus was trisomic, but "correction" occurred and the extra chromosome was lost in all fetal cells but only in some placental cells. Mosaicism likely is chromosome specific, and with chromosomes 2, 7, 8, 10, and 12, it is usually caused by mitotic error. Alternatively, mosaicism for chromosomes 9, 16, and 22 tends to result from partial correction of a meiotic error ([Robinson and colleagues, 1997](#)).

Phenotypic expression of mosaicism depends on many factors, including whether the cytogenetically abnormal cells involve the placenta, the fetus, parts of the fetus, or some combination. If an individual with somatic mosaicism has a high percentage of abnormal cells, the phenotype may be abnormal. Conversely, the phenotype of an aneuploid fetus may be ameliorated by a co-population of normal cells. Suspected but unproven mosaicism may account for the phenotype of surviving fetuses with Turner syndrome as discussed earlier. This may also explain phenotypic variation in some trisomic individuals who have high function.

Confined placental mosaicism may also have either positive or negative effects. It may play a role in survival of some cytogenetically abnormal fetuses. For example, trisomy 18 and 13 fetuses that survive to term may do so only because of early "correction" of the trisomy in some cells destined to become trophoblasts ([Kalousek and co-workers, 1989](#)). Conversely, some cytogenetically normal but severely growth-restricted fetuses may have placental chromosomal abnormalities that presumably impair placental and thus fetal growth ([Kalousek and Dill, 1983](#)). In these cases, the trisomic cells destined to become the fetus lost the extra chromosome (corrected), while some cells that became the placenta remained trisomic. Growth restriction is also influenced by which chromosome was lost during the "correction." If the fetus has two normal copies of the chromosome in question, but both copies came from the same parent, growth may also be impaired. This is referred to as *uniparental disomy* and is discussed later.

Gonadal mosaicism is confined to the gonads and may arise as the result of a mitotic error in the zygote. If the error occurs in cells destined to become the gonad, a portion of the germ cells may be abnormal. Because spermatogonia and oogonia continue to divide throughout fetal life, gonadal mosaicism could also occur as the result of a meiotic error in previously normal dividing germ cells. Gonadal mosaicism may explain de novo autosomal dominant mutations in the offspring of normal parents, causing such diseases as achondroplasia or osteogenesis imperfecta, or X-linked diseases such as Duchenne muscular dystrophy. It also explains the recurrence of such diseases in more than one offspring in a previously unaffected family. Because of the potential for gonadal mosaicism, the recurrence risk after the birth of a child with a disease due to a "new" mutation is approximately 6 percent.

SINGLE-GENE (MENDELIAN) DISORDERS

A mendelian disorder is caused by a mutation or alteration in a single locus or gene, in one or both members of a gene pair. Approximately 0.4 percent of the population has a genetic abnormality caused by a single-gene mutation discovered by age 25, and 2 percent will have single-gene disorder diagnosed during their lifetime ([Table 36-1](#)). As of December 2000, 12,126 monogenic disorders had been identified. While they are classified according to their mode of inheritance—11,357 autosomal, 632 X-linked, 37 Y-linked, and 60 mitochondrial—it must be emphasized that it is the *phenotype* that is dominant or recessive, not the genes. In some dominant diseases, for example, the normal gene may still be directing the production of normal protein, but the phenotype is determined by protein produced by the abnormal gene. Likewise, the heterozygous carrier of some recessive diseases may produce detectable levels of the abnormal gene product, but does not display features of the disease because the phenotype is directed by the product of the normal co-gene.

The expression of many so-called single gene disorders is strongly influenced by modifying genes, or by alterations in a combination of additional genes, often with environmental influences. Some common "single-gene disorders" affecting adults are listed in [Table 36-6](#). Although transmission patterns of these diseases are consistent with mendelian inheritance, their phenotypes are strongly influenced by modifying genes and environmental factors. Ironically, although single-gene (mendelian) disorders were the first genetic conditions identified, diseases caused solely by single genes are actually relatively rare.

AUTOSOMAL DOMINANT

If only one member of a gene pair determines the phenotype, that gene is considered to be dominant. Likewise, a gene with a dominant mutation specifies the phenotype in preference to the normal gene. The carrier of a gene causing an autosomal dominant disease has a 50 percent chance of passing on the affected gene with each conception. Importantly, several factors influence the ultimate phenotype of the affected individual.

PENETRANCE. This term describes whether or not the mutant gene is expressed at all. A dominant gene with some kind of recognizable phenotypic expression in all individuals who carry the gene has 100 percent penetrance. If the carrier of the abnormal gene displays *no* features of the associated disease, the gene is not penetrant. Penetrance is thus described by only two options, yes or no. The degree of penetrance of a specific gene is usually quantitatively expressed as the ratio of gene carriers who have any phenotypic characteristics associated with the altered gene to the total number of gene carriers. A gene that is 80 percent penetrant is expressed in some way in 80 percent of individuals who have that gene. Incomplete or reduced penetrance explains why some autosomal dominant diseases appear to "skip" generations.

Some mechanisms responsible for reduced penetrance have been elucidated in various disorders. For example, in retinoblastoma, reduced penetrance is explained by the fact that an individual carrying the gene must also acquire a somatic mutation affecting the normal retinoblastoma allele in order to develop the disease. If the normal allele is not mutated, the disease is not penetrant. Reduced penetrance does not explain all skipped generations. In some disorders, there is delayed onset of disease. Symptoms of Huntington disease, for example, may not become apparent until age 40. If the parent of an affected individual died before the abnormal gene had been expressed, the gene would appear to have skipped that generation.

EXPRESSIVITY. This refers to the *degree* to which the phenotypic features are expressed. If all individuals carrying the affected gene do not have identical

phenotypes, the gene has *variable expressivity*. Expressivity of a gene can range from complete or severe manifestations to only mild features of the disease. An example of a disease with variable expressivity is neurofibromatosis.

ANTICIPATION. This term describes a phenomenon observed in certain autosomal dominant diseases in which the disease symptoms seem to be more severe and to occur at an earlier age in each successive generation. Important examples are fragile X syndrome and myotonic dystrophy. Bias of ascertainment does account for many cases of apparent anticipation. When an individual with a severe phenotype is identified, the search for other affected family members often reveals milder cases in previous generations. The reverse rarely occurs, however, in that an individual with a very mild phenotype may not even be recognized, and family members in previous generations would not be evaluated. One explanation for anticipation is expansion of triplet repeat regions discussed later.

AUTOSOMAL RECESSIVE

These traits often are expressed only when both copies of the gene function identically. Thus, autosomal recessive diseases require that both gene copies be abnormal. Heterozygotes or carriers who have only one abnormal gene may have some phenotypic alteration, but only individuals who have two copies of the affected gene (homozygotes) have the disease. Phenotypic alterations in gene carriers are usually clinically undetectable, but may be recognized at the biochemical or cellular level. For example, many enzyme deficiency diseases are autosomal recessive. The enzyme level in the carrier will be about half of normal, but because enzymes are made in great excess this reduction usually does not cause disease. It does, however, represent a phenotypic alteration, and can be used for screening purposes ([Chap. 37, p. 978](#)). Other recessive conditions do not produce any phenotypic changes in the carrier, and can be identified only by molecular methods.

Besides screening programs, carriers are usually recognized only after the birth of an affected child or diagnosis of an affected family member. Because the disease is often present in only one generation, this type of inheritance is sometimes referred to as *horizontal transmission*. A couple whose child has an autosomal recessive disease has a 25 percent recurrence risk with each conception. The likelihood that a normal sibling of an affected child is a carrier of the gene is two out of three— $\frac{1}{4}$ of offspring will be homozygous normal, $\frac{2}{4}$ will be heterozygote carriers, and $\frac{1}{4}$ will be homozygous abnormal—thus, three of four children will be phenotypically normal and two of these three will be carriers. The carrier child will not have affected children, unless his or her partner is also a carrier or is affected. Because genes leading to rare autosomal recessive conditions have a low prevalence in the general population, the chance that a partner will be a gene carrier is low unless the couple is related or consanguineous (see below).

INBORN ERRORS OF METABOLISM. Most of these autosomal recessive diseases result from the absence of a crucial enzyme leading to incomplete metabolism of proteins, sugars, or fats. The metabolic intermediates that build up are toxic to a variety of tissues, resulting in mental retardation and other abnormalities.

PHENYLKETONURIA (PKU). This classical example of an autosomal recessive defect results from diminished or absent phenylalanine hydroxylase activity. Homozygotes are unable to metabolize phenylalanine to tyrosine. If the diet is unrestricted, incomplete protein metabolism leads to abnormally high phenylalanine levels that cause neurological damage, mental retardation, and hypopigmented hair, eyes, and skin. (Phenylalanine competitively inhibits tyrosine hydrolase which is essential for melanin production.) The disease is rare and affects 1 in 10,000 to 15,000 white infants. There is tremendous geographic and ethnic variation, with incidences ranging from 5 to 190 cases per million.

PKU is notable for two reasons. First, it is one of the few metabolic disorders for which treatment exists. Homozygotes who ingest a phenylalanine-free diet can avoid many of the clinical consequences of the disease. Thus, early diagnosis is important because limitation of dietary phenylalanine beginning in infancy is essential to prevent neurological damage. The special diet should be continued indefinitely; it is now believed that patients who abandon the phenylalanine-free diet may have some decline in IQ^1 . All states and many countries now mandate newborn screening for phenylketonuria, and about 100 cases per million births are identified worldwide.

The second reason is that phenylalanine readily crosses the placenta and high maternal serum levels can result in pregnancy loss. It can also induce birth defects such as microcephaly with mental retardation and cardiac defects in the heterozygote fetus who otherwise would not be affected. Importantly, these defects can be prevented with dietary treatment ([Williamson and associates, 1981](#)). Women with PKU who plan to conceive and are not already on a phenylalanine-restricted diet are counseled to adhere to the diet before conception and throughout pregnancy. The Maternal Phenylketonuria Collaborative Study enrolled nearly 600 women in a 12-year study ([Platt and colleagues, 2000](#)). They reported that maintenance of serum phenylalanine levels in the 160 to 360 $\mu\text{mol/L}$ (2 to 6 mg/dL) range significantly reduces the risk of fetal abnormalities.

CONSANGUINITY

Two individuals are considered consanguineous if they have at least one ancestor in common. The term usually refers to mating between third-degree relatives such as first cousins who share $\frac{1}{16}$ of genes, half uncle/aunt and niece/nephew, or more distantly related individuals. First cousin marriage is legal in 30 states and is actually preferred in some countries, for example, some parts of the Middle East ([Bennett, 1987](#); [Shami and colleagues, 1991](#)). Incest is defined as a sexual relationship between first-degree relatives such as parent/child or brother/sister, and is universally illegal.

Consanguineous unions are at increased risk to produce children with genetic abnormalities, specifically autosomal recessive or multifactorial diseases. This is because consanguineous partners are more likely to share the same deleterious genes. Individuals from very isolated or restricted religious or ethnic groups may also share many genes. Consanguinity or being a member of a restricted group often prompts a request for preconceptional counseling. First cousin marriages, the most frequent consanguineous mating, carry a twofold risk of abnormal offspring if there is no family history of genetic disease. If there is a family history of genetic disease, the risk increases appreciably.

First-degree relatives share half their genes, second-degree relatives share $\frac{1}{8}$, and third-degree relatives (cousins) share $\frac{1}{16}$. If first cousins marry and one of the partners has a sibling with a rare autosomal recessive disease, the risk of affected offspring is many times higher than if he or she had chosen an unrelated partner. Incest carries a much higher risk of abnormal outcome, because the partners have half their genes in common. Up to 30 to 40 percent of offspring of an incestuous union will be abnormal as a result of both recessive and multifactorial disorders ([Friere-Maia, 1984](#), [Nadiri, 1979](#)).

CO-DOMINANT GENES

If alleles in a gene pair are different from each other, but both are expressed in the phenotype, they are considered to be co-dominant. An example is the genes responsible for hemoglobinopathies. The individual with one gene directing production of sickle hemoglobin gene and the other directing production of hemoglobin C produces both S and C hemoglobins. Genes determining human blood type are also co-dominant, as individuals are capable of expressing simultaneously both A and B red-cell antigens.

X-LINKED AND Y-LINKED GENES

X-linked diseases are usually recessive. The best known X-linked recessive diseases are color blindness, hemophilia A, and Duchenne muscular dystrophy. Women carrying an X-linked recessive gene are generally unaffected, unless unfavorable lyonization—inactivation of one X chromosome in every cell—results in the majority of cells expressing the abnormal gene. When a woman carries a gene causing an X-linked recessive condition, there is a 50-50 chance of passing on the gene with each conception; thus, each son has a 50 percent risk of being affected and each daughter has a 50 percent chance of being a carrier.

Men carrying an X-linked recessive gene are usually affected because they lack a second X chromosome to express the normal dominant gene. When a man has an X-linked disease, all his sons will be unaffected because they cannot receive the affected X chromosome from him. In the rare situation in which the female partner of a man with an X-linked recessive disease is a carrier for the same disease, both their daughters and sons have a 50 percent chance of being affected. For complex reasons, fragile X syndrome does not conform to these rules of X-linked inheritance (see later discussion).

X-linked dominant disorders affect females predominantly because they tend to be lethal in male offspring. Examples include focal dermal hypoplasia, vitamin D-resistant rickets, and incontinentia pigmenti.

The Y chromosome carries genes important for sex determination and a variety of cellular functions such as spermatogenesis and bone development. Deletion of genes on the long arm of the Y chromosome results in severe spermatogenic defects, while genes at the tip of the short arm are critical for chromosome pairing during meiosis and fertility.

NON-MENDELIAN PATTERNS OF INHERITANCE

HEREDITARY UNSTABLE DNA

Mendel's first law states that genes are passed unchanged from parent to progeny. Barring the occurrence of new mutations, that law still applies to many genes or traits. Certain genes, however, are unstable, and their size and consequently their function may be altered as they are transmitted from parent to child.

FRAGILE X SYNDROME (MARTIN-BELL SYNDROME). This syndrome is the most common form of familial mental retardation. It accounts for 4 to 8 percent of all retardation in males and females in all ethnic and racial groups. Affected individuals have mild to severe mental retardation, autistic behavior, attention deficit-hyperactivity disorder, speech and language problems, narrow face with large jaw, long prominent ears, and macro-orchidism in postpubertal males. The carrier rate for clinically important fragile X mutations is variable between populations, ranging from about 1 in 165 to 1 in 1540 ([Rousseau and colleagues, 1995](#)). The incidence of the full fragile X syndrome is generally cited as 1 in 1000 males and 1 in 2000 females ([Rousseau and co-workers, 1995](#); [Turner and colleagues, 1996](#)).

The fragile X mutation is a region of unstable DNA on the X chromosome ([Kremer, 1991](#); [Oberle, 1991](#); [Yu, 1991](#), and all of their colleagues). The region is best described as a series of CGG (cytosine-guanine-guanine) repeats at Xq27. If the number of repeats and thus the region reaches a critical size, it can be methylated and thus inactivated ([Migeon, 1993](#)). The number of repeats and the degree of methylation determines whether or not an individual is affected ([Cuttillo, 1994](#)). Individuals carrying 2 to 49 repeats are phenotypically normal. Those carrying 50 to 199 repeats have a *premutation*, and although they are also phenotypically normal, they may have affected children. Those with more than 200 repeats have the *full* mutation and, if methylation occurs, are affected. The number of repeats usually remains stable when the gene is transmitted by a male. In the female, however, the gene can expand during meiosis. The risk of expansion with maternal transmission generally correlates with the number of repeats in the mother's premutation, and mutations with 100 repeats or more expand 100 percent of the time. Thus, if a woman carries a premutation that increases in size as she transmits it to her offspring, it is possible for her child to manifest fragile X syndrome ([Cuttillo, 1994](#)).

Approximately 80 percent of males and 50 to 70 percent of females carrying the full mutation are retarded ([deVries and co-workers, 1996](#); [Jones, 1997](#); [Sutherland and colleagues, 1991](#)). Males are moderately to severely affected, with an IQ¹ of 35 to 45, while the IQ in females is generally higher ([Nelson, 1995](#)). Surprisingly, 20 percent of males and 10 percent of females carrying the expanded gene are either unaffected or have the mildest phenotype. This phenotypic variability is caused by lyonization (in females) and mosaicism in both for the size of the expansion, the degree of methylation, or both ([Cuttillo, 1994](#)). Both types of mosaicism can occur during mitosis in the zygote, and thus cannot be predicted by analysis of parental genes or fetal cells ([Maddalena and colleagues, 1996](#); [Mingroni-Netto and associates, 1996](#)). The best example of this is provided by [Kruyer and colleagues \(1994\)](#), who described two sets of monozygotic carrier twins in which each twin had a very different phenotype due to discordant mosaicism.

Until recently, the diagnosis of fragile X syndrome was made using cytogenetic techniques, which were unreliable. With the use of restriction endonuclease digestion and Southern blot analysis, the number of CGG repeats and the methylation status of the gene can now be accurately determined (see discussion that follows). Amniocentesis may be preferred for prenatal diagnosis because methylation status is difficult to determine in chorionic villus cells. Women with a confirmed family or personal history of fragile X syndrome should be offered prenatal diagnosis. It is reasonable to refer individuals with a nonspecific history of mental retardation, developmental delay of unknown etiology, or autism for genetic evaluation. From 2 to 6 percent of individuals with these characteristics will be determined to have fragile X ([Curry and colleagues, 1997](#); [Wenstrom and associates, 1999](#)). Universal screening (screening of low-risk women), however, is controversial. It currently is not recommended by either the [American College of Medical Genetics \(1994\)](#) or the [American College of Obstetricians and Gynecologists \(1995\)](#), primarily because screening for fetal disease should not be considered unless accurate prenatal diagnosis is available.

MYOTONIC DYSTROPHY. This is the most common form of adult myopathy with an age of onset from birth to 70 years ([Jones, 1997](#)). Affected family members tend to have successively earlier and more severe symptoms with each generation. The affected gene on the long arm of chromosome 9 contains a region of unstable trinucleotide (CTG) repeats ([Buxton and co-workers, 1992](#)). Normal individuals have 3 to 30 repeats, and although they can expand up to 3000, an increase to as few as 40 has been associated with myotonic dystrophy. In contrast to fragile X, there are three distinct phenotypes, depending on the number of repeats. With around 100 repeats there is mild disease; with around 1300 there is a 90 percent chance of having the full syndrome; and individuals with an intermediate number from 200 to 800 have an intermediate phenotype ([Gennarelli and colleagues, 1996](#)). In contrast to fragile X, the number of repeats can increase from transmission from either parent. Increased repeats cause successively more severe symptoms, i.e., "anticipation."

HUNTINGTON DISEASE. This disorder is characterized by progressive chorea, bradykinesia, and rigidity with an insidious deterioration of intellectual function. The mean age at diagnosis is about 40 years. The gene on chromosome 4 contains a region of CAG triplet repeats. Normal individuals have 10 to 35 CAG repeats, while those with the disease have 36 to 121 repeats. Like myotonic dystrophy, there is a significant correlation between the number of repeats and the age of onset ([Andrew and colleagues, 1993](#)). Interestingly, there is also a correlation between *paternal* inheritance and early disease ([Clarke, 1990](#)). Thus, the gene appears to be most unstable when transmitted by the father.

OTHER DNA-TRIPLET REPEAT DISEASES. These include Friedrich ataxia, X-linked spinal and bulbar muscular atrophy (Kennedy disease), spinocerebellar ataxia types 1 and 2, dentato-rubro-pallido-luysian atrophy, and Machado-Joseph disease.

IMPRINTING

This term describes the process by which certain genes are inherited in an inactivated or *transcriptionally silent* state ([Hall, 1990](#)). This type of gene inactivation correlates directly with the gender of the transmitting parent and is reversible in the next generation. Imprinting affects gene expression by *epigenetic control*; that is, it is a factor that changes the phenotype without permanently altering the genotype. When a gene is inherited in an imprinted state, gene function is necessarily directed entirely by the co-gene inherited from the other parent. Thus, imprinting exerts an effect in part by controlling the "dosage" of specific genes. Certain important genes appear to be *monoallelic*; that is, under normal circumstances only one member of the gene pair is functioning—as opposed to most genes in the genome, which are bi-allelic.

Teleological reasons for imprinting are incompletely understood. The fetus carries the imprinting pattern inherited from its parents in all of its somatic cells but not in its germ cells. In the immediate post-zygote period, the inherited methylation pattern in germ cells is erased and a new imprinting pattern corresponding to the sex of the fetus is imposed. Thus, during reproduction, the subsequent adult will pass on the imprinting pattern unique to its own gender. One interesting example of imprinting concerns chromosomal deletion at 15q11-13 which causes two very different diseases. *Prader-Willi syndrome* is characterized by obesity and hyperphagia; short stature; small hands, feet, and external genitalia; and mild mental retardation. The other disorder is *Angelman syndrome*, which includes normal stature and weight, severe mental retardation, absent speech, and seizure disorder; ataxia and jerky arm movements; and paroxysms of inappropriate laughter. While both diseases are associated with the same deletion, if the maternally derived chromosome 15 region is missing the result is Angelman syndrome, and if the paternally derived chromosome 15 region is missing Prader-Willi syndrome results.

There are a number of other examples of imprinting important to obstetrician-gynecologists. *Complete hydatidiform mole*, which has a paternally derived, diploid chromosome complement, is characterized by the abundant growth of placental tissue, but no fetal structures ([Chap. 32, p. 836](#)). Conversely, *ovarian teratoma*, which has a maternally derived diploid chromosome complement, is characterized by the growth of various fetal tissues but no placental structures ([Porter and Gilks, 1993](#)). It thus appears that paternal genes are vital for placental development and maternal genes are essential for fetal development, but both must be present in every cell in order for normal fetal growth and development. This concept is also illustrated by triploidy, discussed earlier. Imprinting also is operative in some malignancies.

UNIPARENTAL DISOMY

This term describes the situation in which both members of one pair of chromosomes are inherited from the same parent ([Fig. 36-7](#)). This appears to occur as the result of "correction" of a trisomic zygote by loss of a chromosome. The chromosome transmitted by one parent is lost, and the two chromosomes transmitted by the other parent are retained. **Isodisomy** is the unique situation in which an individual receives two identical copies of one chromosome in a pair from one parent. This mechanism explains some cases of cystic fibrosis, in which only one parent was a carrier but the fetus inherited two copies of the same abnormal chromosome ([Spence and co-workers, 1988](#); [Spotila and colleagues, 1992](#)). It has also been implicated in abnormal growth related to placental mosaicism ([Robinson and colleagues, 1997](#)).

MITOCHONDRIAL INHERITANCE

Each human cell contains hundreds of mitochondria, each containing its own genome and associated replication systems. In a sense, mitochondria behave

autonomously. Interestingly, these organelles are derived exclusively from the mother. While human oocytes contain approximately 100,000 mitochondria and mitochondrial DNAs, sperm contains only 100, and these are selectively eliminated after fertilization. Each mitochondrion contains multiple copies of a 16.5-kb circular DNA molecule. This DNA encodes 13 peptides that are subunits of proteins. These are required for oxidative phosphorylation, as well as ribosomal and transfer RNAs.

Because mitochondria contain genetic information, mitochondrial inheritance allows the transmission of genes from mother to offspring without the possibility of recombination. If a mitochondrial mutation occurs, it may segregate into a daughter cell during cell division and thus be propagated. Over time, the percentage of mutant mitochondrial DNAs in different cell lines can drift toward either normal or pure mutant (Wallace, 1995). If an oocyte containing largely mutant mitochondrial DNAs is fertilized, the offspring might have a mitochondrial disease.

Mitochondrial diseases have a characteristic transmission pattern—individuals of both sexes can be affected, but transmission is only through females. Mitochondrial genetic diseases include myoclonic epilepsy with ragged red fibers (MERRF), Leber hereditary optic neuropathy, Leigh syndrome, and pigmentary retinopathy.

POLYGENIC AND MULTIFACTORIAL INHERITANCE

Polygenic traits are determined by the combined effects of many genes. **Multifactorial traits** are determined by multiple genes and environmental factors. It is now believed that the majority of inherited traits are multifactorial or polygenic. Birth defects caused by such inheritance are recognized by their tendency to recur in families, but not according to a mendelian inheritance pattern. The empirical recurrence risk for first-degree relatives is usually quoted as 2 to 3 percent (Thompson and colleagues, 1991). Multifactorial traits can be classified in several ways, but the most logical is to categorize them as:

1. Continuously variable
2. Threshold
3. Complex adult disorders.

CONTINUOUSLY VARIABLE TRAITS. These traits have a normal distribution in the general population. By convention, abnormality is defined as a trait or measurement greater than two standard deviations above or below the population mean. These are typically measurable or quantitative traits such as height or head size, and are believed to result from the individually small effects of many genes combined with environmental factors. Such traits tend to be less extreme in the offspring of affected individuals, because of the statistical principle of regression to the mean.

THRESHOLD TRAITS. These traits do not appear until a certain threshold of liability is exceeded (Fig. 36-8). Factors creating liability to the malformation are assumed to be continuously distributed, and only individuals at the extreme of this distribution exceed the threshold and have the trait or defect. The phenotypic abnormality is thus an all-or-none phenomenon. Individuals in high-risk families have enough abnormal genes or environmental influences that their liability is close to the threshold. Usually for unknown reasons, some factor(s) increases the liability for certain family members still further, and the threshold is crossed. Cleft lip and palate and pyloric stenosis are some examples of threshold traits.

Certain threshold traits have a predilection for one gender, indicating that males and females have a different liability threshold. Thus, when a family includes an affected member who is the less frequently affected gender, it indicates that even more abnormal genes or environmental influences are present. Their first-degree relatives (siblings) thus have an even higher liability for that particular trait. An example is pyloric stenosis, which is more common in males. If a female has pyloric stenosis, she or her parents have even more abnormal genes or predisposing factors than usually necessary to produce pyloric stenosis. The recurrence risk for her siblings or for her future children is thus higher than the expected 2 to 3 percent. Male siblings or offspring would have the highest liability, because they are the most susceptible sex *and* they will inherit more than the usual number of predisposing genes.

Finally, the recurrence risk for threshold traits is also higher if the defect is severe, again suggesting the presence of more abnormal genes or influences. For example, the recurrence risk after the birth of a child with bilateral cleft lip and palate is 8 percent, compared with only 4 percent after unilateral cleft lip without cleft palate (Melnick and associates, 1980).

COMPLEX DISORDERS OF ADULT LIFE. These are traits in which many genes determine the susceptibility to environmental factors, with disease resulting from the most unfavorable combination of both. Examples include common diseases such as heart disease or hypertension. These disorders are usually familial and behave as threshold traits but with a very strong environmental influence. The genetic mechanisms of many common adult diseases have not yet been elucidated, although several associated genes have been identified. In some cases, the identity of the associated gene provides a clue to pathogenesis, while in others the related gene may simply be used as a disease marker. For example, premature cardiovascular disease is associated with the gene for apolipoprotein E, which likely influences pathology of the disease. By way of contrast, the association of type I diabetes with HLA-DR3/4 is less clear. Some multifactorial adult-onset diseases and associated genes are listed in Table 36-7.

EXAMPLES OF MULTIFACTORIAL OR POLYGENIC DEFECTS. A variety of isolated structural birth defects and a number of common diseases in the population are associated with multifactorial or polygenic inheritance. All of these traits have certain characteristics that help to distinguish them from disorders with other modes of inheritance, and which can be cited in patient counseling (Table 36-8). When counseling regarding risks for a familial multifactorial trait, it is important to consider the affected relative's degree of relatedness to the *fetus*, not the parents. An affected first-degree relative (the fetus's parents or siblings) results in a substantial risk increase. After this, risk declines exponentially with successively more distant relationships. Two examples are given next to illustrate principles of these disorders.

NEURAL TUBE DEFECTS (NTDs). The neural folds in the brain and spinal cord regions fuse in the midline, converting the neural plate into the neural tube by days 26 to 28 of embryonic life (Fig. 36-9). Recent data indicate that closure occurs in separate regions that then fuse (Golden and Chernoff, 1995). Clinical data suggest five possible closure sites. Neural-tube defects likely result from either failure of closure in one or more sites, or failure of two sites to meet.

After cardiac defects, isolated (nonsyndromic) neural-tube defects are the most common congenital structural defects with a worldwide incidence of 1.4 to 2 per 1000 live births. They can also occur as part of a genetic syndrome or constellation of abnormalities. They are a major cause of stillbirth, neonatal and infant death, and lifelong severe handicap. With treatment, 80 to 90 percent of infants with isolated spina bifida survive with varying degrees of handicap. Factors that influence eventual neurological function include the size and location of the defect, trauma to exposed neural tissue, timing of surgical closure, degree of associated ventriculomegaly, and occurrence of complications such as infection.

The most common neural-tube anomalies are listed in Table 36-9. **Anencephaly** is the most severe defect, in which the forebrain, meninges, vault of the skull, and scalp all fail to form (Fig. 36-10). It is lethal, resulting in stillbirth or early neonatal demise. Other cranial defects include:

1. **Exencephaly**—failure of scalp and skull formation with exteriorization of an abnormally formed brain
2. **Encephalocele**—extrusion of brain tissue through a defect in the skull
3. **Iniiencephaly**—a defect of the cervical and upper thoracic vertebrae and base of the skull with abnormally formed brain tissue and extreme retroflexion of the upper spine.

Spina bifida involves failure of fusion of the vertebral arches, so that meninges (**meningocele**) or neural tissue plus meninges (**meningomyelocele**) are exposed to the amniotic fluid and eventually to the environment (Fig. 36-11). Neural tissue is damaged by such exposure, causing the structures supplied by the damaged nerves to be dysfunctional. Lesions in the lumbosacral area can lead to paraplegia and lack of bowel or bladder control. Higher lesions result in even greater handicap. Open defects are often associated with *ventriculomegaly* (enlargement of the ventricles) or *hydrocephalus* (enlargement of the cranium due to ventriculomegaly) as a result of a block to cerebrospinal fluid circulation. The increased intracranial pressure may cause pressure atrophy of the developing brain, although neurological dysfunction cannot be reliably estimated from the thickness of the compressed cortical mantle. **Rachischisis** describes the situation in which none of the vertebral arches fuse, and the entire spine is open. This condition is generally incompatible with life.

Neural-tube defects are classical examples of multifactorial inheritance. Their occurrence is influenced by environment, diet, physiological abnormalities such as hyperthermia or hyperglycemia, teratogen exposure, family history, ethnic origin, fetal gender, amniotic fluid nutrients, and various genes. The variety of defects associated with these risk factors suggest that many genes are likely to be involved in neural-tube development. For example, insulin-dependent diabetes is

preferentially associated with cranial or cervical-thoracic defects; hyperthermia is usually associated with anencephaly, and valproic acid exposure almost always causes lumbosacral defects ([Becerra and colleagues, 1990](#); [Hunter, 1984](#); [Lindhout and associates, 1992](#)). Moreover, each defect type appears to have a unique recurrence risk. [Hall and colleagues \(1988\)](#) reported a 7.8 percent recurrence risk with high spina bifida, 0.7 percent with low spina bifida, 2.2 percent with anencephaly, and no increased risk for craniorachischisis, encephalocele, or multiple defects. Because of this, it is not surprising that familial neural-tube defects usually involve the same location ([Cowchock and collaborators, 1980](#); [Toriello and Higgins, 1985](#)). Thus far, only one clearly associated gene has been identified, and its teratogenic effects are strongly influenced by diet.

Although [Hibbard and Smithells \(1965\)](#) postulated more than 30 years ago that abnormal folate metabolism was responsible for many neural-tube malformations, a specific gene defect associated with folic acid metabolism has only recently been implicated. A thermolabile variant of 5,10-methylenetetrahydrofolate reductase (MTHFR) has the mutation 677C>T, which results in a substitution of valine for alanine. This variant enzyme has reduced activity leading to altered homocysteine metabolism. The culpability of this particular enzyme defect makes biological sense. Folic acid supplementation reduces neural-tube defect recurrences by 70 percent and significantly reduces first occurrences ([Czeizel and Dudas, 1992](#); [MRC Vitamin Study Research Group, 1991](#)). Folic acid likely works by overcoming this relative enzyme deficiency. Because some defects occur in fetuses with normal 677C>T alleles, and because folic acid supplementation does not prevent all cases, other unknown genes or factors are presumed to cause some cases. Without folic acid supplementation, the empirical recurrence risk after one affected child is 3 to 4 percent, and after two affected children it is 10 percent. With supplementation, the risk after one affected child is less than 1 percent.

CONGENITAL HEART DISEASE. Cardiac anomalies are the most common birth defects with a worldwide incidence of 7 per 1000 births. They outnumber all other isolated structural defects combined ([Burn and Goodship, 1996](#)). Cardiac anomalies may occur as the result of aneuploidy or other chromosomal abnormality, or be part of a recognized single-gene disorder or another genetic syndrome. The majority of isolated malformations have traditionally been considered multifactorial, with environmental factors playing a major role. More recently, however, the reproductive experiences of adult survivors with congenital heart disease have challenged this view. Specifically, the recurrence of the same or similar defect in the offspring of women with congenital cardiac defects, despite different environmental exposures, suggests that genetic factors are more important, and this supports polygenic inheritance.

Many genes involved in normal and abnormal cardiac development have not yet been identified. Defects associated with gene deletion syndromes provide clues to the function and location of some cardiac genes. For example, association of the DiGeorge deletion with conotruncal cardiac defects has prompted a search for the causative genes within a small region of chromosome 22q11.2.

More than 50 genes believed to be involved in cardiovascular morphogenesis have been identified. These include those directing production of various transcription factors, secreted proteins, extracellular proteins, and protein receptors ([Chin, 1998](#)). Although these gene products seem to be involved in the structural development of the defect, their mechanism(s) remains unknown. For example, reduced elastin production is clearly related to supravalvular aortic stenosis, but the pathophysiological basis is unclear ([Keating, 1994](#)).

Epidemiological studies have contributed to the understanding of environmental influences on heart development. [Ferencz and colleagues \(1997\)](#) described results from the Baltimore-Washington Infant Study. This large, comprehensive case-control study included all live-born infants in a specific geographic region with congenital cardiac disease over an 8-year period. Maternal diabetes, influenza or fever, previous poor obstetrical outcomes, cigarette smoking, exposure to pesticides and solvents, marijuana use, and exposure to certain medications all increased the risk threefold for fetal cardiac anomalies.

The recurrence risk for cardiac malformations is difficult to determine because of multiple potential biases. For example, until relatively recently, patients with severe heart defects often did not reproduce, and many parents with a child with a serious heart defect choose not to have more children. One method used to approximate risk for first-degree relatives is to examine the relatives of children with congenital heart disease to determine *recurrence risk*. [Lin and Garver \(1988\)](#) and [Nora and Nora \(1988\)](#) summarized several studies in which the various cardiac defects were categorized according to the abnormal developmental mechanism. There are two situations in which their data can be used to approximate recurrence risk, as follows.

1. Risk after birth of an affected child. Obstructive defects related to abnormal blood flow of the left side of the heart have a familial recurrence rate four- to sixfold higher than other cardiac defects. Some of these defects include hypoplastic left heart (15 percent risk), bicuspid aortic valve (11 percent risk), and aortic coarctation (8 percent risk). Defects categorized as involving abnormal cell migration (conotruncal defects), cell death (Ebstein anomaly), growth of the extracellular matrix (AV canal), or targeted growth (anomalous pulmonary venous return) had relatively low recurrence rates.

2. Risk if parent or sibling has a cardiac defect. Recurrence risks for some congenital heart defects are shown in [Table 36-10](#). For counseling, if the exact nature of the defect is known, the most specific risk should be quoted. Otherwise, couples can be informed of the empirical risk of having a child with a cardiac defect. This is 5 to 6 percent if the mother has the defect, and 2 to 3 percent if the father has the defect ([Burn and associates, 1998](#)).

MOLECULAR GENETICS

Significant advances in DNA technology in the last decade now allow isolation and sophisticated analysis of human genes. The Human Genome Project, a cooperative international project whose goal was mapping the entire human genome, was completed in 2000. [Watson \(1991\)](#), however, cautions that "Our descendants will be working for hundreds if not thousands of years to fully understand all the information contained in the 3 billion DNA base pairs that constitute the human genome." These 3 billion base pairs make up approximately 80,000 genes in each human nucleus ([Table 36-11](#)). Of these, several thousand have been assigned to a particular chromosome and hundreds have been cloned. The following is a cursory review of molecular genetics as related to obstetrics as well as to prenatal diagnosis, which is discussed in [Chapter 37](#).

ORGANIZATION OF THE GENOME

The 2 meters of DNA in every cell must be packaged according to a very elaborate system in order to be maintained and transmitted without interruption. The DNA is wrapped very compactly around basic proteins called histones to form nucleosomes. These are then organized into solenoid structures and looped around a nonhistone protein scaffold to form chromatin ([Fig. 36-12](#)). As the cell enters prophase, the chromatin begins to condense until it assumes the familiar structure of metaphase chromosomes. Each chromosome is composed of densely packed nontranscribed DNA near the centromeres, called heterochromatin, and less densely packed transcribed DNA called euchromatin.

About 75 percent of the genome is unique, single copy DNA, and the rest consists of various classes of repetitive DNA. Surprisingly, virtually all of the repetitive DNA and a large portion of the single copy DNA has no apparent or recognized function. Less than 10 percent of the genome encodes genes! Single copy DNA is intensely studied because it contains all the genes necessary to make and sustain the organism, and repetitive DNA is of interest because it contains unique markers that identify each individual and can be used to study genetic variation.

CODING DNA

GENES. A gene is a unique series of four purine and pyrimidine bases that specifies the amino acid sequence for a single polypeptide chain of a protein molecule. A gene is not one continuous segment of DNA, but is typically composed of multiple coding sequences called *exons*, interrupted by nontranscribed regions called *introns* that must be excised prior to translation. Each gene also has a regulatory region called a *promoter*, a 5' untranslated region that has regulatory functions, and a 3' untranslated region containing the signal for messenger RNA maturation and function. In the nucleus, genetic information is transcribed from DNA into a single-stranded RNA identical in sequence with one of the strands of the DNA helix. The RNA is processed (the introns are excised) and transported into the cytoplasm where it is translated into the amino acid sequence that constitutes a protein. Post-translational processing of the protein follows in the cytoplasm. The polypeptide chain is folded into a unique three-dimensional structure, and two or more polypeptide chains may combine or the structure may be chemically modified by the addition of carbohydrate or other moieties.

Many genes exist in several alternate but normal forms called **alleles**. For example, CDE and major blood group genes all have several normal alleles. A **mutation** is an alteration of DNA sequencing that occurs in a coding region (gene), results in a change in protein structure or function, and is passed on to future progeny. Mutations can be visible chromosome alterations, such as deletions or insertions, or they may involve a change in one or more of the purine or pyrimidine bases of a single gene. Single nucleotide substitutions that result in the wrong amino acid being selected are called **missense mutations**; those that cause a premature stop codon to be inserted are **nonsense mutations**. Some mutations cause an error in RNA splicing at the intron/exon splice sites. The distinction between an allele and a mutation can be blurred; many normal alleles probably result from ancient mutations that either did not affect survival or conferred some selective advantage. In current usage, the DNA changes characterized as mutations generally have adverse effects on protein structure or function, and occur infrequently in the population.

The vast majority—99.8 percent—of DNA is identical in all humans. There are however, minor differences that distinguish one person from another. These differences, called **polymorphisms**, generally consist of a single nucleotide change about every 200 to 500 base pairs. These changes are primarily in noncoding regions of the genome, but can also be found in introns and in gene coding regions. They are silent, meaning that they do not affect gene structure or function. They can, however, be used for identification and to determine the origin of inherited DNA sequences.

Diseases caused by a single mutation, such as sickle cell disease, are rare. Physiological processes and pathways are highly redundant, and a single mutation located in the coding region of a gene may be clinically silent. Most frequently, pathological phenotypic changes occur only when multiple genes are affected or when specific environmental influences are present. The genetic mutations and other conditions necessary for phenotypic alteration are in general poorly understood. When newly discovered genes are being analyzed, it can thus be difficult to distinguish a normal allele from a polymorphism or a mutation. For example, over 100 variations of the BRCA1 gene, one of the major genes associated with familial breast and ovarian cancers, have been identified. It is not currently known whether all of these variations are actually mutations associated with disease, or if some could be polymorphisms or allelic variants ([Collins, 1996](#)). The ability to distinguish alleles from mutations is obviously essential to any molecular screening program.

CONTROL OF GENE EXPRESSION

METHYLATION. Genomic DNA methylation is believed to be the major form of DNA modification that permits control of many aspects of gene expression ([Thompson and McInnes, 1991](#)). It occurs only at one specific nucleotide in the human genome: the cytosine of a CpG dinucleotide repeat. Most CpG dinucleotides are located in gene regulatory regions, where methylation would prevent transcription and thus effectively turn off that gene.

Methylation is very common as about half of all CpG sequences are methylated ([Barsh and Epstein, 1996](#)). Methylation is believed to be the mechanism for imprinting and plays a role in producing the fragile X phenotype discussed earlier. Its most important function, however, is to control the tissue-specific activation of certain genes. Every cell in the body contains the entire genome, but the body contains many pathophysiologically different cells because the expression of genes that are not essential for each specific tissue type is prevented by methylation. For example, the globin genes are methylated in all nonerythroid tissues, ensuring that only erythrocytes produce hemoglobin ([Barsh and Epstein, 1996](#)).

NEW MUTATIONS AND GENE REGULATION

New mutations are also linked to DNA methylation. As previously stated, most CpG dinucleotides appear to be located primarily in gene regulatory regions. They are also found within certain gene coding regions. The function of the CpGs within gene coding regions is not completely understood, and cytosine methylation here does not prevent gene transcription. However, if a methylated cytosine residue is deaminated to thymidine, the methylcytosine on the opposite strand is likely to be changed to thymidine. This mutation can lead to premature termination of translation or production of an abnormal protein. This specific mutation is extremely common. Methylated CpGs are the single most mutated dinucleotides in the genome and cause a third of all germline point mutations leading to genetic disease ([Mancini and associates, 1997](#); [Ollila and colleagues, 1996](#); [Tornaletti and Pfeifer, 1995](#)). Certain *hot spots* of the human genome have an abundance of CpGs and are especially vulnerable. Mutations at sites with multiple CpG dinucleotides occur at a frequency 10- to 40-fold higher than at any other sites and account for more than a third of nucleotide substitutions in inherited diseases ([Cooper and Krawczak, 1990](#); [Yousoufian and co-workers, 1986](#)).

CpG dinucleotides have been associated with mutations in a variety of genes. The most mutable nucleotide in the entire genome is a CpG dinucleotide in the fibroblast growth receptor 3 gene (FGFR3 1138 guanosine), which accounts for more than 97 percent of all cases of achondroplasia ([Bellus and colleagues, 1995](#)). The majority of new mutations causing hemophilia A, half of point mutations causing mucopolysaccharidosis type II, and 10 to 15 percent of mutations causing retinoblastoma are in CpG doublets ([Mancini and collaborators, 1997](#); [Rathmann and associates, 1996](#)). Other genes with high mutation rates are those causing neurofibromatosis, polycystic kidney disease, and aniridia. Certain lethal autosomal dominant diseases such as osteogenesis imperfecta or thanatophoric dwarfism *always* result from new mutations. These affected individuals have "reduced reproductive fitness"; that is, they die before they can reproduce.

OTHER FORMS OF GENE REGULATION. In a small number of genes, the mRNA sequence is modified ("mRNA editing") before it is transcribed, so that it is no longer complementary to the DNA template ([Barsh and Epstein, 1996](#)). The initiation of mRNA translation can also be regulated, controlling the quantity of gene product produced. Finally, DNA can actually be rearranged to produce a unique protein such as immunoglobulin ([Harriman and colleagues, 1993](#)).

NONCODING DNA

Approximately 1 percent of all the nucleotides in the noncoding regions are polymorphic. These sites can be identified by *restriction endonuclease* digestion, or they may be areas of repeated sequences with variable length.

RESTRICTION FRAGMENT LENGTH POLYMORPHISMS (RFLPs). The entire human genome, composed of 3 billion base pairs of DNA, is so large that searching for a specific gene within it is a monumental task. The first step is to break the genomic DNA into manageable fragments. This is accomplished by bacterial enzymes termed **restriction endonucleases**. Each endonuclease locates and cleaves a specific sequence of base pairs, wherever it occurs along the genome. As shown in [Figure 36-13](#), some enzymes recognize sequences of four nucleotides, some six, and others seven. More than 200 different restriction enzymes have been identified. The number and size of fragments produced by enzyme digestion are determined by the frequency or location of the particular sequences recognized by the enzyme. Each enzyme thus produces its own unique pattern of DNA fragments.

Certain restriction endonuclease sites are the same in all humans. Others, however, are unique to each individual. These unique endonuclease sites, leading to unique DNA fragment lengths, are called restriction fragment length polymorphisms, or RFLPs. RFLPs are not mutations or abnormalities, but are merely individual differences in nucleotide sequences that are present roughly once in every 250 base pairs throughout the genome ([Marian, 1995](#)). Each RFLP generally has two alleles and is inherited in mendelian fashion. Because of this, they can be used for identification purposes, for diagnostic testing, or to confirm or rule out transmission of a specific DNA segment from parent to child. The different cleavage locations and fragment lengths obtained with different endonucleases can also be used as *markers* to help locate a particular gene or to facilitate analysis of the inheritance pattern of a trait.

REPETITIVE DNA. These segments are characterized by short nucleotide sequences that are repeated many times throughout the genome. A large part of the noncoding genome consists of repetitive DNA. They are of interest because they include polymorphisms that can be used as markers. They can also be very useful for following alleles through a family and have been used to analyze certain genes. **Clustered repetitive DNA** makes up 10 to 15 percent of the genome ([Elsa and Patel, 1998](#)). These segments are called *simple sequence DNA* or *satellite DNA* because of their physical properties. This class of DNA includes several distinct types of repeated sequences. One class is characterized by a *variable number of tandem repeats (VNTRs)*, consisting of multiple copies of short DNA sequences. VNTRs are more *polymorphic* than RFLPs because they usually have up to several dozen alleles compared with only two alleles at each RFLP site. **Short tandem repeats (STRs)**, also called CA dinucleotides or GT repeats, are areas of dinucleotide or trinucleotide repeats scattered throughout the genome. STRs are also highly polymorphic, with 4 to 10 alleles typically identified at each site. VNTRs and STRs are considered more *informative* than RFLPs because their allelic variation makes them more useful for identification and other purposes. **Interspersed repetitive DNA** accounts for 15 percent of the total DNA, and occurs randomly throughout the genome. These sequences include **SINES (short interspersed sequences)** and **LINES (long interspersed sequences)**.

All these repetitive sequences and other types of polymorphic markers can be used to determine the relative locations of markers to each other and to gene(s) of interest. Thus, they can be used to generate a DNA map. Such a linkage map of the whole genome, containing almost 6000 markers located less than 1 million base-pairs apart, has already been accomplished by the Human Genome Project ([Murray and co-workers, 1994](#)).

GENETIC TESTS

CYTOGENETIC ANALYSIS. Any tissue containing dividing cells or cells that can be stimulated to divide is suitable for cytogenetic analysis. The dividing cells are blocked in metaphase and the chromosomes are stained to reveal light and dark bands. The banding pattern of each chromosome facilitates its identification and detection of any deleted, duplicated, or rearranged segments. The accuracy of band analysis increases along with the number of bands produced. Most laboratories now routinely perform high-resolution metaphase banding, which yields 350 to 550 visible bands per haploid chromosome set. Banding of prophase chromosomes generally yields 850 bands.

Because only dividing cells can be evaluated, cells must be cultured for analysis. The rapidity with which results are obtained thus correlates with the rapidity of cell growth in culture. Bone marrow cell results are usually available in less than a day. Adult blood yields results in 3 to 4 days. Fetal blood often produces results in 24 to 48 hours. Amniocytes, which are fetal fibroblasts, sloughed gastrointestinal mucosal cells, and amnion cells, require 7 to 14 days. Fibroblasts usually require 3 to 6 weeks, but this is often because the skin sample is obtained postmortem and stimulation of growth is difficult.

FLUORESCENCE IN SITU HYBRIDIZATION (FISH). This is a rapid method for determining ploidy for a few specific chromosomes, or confirming the presence or absence of a gene or large DNA sequence (Fig. 36-14). It is not comparable to cytogenetic evaluation because the chromosomes appear squat and the banding patterns are much less distinctive. Chromosome duplications, deletions, and rearrangements often cannot be detected by FISH. Cells are fixed on a glass slide, and fluorescently labeled chromosome or gene probes are allowed to hybridize to the fixed chromosomes. Each probe is complementary to a unique area of the chromosome or gene, thus preventing cross reaction with other chromosomes. If the chromosome or gene of interest is present, hybridization is detected as a bright signal visible by microscopy. The number of signals indicates the number of chromosomes or genes of that type in the cell being analyzed. FISH is usually used when ploidy status would change clinical management, and time constraints prevent waiting for a cytogenetic analysis.

SPECTRAL KARYOTYPE ANALYSIS. This is a FISH procedure in which a labeled probe for every chromosome is used simultaneously. Chromosomes can be distinguished from each other because each probe emits a unique, defined spectrum of a different color. The results are analyzed by computer, making it a rapid and accurate test. It is currently available for research only.

LINKAGE ANALYSIS. RFLPs, STRs, and other markers can be used to locate a specific gene for research or diagnostic purposes if certain criteria are met (Beaudet and Ballabio, 1994). First, a large family with multiple members affected by the disease in question must be identified. Next, specific markers scattered throughout the genome are selected for study or, if the gene is believed to be located on a specific chromosome, markers on that chromosome are chosen. DNA from each family member is then analyzed to determine whether any of the selected markers are transmitted together (segregate) with the disease. If individuals with the disease have the marker, and individuals without the disease do not, the gene causing the disease and the marker are said to be *linked*, or close to each other on the same chromosome.

Linkage analysis allows determination of locations of different genes and their approximate distances from each other. The approximate distance between genes or markers is estimated using the crossover frequency, a measure of how often a crossover moves the gene away from the marker to the other chromosome in the pair. The farther apart the genes or markers are, the more likely they are to crossover. This then provides the basis for more detailed molecular study. It can also be used for diagnosis if members of the affected family have informative markers with multiple alleles. Thus, they are helpful if the marker associated with the disease-causing gene represents one allele, and the marker associated with that normal gene is a different allele.

In cases in which the specific gene has not been identified, linkage analysis can be used to estimate the likelihood that an individual, for example, a fetus, has inherited the abnormal gene. Linkage analysis is imprecise, and dependent on family size, availability of family members for testing, presence of informative markers near the gene, and frequency of crossover events. In informative cases it provides some information about the likelihood of inheritance.

COMPLEMENTARY DNA (cDNA). When the nucleic acid sequence of a gene or DNA region of interest is known, it can be studied directly using complementary DNA. This cDNA is a laboratory-made copy of a DNA segment or gene. It is synthesized utilizing *reverse transcriptase*, an enzyme isolated from tumor viruses which can synthesize a DNA copy from nuclear messenger RNA. cDNA is usually single stranded and, because messenger RNA is the template, it does not contain the introns which are removed during processing of mRNA. Radioactive bases are inserted into the sequence to label cDNA so that the resulting probe can be visualized if it bonds with a matching sequence or identical gene.

Many isolated genes or DNA fragments have been collected in cDNA *libraries*. The source of the copied genes is usually a single tissue or chromosome, which substantially aids the search for specific genes. For example, to study the β -globin gene, it would be much easier to isolate the gene from a cDNA library prepared from red blood cells, where β -globin represents the major mRNA transcript, than from a library representing the whole genome, where it is present at only one part per million. Likewise, a search for a gene thought to be on chromosome 9 would be easier if the chromosome 9 library was used to focus the search.

FLUORESCENCE-ACTIVATED CHROMOSOME SORTING. Large quantities of a specific chromosome can be obtained by fluorescence-activated chromosome sorting. Chromosomes are stained with fluorescent dyes, and are distinguished from each other by intensity of fluorescence. Stained metaphase chromosomes are passed through a laser beam which deflects each chromosome according to its unique intensity.

GEL SEPARATION. Once the desired chromosome has been isolated, it can be fragmented with endonuclease. The fragments are screened for the gene or DNA sequence of interest. This process is greatly facilitated by separating the fragments with electrophoresis. Smaller fragments move faster and farther than larger fragments. The DNA fragments can be visualized directly or by fluorescent staining to facilitate removal for further study.

POLYMERASE CHAIN REACTION (PCR). This is a rapid technique for synthesizing large amounts of a specific DNA sequence or gene (Beaudet and Ballabio, 1994). Using PCR, a million copies of the original gene or DNA segment can be made in a few hours using very minute quantities of DNA. However, either the entire gene sequence or the sequences at the beginning and end of the gene must be known. PCR involves three steps that are repeated many times. First, double-stranded DNA is denatured by heating. Oligonucleotide primers anneal to the target sequence on each strand of separated DNA. A mixture of nucleotides and heat-stable DNA polymerase is added, and new complementary strands of DNA are synthesized. In just a few minutes, the original DNA has been duplicated. The procedure is repeated over and over with exponential amplification of the DNA segment. PCR is used to generate large quantities of DNA for testing or it is used to amplify a particular gene or mutation to identify it.

SOUTHERN BLOTTING. Named for its inventor, Edward Southern, this technique allows identification of one or several DNA fragments of interest from among the million or so typically obtained by enzyme digestion of the human genome. It applies the principles of gel separation and nucleic acid hybridization illustrated in Figure 36-15, but on a much larger scale. The cDNA probe may be a normal gene, in which case hybridization confirms the presence of a normal copy while lack of hybridization indicates a mutation. Because hybridization can occur even with incomplete sequence homology, only relatively large mutations or changes such as deletions can be detected by cDNA probes.

The probe can also be a fragment of DNA produced by endonuclease digestion. In this case, individuals with a normal gene would have fragments of a different size than individuals carrying the abnormal gene. Before the sickle cell gene was identified, this method was used for prenatal diagnosis by Chang and Kan in 1982. They developed an assay using the restriction enzyme Mst II. The sickle cell mutation results in loss of the Mst II recognition site, yielding one large fragment instead of two smaller ones after endonuclease digestions.

Basic principles of the Southern blot technique can also be applied to RNA, in which case it is called **Northern blotting**, and to proteins, as **Western blotting**.

ALLELE SPECIFIC OLIGONUCLEOTIDE (ASO) PROBES. If a mutation of interest consists of a change in only one or two base pairs, a cDNA probe will not detect it. A few mismatches will not prevent the cDNA probe from hybridizing to the gene. For single nucleotide mutations, an allele specific oligonucleotide probe must be used instead. An ASO is a short DNA probe, 15 to 25 bases in length, which is synthesized by sequential addition of each nucleotide and is homologous to a specific DNA sequence (Layman, 1992). ASOs can be used instead of cDNA in the Southern blotting technique shown in Figure 36-15. They are useful for testing family members at risk for a small, well-characterized familial mutation.

MULTIPLEX POLYMERASE CHAIN REACTION. If primers spanning the DNA region of interest are available, PCR can be used to amplify any DNA segment, including genes with deletions or mutations. If a variety of mutations in one gene have been identified in association with a certain disorder, they can all be amplified simultaneously using multiplex PCR.

OLIGONUCLEOTIDE LIGATION ASSAY (OLA). This technique provides great sensitivity in detecting single-base insertions, deletions, or substitutions. Two probes, each corresponding to an adjacent region of the gene in question, are allowed to hybridize to contiguous regions of the DNA region of interest. They are then ligated using DNA ligase. The label attached to one probe is released by the ligation, indicating that the DNA sequence of interest corresponds exactly to the sequences of the two probes. This procedure provides a higher degree of accuracy than can be achieved with single-probe assays (Winn-Deen, 1996).

LIGATION CHAIN REACTION (LCR). LCR is the amplification counterpart of OLA, and may be used to screen for many different small or single-gene mutations simultaneously. In a single tube, the specimen is submitted to multiplex PCR, and then evaluated with simultaneous OLA analysis for multiple different mutations. LCR is used by many laboratories for cystic fibrosis screening for 30 of the most common mutations.

CLONING. A clone is a large number of molecules or cells all identical to one ancestral molecule or cell (Lewin, 1997). Cloning refers to the replication of genetic material, although a new definition has been created by the popular media that includes replication of whole animals. Technically, cloning includes several laboratory techniques that enable pieces of DNA to be copied in large quantities by lower organisms. These techniques utilize various vectors, which are DNA molecules that replicate autonomously in its host cell. Restriction enzymes are used to cleave both the DNA sequence of interest and the vector DNA at appropriate sites, and DNA

ligase is used to insert the DNA segment into the vector. The inserted DNA will then be replicated along with vector DNA, and large quantities of the DNA insert can then be retrieved for study.

The first vectors used for cloning were bacterial plasmids which are circular double-stranded DNA molecules that replicate separately from bacterial chromosomes. Plasmids are used for small DNA inserts, usually less than 5 to 10 kb in size. DNA fragments were later cloned in bacteriophages with inserts up to 20 kb; or modified plasmids called cosmids with inserts up to 50 kb. [Burke and colleagues \(1987\)](#) then developed a method to insert 100 to 1000 kb of DNA into a *yeast artificial chromosome* or YAC. These chromosomes have their own centromeres and telomeres and replicate like normal yeast chromosomes. YAC libraries, with each YAC containing a different fragment of the genome, have been established to greatly simplify gene isolation.

POSITIONAL CLONING. This is sometimes referred to as "reverse genetics" because it involves attempting to clone the gene responsible for a specific disease based on its location, without knowing the nature of the gene product. This is only possible once the gene has been localized to a specific part of a given chromosome ([Gelehrter and Collins, 1990](#)). Localization or mapping of the abnormal gene to a specific chromosome region usually involves narrowing the search to a sequence of over a million base pairs. This is easier if the affected individual also has a cytogenetic abnormality such as a chromosomal deletion to mark the most likely location. Examples of genes that have been cloned using this technique include cystic fibrosis, Duchenne muscular dystrophy, retinoblastoma, colonic polyposis, neurofibromatosis, and Huntington disease ([Beaudet and Ballabio, 1994](#)).

DNA CHIPS. These take advantage of the principles of PCR and nucleic acid hybridization to screen DNA for many genes or mutations simultaneously. Many cDNA probes or ASOs, each representing a different gene mutation, are tagged with different colored fluorescent dyes and arrayed on a tiny chip. DNA from the test individual is amplified by PCR and exposed to the probes fixed on the chip. Hybridization to any of the probes is recognized by the color pattern, and indicates that the individual carries the mutation represented by that particular cDNA. It is anticipated that this technology will revolutionize genetic screening. For example, although over 800 mutations causing cystic fibrosis have been identified, most laboratories currently test patient samples only for a panel of 16 to 32 of the most common mutations. Using a DNA chip, the patient could be screened for all 750 mutations simultaneously.

TABLE 36-2. Standard Nomenclature for Chromosome Karyotypes

Karyotype	Description
46,XY	Normal male chromosome constitution
47,XX, + 21	Female with trisomy 21 Down syndrome
47,XY,+21/46,XY	Male who is a mosaic of trisomy 21 cells and normal cells
46,XY,del(4)(p14)	Male with distal deletion of the short arm of chromosome 4 band designated 14
46,XX,dup(5p)	Female with duplication of the short arm of chromosome 5
45,XY,-13,-15,t(13q;14q)	A male with a balanced Robertsonian translocation of chromosome 13 and karyotype shows that one normal 13 and one normal 14 are missing
46,XY,t(11;22)(q23;q22)	A male with a balanced reciprocal translocation between chromosomes 11 and 22; break-points are at 11q23 and 22q22
46,XX,inv(3)(p21;q13)	An inversion of chromosome 3 that extends from p21 to q13; because it includes the centromere, this is a pericentric inversion
46,X,r(X)	A female with one normal X chromosome and one ring X chromosome
46,X,l(xq)	A female with one normal X chromosome and an isochromosome of the long arm of the X chromosome

TABLE 36-6. Some Relatively Frequent Mendelian Disorders Affecting Adults

Autosomal Dominant

Achondroplasia
Acute intermittent porphyria
Adult polycystic kidney disease
BRCA1 and BRCA2 breast cancer
Familial hypercholesterolemia
Familial hypertrophic cardiomyopathy
Hereditary hemorrhagic telangiectasia
Hereditary spherocytosis
Huntington chorea
Marfan syndrome
Myotonic dystrophy
Neurofibromatosis
Osteogenesis imperfecta tarda
Polyposis of the colon
Tuberous sclerosis
von Willebrand disease

Autosomal Recessive

Albinism
Cystic fibrosis
Deafness
Friedrich ataxia
Hemochromatosis
Hereditary emphysema
Homocystinuria
Phenylketonuria
Sickle-cell anemia
 β -Thalassemia
Wilson disease

X Linked

Chronic granulomatous disease
Color blindness
Fabry disease
Fragile X syndrome
Glucose-6-phosphate deficiency
Hemophilia A and B
Hypophosphatemic rickets
Muscular dystrophy
Ocular albinism
Testicular feminization

TABLE 36-7. Multifactorial Adult-Onset Disease and Their Associated Genes

Approach	Disease	Major Gene	
Working from the phenotype down, using physiological abnormalities	Coronary artery disease	Hypercholesterolemia; combined hyperlipidemia	
	Hypertension	Ion transport abnormalities	
	Pernicious anemia	Atrophic gastritis	
	Peptic ulcer	Hyperpepsinogenemia I	
	Lactose intolerance	Lactase deficiency	
	Hemochromatosis	Increased iron absorption	
	Diabetes mellitus	Glucose intolerance; pancreatic autoimmunity	
	Colon cancer	Single adenomatous polyp	
	Working from the genotype up, using genetic markers	Celiac disease	Associated with HLA-DR3
		Hemochromatosis	Associated with HLA-A3, linked to HLA region (chromosome 6)
Insulin-dependent diabetes		Associated with HLA-DR3 and HLA-DR4	
Rheumatoid arthritis		Associated with HLA-DR4	
Ankylosing spondylitis		Associated with HLA-B27	
Alzheimer disease		Linked to amyloid β -protein RFLP (chromosome 21)

TABLE 36-8. Characteristics of Multifactorial Traits

1. Multiple family members are affected, but there is no specific inheritance pattern.
2. The risk to first-degree relatives is approximately the square root of the population risk.
3. The risk is sharply lower for second-degree relatives, and declines rapidly for more distant relatives.
4. The recurrence risk is higher if more than one family member is affected.
5. The recurrence risk is higher if the defect is severe.
6. If the trait is more frequent in one gender, the risk for relatives is higher if the person with the defect is of the less frequently affected gender.
7. The concordance rate in dizygotic twins is less than a quarter of the rate in monozygotic twins.
8. The recurrence risk is higher if the parents are consanguineous.

TABLE 36-9. Basic Types of Neural-Tube Defects (Myelodysplasia)

Defect	Definition
Spina bifida occulta	Vertebral defect characterized by failure of closure of the posterior elements of the vertebral arch without a sac containing neural tissue visible on the back. The defect may or may not be associated with an abnormality of the spinal cord.
Spina bifida cystica	Vertebral defect with cystic protrusion of the meninges or of the spinal cord and meninges.
Meningocele	Protrusion of the meninges and cerebrospinal fluid into a sac covered by epithelium. Clinical symptoms vary according to underlying spinal cord anomalies.
Myelomeningocele	Most common and serious defect that includes the spinal cord, nerve roots, meninges, and cerebrospinal fluid. Commonly occurs in the lumbar area. The level of the lesion is usually reflected in severity of the clinical deficit, with higher lesions having more pronounced deficits.
Lipomeningocele	Vertebral defect associated with a superficial fatty mass that merges with lower levels of the spinal cord. Neurological deficits vary. There is no associated hydrocephalus.
Encephalocele	A protrusion of scarred brain, cerebrospinal fluid, and meninges through a bony skull defect. It is usually occipital, but can be frontal or through the skull base.
Anencephaly	Failure of fusion of the cranial end of the neural tube, resulting in exposure of a malformed brain.

FIGURE 36-15. Southern blotting analysis. Genomic DNA is isolated from leukocytes or amniocytes and digested with a restriction enzyme. This yields a series of reproducible fragments that are separated by agarose gel electrophoresis. The separated DNA fragments are then transferred ("blotted") to a nitrocellulose membrane that binds DNA. The membrane is treated with a solution containing a radioactive single-stranded nucleic acid probe, which forms a double-stranded nucleic acid complex at membrane sites when homologous DNA is present. These regions are then detected by autoradiography using x-ray film.

37. Prenatal Diagnosis and Fetal Therapy

Prenatal diagnosis is the art and science of identifying structural or functional abnormalities in the developing fetus. As discussed in [Chapter 36](#), 2 to 3 percent of all neonates have a major abnormality discovered at birth. Congenital abnormalities have a major impact on the health of the pediatric population and have emerged as a major cause of neonatal death; indeed, more than a fourth of all pediatric hospital admissions result from genetic disorders ([Ling, 1992](#)). Prenatal diagnosis is thus an important bridge between obstetrics and pediatrics, and concerns a unique group of patients with specific medical, social, and psychiatric needs. Many fetal anomalies can be identified prenatally, and technology has provided an ever-expanding number of prenatal treatment options. In other cases, prenatal diagnosis allows optimization of delivery or consideration of pregnancy termination, but in either event, it offers an opportunity to influence the incidence and severity of genetic disease.

Prenatal diagnosis typically involves the evaluation of three major categories of patients:

1. Fetuses at high risk for a genetic or congenital disorder.
2. Those at unknown risk for common congenital abnormalities.
3. Fetuses discovered sonographically to have structural or developmental abnormalities.

Current prenatal (fetal) therapy includes optimization of the intrauterine environment and delivery conditions, blood transfusion, administration of medication, amnioreduction, placement of shunts, and surgery. The near future will likely include hematopoietic stem cell transplantation and other methods for gene transfer.

FETUSES AT HIGH RISK FOR GENETIC OR CONGENITAL DISORDERS

FETAL ANEUPLOIDY

At least 8 percent of conceptuses are aneuploid, accounting for 50 percent of first-trimester abortions and 5 to 7 percent of all stillbirths and neonatal deaths ([Hook, 1992](#); [Rimoin and colleagues, 1997](#)). Chromosome defects compatible with life but causing significant morbidity occur in 0.65 percent of newborns, and another 0.2 percent have structural chromosomal rearrangements that will eventually affect reproduction ([Milunsky, 1992](#)).

Women aged 35 and older have traditionally, if somewhat arbitrarily, been offered genetic amniocentesis because at age 35 the incidence of trisomy starts to rapidly increase ([Fig. 37-1](#)). Also at this time, the term risk of any aneuploidy roughly equals the oft-quoted risk of amniocentesis-related pregnancy loss of 1 in 200, thus justifying the test ([Table 37-1](#)). Because only 8 to 12 percent of all children are born to these older women, at most only 20 percent of all Down syndrome pregnancies would be identified by this policy. Put another way, because younger women have the majority of pregnancies, younger women give birth to the majority (80 percent) of all children with Down syndrome ([Shreinemachers and co-workers, 1982](#)).

Several safe, accurate, and well-established procedures to obtain fetal cells for definitive fetal diagnosis are currently available. The challenge comes in determining which women are at high risk for fetal aneuploidy and should be offered these tests. "High risk" can be defined in many ways. Most commonly, it means a risk greater than fetal loss associated with the diagnostic procedure being considered. Thus, if the risk of postamniocentesis pregnancy loss is approximately 1 in 200, a genetic amniocentesis would not typically be offered unless the risk of fetal aneuploidy was estimated to be greater than 1 in 200. As listed in [Table 37-2](#), women with a risk of fetal aneuploidy high enough to justify an invasive diagnostic procedure include the following:

- 1. Women with a singleton pregnancy who will be at least age 35 at delivery.** The midtrimester risk of a 35-year-old woman to be carrying a fetus with Down syndrome is 1 in 250 and the risk of any numerical aneuploidy is 1 in 132 ([Table 37-1](#)). These numbers are higher than the term risks because a large proportion of aneuploid pregnancies is lost spontaneously before term delivery. The risks at term are 1 in 384 for Down syndrome and 1 in 204 for all numeric aneuploidies.
 - 2. Women with a dizygotic twin gestation who will be at least age 31 at delivery.** With two fetuses, the laws of probability dictate that the chance that one or both will have Down syndrome is greater than if there was only one fetus. The risk of trisomy 21 in a twin pregnancy must be calculated after considering the maternal age-related Down syndrome risk, the maternal race- and age-related incidence of dizygotic twinning, and the probability that either or both fetuses could be affected. The analysis by [Meyers and colleagues \(1997\)](#) shown in [Table 37-3](#) indicates that, for both white and African American women, the midtrimester risk of fetal Down syndrome in a dizygotic twin pregnancy at age 31 is approximately 1 in 190, thus justifying the risk of an amniocentesis. Counseling in this situation should also include a discussion of options for pregnancy management if only one fetus is affected. These options include terminating both twins, selective second-trimester termination of the affected fetus only, continuing the pregnancy with monitoring of the normal fetus only, or continued monitoring of both fetuses.
 - 3. Women who have previously had a pregnancy complicated by autosomal trisomy.** Women who have had at least one trisomic pregnancy have approximately a 1 percent occurrence with the same or different autosomal trisomy. This is so until their age-related risk exceeds 1 percent at which time the higher risk predominates ([Warburton, 1987](#)).
 - 4. Women who have previously had a pregnancy complicated by triple X (47, XXX) or Klinefelter syndrome (47, XXY).** The extra X may be maternal or paternal in origin. As with autosomal trisomies, the recurrence risk is 1 percent until the maternal age-related risk exceeds 1 percent, at which time this risk predominates ([Gardner and Sutherland, 1996](#)). Women whose previous child was 47, XYY are *not* at high risk for recurrence, as the extra chromosome in this situation is paternal in origin, and paternal errors have minimal chance of recurring. Likewise, 45, X has a very low recurrence risk.
 - 5. Women or their partners who are chromosome translocation carriers.** The risk of having abnormal offspring must be estimated individually, taking into account the chromosomes involved, the sex of the transmitting parent, and the method of ascertainment. For most translocations, the observed risk of abnormal live-born children is less than the theoretical risk, because a portion of gametes produces nonviable conceptions. The observed risk specific to the translocation can be provided by a geneticist or genetic counselor. In general, however, translocation carriers identified after the birth of an abnormal child have a 5 to 30 percent risk of having unbalanced offspring, while those identified for other reasons, for example during an infertility workup, have a 0 to 5 percent risk ([Gardner and Sutherland, 1996](#)).
 - 6. Women or their partners who are carriers of chromosome inversions.** Each carrier's risk is determined by the method of ascertainment, the chromosome involved, and the size of the inversion, and thus should be determined individually. In general, the observed risk is approximately 5 to 10 percent if ascertainment occurred after the birth of an abnormal child, and 1 to 3 percent if ascertainment occurred by some other means ([Gardner and Sutherland, 1996](#)).
 - 7. History of triploidy.** Over 99 percent of triploid conceptions are lost in the first or early second trimesters ([Chap. 32, p. 837](#)). Rarely, a fetus will develop. If the triploidy involved a fetus surviving past the first trimester, the recurrence risk is 1 to 1.5 percent, sufficient to justify prenatal diagnosis ([Gardner and Sutherland, 1996](#)).
 - 8. Repetitive spontaneous first-trimester pregnancy losses.** If an abortus is karyotyped, it is unclear as to how to use the data. A history of one early loss caused by a fetal trisomy does not increase the maternal age-related risk for recurrent trisomic pregnancy. The majority of *repetitive* early losses are euploid ([Boue and co-workers, 1976](#); [Morton and associates, 1987](#); [Stray-Pedersen and Stray-Pedersen, 1984](#); [Warburton and colleagues, 1987](#)). The few repetitive early pregnancy losses associated with an aneuploidy tend to be caused by maternal or paternal inversions or translocations. These nontrisomic aneuploidies do increase the risk of having another pregnancy with the same karyotypic abnormality. This justifies prenatal diagnosis in subsequent pregnancies if there is not early loss. Considering these facts, karyotyping the *parents*, but not the aborted tissue, after repetitive early losses yields the most useful information about recurrence risks ([Warburton and associates, 1987](#)).
 - 9. Parental aneuploidy.** Trisomic individuals are often sterile. However, women with trisomy 21 or with 47, XXX, as well as men with 47, XYY are usually fertile and have a 30-percent risk to have trisomic offspring. Men with trisomy 21 or those with 47, XYY are usually sterile.
- ∴ A fetus with a major structural defect identified by ultrasound.** This increases the risk of aneuploidy sufficiently to warrant genetic testing of the fetus, regardless of maternal age or parental karyotypes ([Marchese and colleagues, 1985](#); [Waldimiroff and co-workers 1998](#); [Williamson and Pringle, 1987](#)).

ISOLATED STRUCTURAL ANOMALIES

Certain structural malformations are multifactorial or polygenic in origin, and thus have a recurrence risk for first-degree relatives of at least 2 to 3 percent. This warrants prenatal counseling and diagnosis. Any woman whose fetus has an affected first-degree relative—sibling, mother, or father—should be offered evaluation. The risk conferred by an affected second-degree relative—aunt, uncle, grandparents, half-siblings—is much lower, but many such patients will still request evaluation. For most multifactorial disorders, the risk resulting from affected third-degree relatives—cousins—is not substantively different than background risk ([Thompson and colleagues, 1991](#)). For life-threatening or otherwise severe malformations, efforts should be made to complete the evaluation as early in the pregnancy as possible, allowing time for pregnancy termination to be considered. If the parents have decided that they will continue the pregnancy regardless, and the method and location of the delivery will not be altered by the presence of the defect, for example with familial cleft lip, an ultrasound is done for patient reassurance. [Table 37-4](#) lists the kinds of structural defects that can be identified by an ultrasound examination performed by an experienced sonologist using high-resolution equipment.

CONGENITAL HEART DEFECTS. These are the most common isolated structural defects. They have an incidence of 7 per 1000 and a recurrence rate as high as 11 to 13 percent for obstructive left-sided lesions ([Burn and colleagues, 1998](#)). Prenatal diagnosis typically involves a careful sonographic evaluation of the heart, usually including an echocardiogram, at approximately 20 to 22 weeks ([Chap. 41, p. 1123](#)). This gestational age is optimal because it is advanced enough to allow visualization of all cardiac structures, but still early enough to allow time for a complete workup and consideration of pregnancy termination if an anomaly is found. If the previous lesion was related to abnormal blood flow—for example, hypoplastic left heart, coarctation of the aorta, or pulmonary or aortic stenosis—then a follow-up examination should be scheduled at 24 to 26 weeks. Flow-related defects are believed to result from a change in blood flow through the still-developing cardiac chambers, and have been reported to develop as late as the third trimester ([Hornberger and associates, 1996](#)).

NEURAL-TUBE DEFECTS. Women at increased risk of having a child with a neural-tube defect are offered alpha-fetoprotein *testing* as part of the diagnostic workup. The patient should be counseled and offered prenatal diagnosis with targeted ultrasound and amniocentesis if indicated. As shown in [Table 37-5](#), factors indicating increased risk include the following:

- 1. Family history of neural-tube defects.** This is the most important risk factor for neural-tube defects. Because they are multifactorial in inheritance, the risk to a first-degree relative is approximately 2 to 3 percent. While this is lower than the risk of an autosomal dominant or recessive disorder it is 20 to 30 times higher than the risk of neural-tube defects in the general population. The level of risk is directly related to the number of affected relatives and their degree of relatedness to the *fetus*, and should be estimated individually for each family ([Bonaiti-Pellie and Smith, 1974](#)).
- 2. Exposure to certain environmental agents.** A few of these have been implicated in neural-tube defect formation. Exposure must occur during the first 28 days of gestation when the neural tube is developing. **Hyperglycemia**, usually from insulin-dependent diabetes, increases the risk for neural-tube defects ([Becerra and colleagues, 1990](#)). The exact mechanism is unknown, but may involve inhibition of fetal glycolysis, a functional deficiency of arachidonic acid or myoinositol in the developing embryo, or alterations in the yolk sac ([Reece and Hobbins, 1986](#)). **Hyperthermia** during neural-tube formation has also been implicated to cause defects. Maternal fever and sauna baths have both been reported to increase the relative risk up to sixfold. The duration and intensity of temperature elevation necessary to produce an effect, as well as the embryological mechanism are unknown ([Milunsky, 1992](#)). Women concerned about exposing their fetus to acetaminophen should be counseled that exposure to a high fever is more dangerous than exposure to the medication. Certain **drugs** are thought to be causative. *Anticonvulsants*, most notably *valproic acid* and *carbamazepine*, impart a significantly increased malformation risk ([Chap. 38, p. 1013](#)). *Aminopterin* and *isotretinoin* have been associated with a constellation of abnormalities that can include anencephaly or encephalocele.
- 3. Neural-tube defects occurring as part of a genetic syndrome with a known recurrence risk.** Some inherited syndromes known to include neural-tube defects include Meckel-Gruber, Roberts-SC phocomelia, Jarco-Levin, and HARDE syndromes. These are all autosomal recessive with 25 percent recurrence risk. Trisomies 13 and 18 and triploidy all have a 1 percent recurrence risk ([Jones, 1997](#)). Cloacal exstrophy and sacrococcygeal teratoma may be associated with spina bifida. Amniotic bands may cause spina bifida or anencephaly, but these are believed to occur sporadically and have minimal recurrence risk.
- 4. Individuals belonging to high-risk racial or ethnic groups and/or living in high-risk geographic regions.** The United Kingdom has the highest frequency of neural-tube defects, with an incidence of almost 1 percent compared with 0.2 percent in the United States. China, Egypt, and India also have a very high incidence. The frequency of defects in these areas is probably related to both the ethnic (genetic) background of the inhabitants and environmental influences such as diet. This is illustrated by Indian Sikhs living in British Columbia, Canada, who experience less than half the neural-tube defect rate of Sikhs living in India ([Thompson and co-workers, 1991](#)). Likewise, individuals of Celtic origin living in the United States and ingesting a fortified American diet are at lower risk than those living in the United Kingdom ([Main and Mennuti, 1986](#); [Thompson and co-workers, 1991](#)). These interactions are discussed in greater detail in [Chapter 36 \(p. 958\)](#).

FAMILIAL GENETIC DISEASE

Couples with a personal or family history of a heritable genetic disorder should be offered genetic counseling. Using various laboratory methods discussed in [Chapter 36](#), potential parents can often be offered prenatal diagnosis or at least be provided with a more precise risk of having an affected child. Specific molecular tests for some common genetic diseases are available. The risk of diseases for which the responsible gene has not been identified can sometimes be estimated by comparing fetal DNA with that of affected and unaffected family members (RFLP analysis). The risk of diseases for which no laboratory test has been developed may, in some cases, be refined by ultrasound examination—if the disease is associated with fetal structural abnormalities, or by determination of fetal sex—if the disease is X-linked.

Although ongoing research will undoubtedly result in the development of genetic tests for a great number of diseases, a major issue that remains unresolved for many disorders is phenotype prediction. Because of variable penetrance and expressivity, identification of a specific disease gene is often not enough to predict the phenotype of the affected fetus, even when there have been other affected siblings or family members. The phenotypes of cystic fibrosis, for example, can vary widely within a family ([Chap. 36, p. 956](#)). Phenotype prediction is especially difficult when there are no other living affected family members, as would be the case if prenatal diagnosis was offered because of a remote family history or after screening parents at unknown risk.

ETHNIC GROUPS AT HIGH RISK. Although single-gene disorders are generally rare, some ethnic groups are at higher risk than the general population to have certain diseases, and should be counseled and offered genetic testing accordingly. Most of these diseases are caused by otherwise rare autosomal recessive genes that have increased in frequency in certain racial or ethnic groups after generations of mating only within those groups. Individuals from specific geographic regions can also be at increased risk because of genetic isolation, or a phenomenon called the *founder effect*. Autosomal recessive diseases found with increased frequency in ethnic groups living in the United States are listed in [Table 37-6](#) and discussed next.

AFRICAN, MEDITERRANEAN, CARIBBEAN, LATIN AMERICAN, OR MIDDLE EASTERN DESCENT. A number of clinically significant hemoglobin mutations are more prevalent in patients from these areas. Their clinical impact is considered in [Chapter 49 \(p. 1314\)](#). African Americans are at increased risk of having sickle cell anemia, a severe hemolytic disorder and the most common hemoglobinopathy in the United States. Southeast Asians are at increased risk to carry hemoglobin E, the second most common abnormal hemoglobin in the world.

MEDITERRANEAN OR ASIAN ORIGIN. These individuals are at increased risk of having α - or β -thalassemia ([Chap. 49, p. 1320](#)).

JEWISH ANCESTRY. These individuals are at increased risk for Tay-Sachs, Canavan, and Gaucher disease, each of which is caused by a different enzyme deficiency (hexosaminidase A, aspartoacylase, and glucocerebrosidase, respectively). The carrier rate among individuals of Ashkenazi Jewish heritage is 1 in 30 for Tay-Sachs disease, 1 in 40 for Canavan disease, and 1 in 12 to 25 for Gaucher disease. The [American College of Obstetricians and Gynecologists \(1995b\)](#) recommends that counseling and carrier screening for Tay-Sachs and Canavan disease be offered to all patients of Jewish heritage. Prenatal diagnosis is possible for both diseases. Gaucher disease is more complex because diagnosis requires molecular analysis, and there are three phenotypes that range from mild to severe. Prenatal screening for Gaucher disease, as well as Niemann-Pick, Bloom syndrome, and Fanconi anemia are controversial ([Zauri and associates, 1998](#)).

CAUCASIANS OF NORTHERN EUROPEAN DESCENT. Cystic fibrosis is the most common monogenic disorder in this population. It is transmitted in autosomal recessive fashion and has a carrier frequency of about 1 in 25 in Caucasian Americans, 1 in 30 in Native Americans, 1 in 50 in Hispanics, and it ranges from 1 in 90 to 1 in 25 in individuals of Jewish heritage ([National Institutes of Health, 1997](#)). More than 800 different gene mutations are known to cause cystic fibrosis. The most common cystic fibrosis mutation in Caucasians is $\Delta F508$ (75 percent) and in the Jewish population are 5T and W12828 (50 percent). If a specific gene mutation or mutations have been identified in an affected family, individuals at risk can be screened for those particular mutations. If both members of the couple carry a cystic fibrosis mutation, prenatal diagnosis is possible.

SCREENING FOR COMMON CONGENITAL ABNORMALITIES

The majority of neural-tube defects, Down syndrome, and many other fetal abnormalities occur in families with no prior history of birth defects. Prenatal evaluation of only high-risk women would thus fail to identify most affected pregnancies. Women with no family history of genetic abnormalities can now be offered screening tests for certain fetal disorders. The screening test does not provide a diagnosis, but identifies individuals whose risk is high enough that they would benefit from further evaluation. A positive screening test must be followed by a definitive test. Screening tests by design have a high false-positive and false-negative rate.

Genetic screening tests should meet the criteria generally accepted for other types of screening tests. These include that the disorder is well defined and serious; treatment or prevention is available, but not possible without the screening test; the test is cost effective and reliable; and there is a reliable diagnostic test ([Wald and associates, 1997](#)).

NEURAL-TUBE DEFECTS (NTDs)

The pathogenesis of neural-tube defects (NTDs) is discussed in [Chapter 36 \(p. 958\)](#). These defects are the second most common serious fetal malformation in the United States ([Centers for Disease Control and Prevention, 1995b](#)). Because only 5 percent of children with NTDs are born into families with other affected members, the majority occur in families with no prior history. Prior to the late 1970s, there was no way to identify these (unexpectedly) affected pregnancies, but then it was discovered that amniotic fluid and maternal serum alpha-fetoprotein was a marker for affected pregnancies.

ALPHA-FETOPROTEIN (AFP). This glycoprotein is synthesized by the fetal yolk sac early in gestation and later by the gastrointestinal tract and liver ([Chap. 7](#)). It circulates in fetal serum and passes into fetal urine and amniotic fluid. Although its function is unknown, it is the major serum protein in the embryo-fetus, analogous to albumin. Its concentration increases steadily in both fetal serum and amniotic fluid until 13 weeks, after which these levels rapidly decrease ([Burton, 1988](#)). AFP passes into the maternal circulation by diffusion across the placental membranes and may also be transported via the placental circulation ([Brumfield and colleagues, 1990](#)). It is found in steadily increasing quantities in maternal serum after 12 weeks ([Fig. 37-2](#)). When there is a fetal abnormality such as an opening uncovered by integument somewhere in the body or a number of other problems, then maternal AFP serum levels are increased.

[Brock and Sutcliffe \(1972\)](#) showed that amniotic fluid AFP levels were much higher in pregnancies complicated by fetal anencephaly. Subsequently, [Brock and colleagues \(1973\)](#) demonstrated that maternal serum AFP levels were also elevated in affected pregnancies. The first large prospective trial for maternal serum AFP screening was the [UK Collaborative Study on Alphafetoprotein in Relation to Neural-tube Defects \(1977\)](#). Screening for neural-tube defects was subsequently confirmed by others and adopted in the United States and Europe ([Burton and associates, 1983](#); [Haddow and colleagues, 1983](#); [Milunsky and co-workers, 1980](#)).

MATERNAL SERUM AFP SCREENING. This is usually done between 15 and 22 weeks, although it has the greatest sensitivity at 16 to 18 weeks. Factors that influence the result include maternal age, weight, race, diabetic status, and number of fetuses as well as gestational age determined by accurate menstrual history or sonography. Maternal serum AFP is measured in ng/mL and reported as a multiple of median (MOM) of the unaffected population. The latter is used because AFP levels do not follow a Gaussian distribution, and because it aids comparison of results from different laboratories and populations ([Fig. 37-3](#)). A confirmed increase in maternal serum AFP to greater than or equal to 2.0 to 2.5 MOM (for most laboratories) indicates increased risk for a fetal NTD or other structural anomaly and warrants further evaluation.

Evaluation for elevated maternal serum AFP begins with a basic ultrasound examination to determine fetal age and the number of fetuses, and to exclude fetal death ([Fig. 37-4](#)). Incorrect gestational age assessment accounts for a large proportion of abnormal test results. In some cases, a repeat serum AFP measurement may be helpful. As can be seen in [Figure 37-3](#), the distributions of serum AFP levels overlap in affected and unaffected pregnancies. If the level is within the range of the overlap—the indeterminate zone of 2.5 to 3.5 MOM—then repeating the measurement may determine to which distribution the sample belongs, that is, affected or unaffected. Because repeated sample values tend to regress toward the mean of population to which they belong, a truly elevated serum AFP level will still be elevated in the repeat sample, while a level corresponding to an unaffected pregnancy may normalize.

Maternal serum AFP levels greater than 3.5 MOM need not be repeated, as levels this high are outside the AFP distribution of unaffected pregnancies and clearly indicate increased fetal risk. In general, the likelihood that the fetus is affected increases along with the AFP level. In a study of 773 women with elevated serum AFP levels, [Reichler and colleagues \(1994\)](#) reported that there was a progressive increase in the frequency of neural-tube defects, ventral wall defects, and total anomalies as a direct function of maternal serum levels ([Fig. 37-5](#)). Approximately 40 percent of pregnancies were abnormal when the AFP level was greater than 7 MOM.

The majority of women with an abnormally elevated maternal serum AFP level do not have a fetus with a neural-tube defect. In some, other fetal anomalies or pregnancy abnormalities are the cause of increased levels ([Table 37-7](#)). The [American College of Obstetricians and Gynecologists \(1996c\)](#) recommends that all pregnant women be offered second-trimester maternal serum AFP screening. This is done only within a coordinated system that includes quality control, counseling, follow-up, and high-resolution sonographic facilities. Using an MSAFP level of 2.0 or 2.5 MOM as the upper limit of normal, most laboratories report a screen-positive rate of 3 to 5 percent, a sensitivity of at least 90 percent, and a positive-predictive value of 2 to 6 percent ([Milunsky and associates, 1989](#)). Because only 1 in 16 to 33 women with an elevated serum AFP level actually has an affected fetus, women should be counseled regarding the high false-positive rates, risks with amniocentesis, and the rationale for the screening program.

ULTRASOUND EXAMINATION. When elevated serum AFP levels are confirmed, the fetus is evaluated by targeted ultrasound. As shown in [Figure 37-6](#), anencephaly and other major cranial defects are usually readily visualized. Most spine defects can be detected as well ([Limb and Holmes, 1994](#)). They may be diagnosed by visualization of the open spinal lesion itself ([Fig. 37-7](#)). In some cases, the lesions are suspected following identification of certain associated cranial abnormalities ([Chap. 41, p. 1120](#)). In a review of 234 fetuses with spina bifida from nine different studies, [Watson and associates \(1991\)](#) reported that 99 percent had at least one of five specific cranial anomalies detected by ultrasound. These include frontal notching, also called the *lemon sign* ([Fig. 37-8](#)); ventriculomegaly with the lateral ventricle width greater than 10 mm; obliteration of the cisterna magna; small biparietal diameter; and elongated cerebellum referred to as the *banana sign* ([Fig. 37-8](#)). These cranial anomalies are most clearly visible in the second trimester, and some (lemon sign) may resolve later in pregnancy. Some authors recommend that a woman with an elevated serum AFP level could be counseled that the risk of a neural-tube defect is reduced by 95 percent if no spine defects or cranial findings are seen ([Hogge, 1989](#); [Morrow, 1991](#); [Van den Hof, 1990](#), and their colleagues). In fact, nearly 100 percent accuracy of detection of neural-tube defects with ultrasound has been reported ([Nadel and colleagues, 1990](#); [Sepulveda and associates, 1995](#)).

Ultrasound is also helpful in identifying other causes of elevated AFP levels such as fetal death or multiple gestation; structural abnormalities such as gastroschisis, omphalocele, bladder exstrophy, sacrococcygeal teratoma, cystic hygroma, hydrops, esophageal or intestinal obstruction, and renal abnormalities; and placental abnormalities such as chorioangioma or oligohydramnios ([Table 37-7](#)).

Although during the first decade of AFP screening, all women with elevated serum levels were offered amniocentesis routinely, current ultrasound resolution has made the need to measure amniotic fluid AFP controversial. Although some investigators have reported nearly 100 percent diagnostic accuracy with ultrasound without amniocentesis, others have not. Perhaps more realistic "real world" findings were described by [Platt and co-workers \(1992\)](#) from a statewide screening program that included ultrasound performed by a variety of practitioners. They reported that 6 of 161 open spina bifida cases were not recognized. Alternatively, amniotic fluid AFP analysis identifies all open neural-tube defects but misses the 3 to 5 percent of fetuses whose spinal defect is covered by skin ([Crandall and Matsumoto, 1984](#)). The decision for amniocentesis thus is individualized, and considers both ultrasound quality and patient desires.

AMNIOCENTESIS. Amniotic fluid AFP levels are measured if an NTD is suspected or if the ultrasound is nondiagnostic in the presence of elevated maternal serum AFP. If elevated, the presence or absence of acetylcholinesterase is determined in amniotic fluid. The presence of this enzyme verifies that there is exposed neural tissue or another open fetal defect. Elevation of the amniotic fluid AFP level without acetylcholinesterase suggests another etiology or from fetal blood contamination. Importantly, it frequently is prognostic of other adverse outcomes ([American College of Obstetricians and Gynecologists, 1996c](#)).

There is another reason for amniocentesis with sonographic diagnosis of an isolated neural-tube defect. Because of a small associated risk of aneuploidy, which would affect the prognosis considerably, fetal karyotyping may be indicated. [Hume and associates \(1996\)](#), in a review of over 17,000 prenatal diagnosis cases, observed a 2 percent rate of aneuploidy in the 106 fetuses with isolated neural-tube defects. [Harmon and colleagues \(1995\)](#) found that 7 of 43 fetuses with isolated neural-tube defects were aneuploid.

If the targeted ultrasound survey is normal when the maternal serum AFP level is clearly outside the indeterminate zone—that is, greater than 3.5 MOM—then amniocentesis for fetal karyotype is controversial. [Thiagarajah and colleagues \(1995\)](#) studied 658 women with elevated maternal serum AFP levels and concluded that there was no justification for routine fetal karyotyping with a normal targeted ultrasonography. In contrast, [Feuchtbaum and associates \(1995\)](#) reported results from 8097 women who underwent amniocentesis and fetal karyotyping under these circumstances and they found a twofold increased rate of chromosomal anomalies

compared with the general population. [Watson and colleagues \(1991\)](#) reported an aneuploidy rate of 1 in 164 composed of sex chromosome abnormalities, translocations, or triploidies.

Some clinicians evaluate the fetal karyotype only if both the maternal serum and amniotic fluid AFP are elevated. [Gonzalez and associates \(1996\)](#) reported that routine karyotyping was not necessary in women with elevated serum AFP but with normal amniotic fluid levels. If the amniotic fluid AFP was abnormal, however, the incidence of chromosomal abnormalities was elevated fivefold over background risk.

INCIDENTAL AMNIONIC FLUID AFP MEASUREMENT. When amniocentesis is done primarily for fetal cytogenetic analysis such as advanced maternal age, amniotic fluid AFP is often routinely measured. It is not known if this practice is cost-effective. In a retrospective analysis of 1737 such amniotic fluid specimens, [Sepulveda and associates \(1995\)](#) reported that ultrasonography correctly identified all fetuses with abnormal amniotic fluid AFP levels, and that routine measurement was probably unnecessary if targeted ultrasonography was normal. [Shields and colleagues \(1996\)](#), in a review of almost 7000 women who underwent second-trimester genetic amniocentesis, reported that measurement of amniotic fluid AFP did not increase the detection of fetal anomalies.

OTHER CAUSES OF ELEVATED SERUM AFP LEVELS. Maternal serum screening as described has a sensitivity of about 90 percent, but unfortunately has a positive-predictive value of only 2 to 6 percent ([Milunsky and colleagues, 1989](#)). Thus, the majority of women with elevated levels do not have a fetus with a neural-tube defect; however, some may be at increased risk for other conditions shown in [Table 37-7](#).

UNEXPLAINED ELEVATED ABNORMAL AFP LEVELS. Even if there are no obvious fetal abnormalities, unexplained high serum levels may forecast a poor pregnancy outcome. Several large studies have documented increased perinatal morbidity and mortality, including low birthweight, oligohydramnios, placental abruption, and fetal death in these women ([Katz, 1990](#); [Simpson, 1991](#); [Waller, 1991](#), and their associates). [Wenstrom and co-workers \(1992\)](#) showed that the first serum determination is most predictive and that serial measurements are not helpful. [Simpson and colleagues \(1991\)](#) did a cohort study and reported that there was a significant association between second-trimester but not third-trimester elevation of maternal serum AFP levels and preterm prematurely ruptured membranes, preterm birth, and low-birthweight infants. [Ramus and associates \(1996\)](#), in a study of 241 women with unexplained serum AFP elevations, reported a higher incidence of preterm delivery compared with women who had normal levels (22 versus 11 percent). The incidence of preterm delivery was highest (47 percent) in the 38 women who had both an otherwise unexplained elevated serum level along with placental sonolucencies on ultrasound.

Unfortunately, neither the etiology of the majority of elevated serum values, nor the most appropriate management for these women is clear. There is no evidence that such outcomes are favorably affected by any specific program of maternal or fetal surveillance ([American College of Obstetricians and Gynecologists, 1996c](#); [Cunningham and Gilstrap, 1991](#)).

MANAGEMENT OF THE FETUS WITH A NEURAL-TUBE DEFECT. Other than termination of pregnancy, options are limited. Anencephaly, exencephaly, and iniencephaly are lethal disorders, but some women with these diagnoses elect to continue their pregnancy and should receive routine prenatal care. Antenatal fetal testing, intrapartum fetal heart rate monitoring, and cesarean delivery for fetal indications are not recommended.

A woman whose fetus has another type of neural-tube defect may benefit from counseling by a pediatric neurosurgeon, neurologist, or other specialists in pediatric development. The fully informed couple is more likely to make the best decision and to be prepared for pregnancy outcomes.

If pregnancy is continued, serial sonographic examinations are done. Generally, delivery at term is optimal. Rapidly increasing ventriculomegaly, however, may prompt delivery before term so that a shunting procedure can be performed. The optimal timing and method of delivery remain controversial. All studies of vaginal versus cesarean delivery are retrospective, and all suffer from various biases ([Bensen and co-workers, 1988](#); [Luthy and colleagues, 1991](#); [Sakala and Andree, 1990](#)). Theoretically, cesarean delivery possibly avoids mechanical trauma and infection of the fetal spine. It also allows precise timing of the delivery so that the appropriate consultants can be available.

DOWN SYNDROME

The vast majority—97 percent—of Down syndrome pregnancies occur de novo in families with no previous history of this or other aneuploidy. Moreover, 80 percent are born to women who are younger than age 35 ([Chap. 36, p. 942](#)). Prior to the mid-1980s, diagnosis was limited to women 35 and older by genetic amniocentesis. In 1984, [Merkatz and colleagues](#) reported that Down syndrome screening was possible because these pregnancies were associated with unusually low maternal serum AFP levels. [Cuckle and colleagues \(1984\)](#) and [Haddow and associates \(1983\)](#) confirmed this, and neural-tube defect screening programs began to include Down syndrome screening. Because maternal age-related risk is still the most powerful predictor of fetal aneuploidy, screening programs eventually calculated risk by converting the serum AFP level to a likelihood ratio. The maternal age-related risk was multiplied by this ratio ([New England Regional Genetics Group, 1989](#)). Women with a calculated Down syndrome risk greater than a predetermined cutoff—usually either the midtrimester or term risk of a 36-year-old—were offered amniocentesis for definitive diagnosis.

MULTIPLE MARKER SCREENING. Serum analytes other than AFP were also found to be altered by fetal aneuploidy. These include elevated serum levels of chorionic gonadotropin and decreased unconjugated estriol with Down syndrome ([Bogart and colleagues, 1987](#); [Wald and associates, 1988a, 1988b](#)). Although both hCG and estriol can individually distinguish Down syndrome from euploid pregnancies, when used together with AFP, they are more predictive. Thus, the three relative risks are combined and multiplied by the age-related risk. This combination is termed the *expanded AFP test*, *AFP plus, triple screen*, or *multiple marker screening test*. The test has been validated and has become the preferred Down syndrome screening test in most centers ([Burton, 1993](#); [Cheng, 1993](#); [Haddow, 1992](#); [Wenstrom, 1993](#), and their colleagues). At a cutoff associated with about a 5 percent screen-positive rate, the multiple marker screening test identifies approximately 60 percent of all Down syndrome pregnancies in women under age 35 ([Table 37-8](#)). In women over 35, it detects over 75 percent of Down syndrome and a portion of other aneuploidies ([Haddow and co-workers, 1994](#)).

Many permutations of these analytes are in current use. Estriol measurement is a subject of debate, and some centers offer AFP and hCG alone. Some prefer free β -hCG measurement to the intact hCG molecule. A variety of other multiple-marker screening tests has been reported ([Bahado-Singh, 2001](#); [Morris, 2001](#); [Wenstrom, 1999](#), and their colleagues).

The multiple-marker test has a high false-positive rate, and only 6 percent of all screen-positive samples are associated with an affected fetus. Likewise, it has a false-negative rate. A negative multiple-marker screening test indicates "no increased risk," but does not mean that the fetus is normal. If gestational age is confirmed by sonography, these women with a positive screen are offered amniocentesis for karyotyping ([American College of Obstetricians and Gynecologists, 1996c](#)).

FIRST-TRIMESTER DOWN SYNDROME SCREENING. Identification of fetal aneuploidy earlier than is currently possible with traditional amniocentesis is desirable for many reasons, including that more options for pregnancy termination would be available. First-trimester screening protocols under study include maternal serum analyte screening, ultrasound evaluation, a combination of both, or urinary screening. The most discriminatory analytes at this gestational age appear to be free β -hCG and pregnancy-associated plasma protein A (PAPP-A) ([Haddow and associates, 1998](#); [Wald and colleagues, 1998](#)). The median free β -hCG level in affected pregnancies is approximately 1.79 MOM, while the median PAPP-A level is approximately 0.43 MOM.

Dimeric inhibin A and AFP levels are too similar in affected and unaffected pregnancies to be of value in first-trimester screening ([Wald and associates, 1988b](#)). Some problems include that free β -hCG is not markedly elevated in Down syndrome pregnancies until 12 weeks, while PAPP-A loses discrimination after 13 weeks. Accurate assessment of gestational age and careful timing of the screening test are thus essential ([Wald and co-workers, 1998](#)). Several investigative protocols combine maternal serum analytes, ultrasound assessment of the nuchal fold, long bone measurements, and other parameters as discussed later.

SERUM SCREENING IN WOMEN OVER AGE 35. If serum screening were totally accurate, empirical amniocentesis could be avoided. There is, however, no currently available screening test capable of determining with 100 percent accuracy which women over 35 have an aneuploid fetus. For some older women, serum screening facilitates the decision to undergo invasive testing.

ELECTIVE GENETIC AMNIOCENTESIS IN WOMEN UNDER AGE 35. Maternal age 35 was chosen somewhat arbitrarily as the age cutoff above which genetic amniocentesis should be routinely offered to all women. As discussed, this cutoff was chosen in part because, at age 35, the midtrimester risk of any aneuploidy roughly equals the risk of amniocentesis-associated pregnancy loss. With development of more sophisticated sonographic guidance, there now is a lower procedure-associated loss rate in many centers. Also, the relative weights of the two risks being considered—risk of aneuploidy versus the risk of pregnancy loss—may not be considered equal by all women. Thus, these must be determined individually according to each couple's own values and belief ([Pauker and Pauker, 1994](#)).

Because of the foregoing, some women under 35 may request amniocentesis despite reassuring maternal serum screening and ultrasound findings. [Druzin and co-workers \(1993\)](#) offered elective amniocentesis to 592 women younger than 35, and 161 (22 percent) accepted. There were no procedure-related losses. They concluded that they did not invoke any psychological issues to compel young women to accept invasive testing, and that the women were able to resist the "technological imperative." Each diagnostic center must develop its own protocol to handle such requests. Some consider requests by women at least 30 years old, who have a midtrimester risk for all aneuploidies of 1 in 384, to be reasonable, but they discourage younger women.

URINARY ANALYTES. Screening for fetal Down syndrome by urine testing is appealing because of ease and simplicity. Maternal urinary total estriol and the various forms of degraded hCG (intact and nicked hCG, free α - and β -subunits, and β -core fragment) seem to have the most potential for Down syndrome screening ([Canick and co-workers, 1995](#); [Cuckle and colleagues, 1994](#)). In a large multicenter international trial to investigate first trimester urinary β -core hCG fragment screening, [Cuckle and associates \(1999\)](#) reported a low discriminatory power. They analyzed 6730 samples from 16 centers, and only a fourth of all aneuploidies screened positive. Further research in this area is ongoing.

SCREENING FOR HERITABLE GENETIC DISEASES

The development of molecular tests for various genetic diseases has raised the possibility of population screening. Current debate centers on screening for fragile X and cystic fibrosis, but will no doubt extend to other conditions as more disease-specific genes are identified. The issues complicating fragile X and cystic fibrosis screening illustrate problems likely to be faced with other genetic screening tests. The wide range of phenotypes and the difficulty in predicting phenotypes make it unclear that the diseases in question are always well-defined and serious; there is often no treatment available other than pregnancy termination; the tests are usually expensive; and a reliable diagnostic test does not always exist.

FRAGILE X SYNDROME

This is the most common cause of familial mental retardation, and is discussed in detail in [Chapter 36 \(p. 954\)](#). Although it is an X-chromosome linked anomaly, inheritance of fragile X does not conform to the usual rules governing X-linked traits. This is because the fragile X mutation is an unstable region of repeated CGG trinucleotides that can expand only when transmitted by a female. When the expansion reaches a critical size (more than 230 repeats), it is methylated and thus inactivated. Female carriers of a "premutation" who have 56 to 229 CGG repeats are at risk to pass on an expanded gene, and the individual inheriting the gene is at high risk to exhibit fragile X phenotype ([Fisch and colleagues, 1995](#)).

CARRIER SCREENING. Based on current knowledge, fragile X does not meet criteria established for a good screening test. The prevalence of the premutation in the general population is unknown, so it is not clear who should be offered testing. It is estimated to be approximately 1 in 700, an incidence that is much lower than that of other genetic diseases for which screening is usually considered ([Hagerman and co-workers, 1991](#)). Currently, it is not possible to predict whether a female carrier will pass on an expanded gene. Scandinavian studies have demonstrated that even large premutations can be passed unchanged through several generations ([Holmgren and co-workers, 1988](#)). Finally, phenotype prediction in a fetus carrying the full mutation is also imprecise. Because of lyonization, as many as half of females inheriting the full fragile X mutation will be intellectually normal ([deVries and colleagues, 1996](#)). There also is wide phenotypic variation due to mosaicism in males inheriting the gene.

TESTING. Given the preceding concerns, it is currently recommended that any individual with unexplained mental retardation be tested for fragile X, especially if there are clinical findings consistent with the syndrome, or a family history ([Cutillo, 1994](#)). In this setting, approximately 2 to 6 percent of males and 2 to 4 percent of females will be determined to have the full mutation ([Curry and associates, 1997](#)). Family members of patients with documented fragile X syndrome should also be offered fragile X testing. The goal is to identify premutation carriers and allow them to make informed reproductive choices. Based on available data, it seems unlikely that it will be cost effective to test relatives of patients with unexplained mental retardation *not* known to be due to fragile X ([Curry and co-workers, 1997](#); [Wenstrom and collaborators, 1999a](#)). Testing of women without a family history of neurodevelopmental disorders is not recommended by the [American College of Obstetricians and Gynecologists \(1995c\)](#).

CYSTIC FIBROSIS

This autosomal recessive disorder is caused by a gene with a frequency of about 1 in 25 in Caucasians of Northern European heritage. As discussed in [Chapter 46 \(p. 1243\)](#), in its classical form it is marked by abnormal sweat chloride levels, chronic pulmonary disease, pancreatic insufficiency, liver disease, and obstructive azoospermia ([Rosenstein and Zeitlin, 1998](#)). The tremendous range of clinical expression likely reflects both the degree to which protein function is changed by the mutation, and variation in susceptibility to environmental factors associated with the altered protein. Although there have been improvements in care, there is no advantage to diagnosing cystic fibrosis prenatally other than to consider pregnancy termination.

CARRIER SCREENING. The CF gene on the long arm of chromosome 7 encodes the protein that is the *cystic fibrosis conductance transmembrane regulator (CFTR)*. Over 800 mutations in this large gene have been described thus far. Because it is not possible to screen for all known mutations during carrier testing, unless there is a family history, most laboratories screen for the 16 to 32 mutations causing most CF cases. The Δ F508 mutation is always included as it accounts for 75 percent of cases in Caucasians, and the 5T and W1282X mutations are included if the patient is Jewish. It is obvious that a negative test does not preclude possibilities of carrying another of the over 800 known mutations. Negative screening for 32 mutations does, however, reduce the risk substantively from the background rate.

Because CF is a recessive disorder, a fetus must inherit an affected gene from each parent to have the disease. If only one partner undergoes CF screening, the couple's risk to have a child with CF can be calculated assuming that the other partner has a 1 in 25 background risk. Some patients will be reassured by this analysis if the only goal is to determine the risk to the fetus. The key to CF screening is knowing which mutations to test for, which requires knowledge of the CF mutations common to different heritages. Currently, CF screening is most accurate for Caucasians of Northern European descent and for those of Ashkenazi Jewish heritage.

FETAL TESTING. If both parents are carriers, the fetus can be tested for homozygosity for the same mutation. Phenotype prediction is fairly accurate if the mutations are Δ F508 or W1282X. Other mutations are less closely associated with disease symptoms, making phenotype prediction and decisions about the fate of the pregnancy difficult. Importantly, there is poor genotype-phenotype correlation of these other mutations with pulmonary disease, which is the most severe aspect of CF. For all of these reasons, individuals who have an affected first- or second-degree relative should be offered counseling and possible cystic fibrosis screening. Although some authors have recommended that screening be offered to all pregnant women, the [American College of Obstetricians and Gynecologists \(1991, 1995a\)](#) recommends against widespread screening until the standard screening battery includes more mutations and thus reduces the risk further.

ULTRASOUND SCREENING

INCIDENTAL FINDING OF A MAJOR STRUCTURAL DEFECT

Major structural fetal anomalies or minor dysmorphic features are often discovered in otherwise low-risk pregnancies during ultrasonography performed for other indications. In addition to concerns about the anomaly itself, the *etiology* of the anomaly is important. For example, if the defect is part of a genetic syndrome, the fetus may have other abnormalities that are undetectable by ultrasound but which affect the prognosis—for example, mental retardation. Fetal aneuploidy is usually at the top of the differential diagnosis list, because such fetuses often have major anatomical malformations and minor dysmorphic features. The specific risk associated with several relatively common major anomalies is listed in [Table 37-9](#).

Fetal aneuploidy can only be diagnosed by evaluating the karyotype. The nature of the structural abnormality is used to estimate the risk of aneuploidy and to facilitate decisions regarding invasive testing. In general, any abnormality involving a major organ or structure, or the finding of multiple minor structural abnormalities in the same fetus, indicate a sufficiently significant risk of aneuploidy to justify amniocentesis ([Wladimiroff and associates, 1998](#); [Williamson and colleagues, 1987](#)). Although some combinations of anomalies may indicate a genetic syndrome not resulting from aneuploidy, fetal karyotype analysis is still warranted because aneuploidy-associated abnormalities can mimic other syndromes.

SONOGRAPHIC SCREENING FOR MAJOR STRUCTURAL ANOMALIES

Routine early second-trimester ultrasonography specifically to look for structural fetal abnormalities in low-risk women is controversial. Before this issue can be resolved, the detection and false-negative rates for such screening examinations need to be determined. The largest study to date addressing these issues is the RADIUS trial reported by [Ewigman and colleagues \(1993\)](#) and discussed in [Chapter 41 \(p. 1114\)](#). Almost 16,000 low-risk women were examined sonographically and one important finding was that only 17 percent of all major congenital anomalies were detected before 24 weeks. Although tertiary centers have higher detection rates, it appears that even under ideal circumstances, the detection rate for major anomalies may not be high enough to warrant routine screening with ultrasound in low-risk

women.

SONOGRAPHIC SCREENING FOR MINOR ABNORMALITIES

By themselves, minor abnormalities or dysmorphisms usually do not affect the fetal prognosis in any substantive way, but they are of extreme interest because they can be associated with fetal aneuploidy. To date, dysmorphisms have been studied mostly in high-risk women. It is controversial whether ultrasound evaluation for fetal dysmorphisms should be offered as a Down syndrome screening test in low-risk women—instead of or as a supplement to maternal serum screening. Down syndrome risks resulting from ultrasonically detected dysmorphisms such as thickened nuchal fold, mild hydronephrosis, echogenic bowel, slightly shortened long bones, choroid plexus cysts, and others derived from high-risk women are listed in [Table 37-10](#). Nuchal fold thickness appears to be the best discriminator of affected and unaffected pregnancies in the first trimester.

NUCHAL FOLD. This fold is seen as a sonolucency at the back of the fetal neck in the midsagittal plane. Although its precise etiology and significance are unknown, it may represent one end of the spectrum of lymphatic obstruction sequence. Most data regarding the utility of nuchal fold measurements have been obtained in the first trimester. Several investigators have reported that, even under optimal circumstances, first-trimester nuchal fold measurements typically identify less than half of all Down syndrome cases ([Brambati and colleagues, 1995](#); [Haddow and Palomaki, 1996](#)).

The nuchal fold is difficult to measure accurately and reproducibly at this early age ([Roberts and co-workers, 1995](#)). Normal measurements are between 0 and 5 mm, with an overlap of 2 to 3 mm in affected and unaffected populations. Flexion or extension of the head can change measurements by as much as 0.62 mm, while an unfavorable fetal position or maternal obesity may prevent measurement. [Roberts and colleagues \(1995\)](#) and [Haddow and Palomaki \(1996\)](#) have reported that first-trimester measurement is technically impossible in up to 20 percent of women. Finally, most prevalence data is from high-risk pregnancy, and it is unclear whether these can or should be extrapolated to younger, low-risk women ([Wald and colleagues, 1998](#)).

MATERNAL AGE. If one of a number of minor dysmorphisms is identified, then a better risk estimate can sometimes be calculated for Down syndrome using maternal age ([Vintzileos and associates, 1995](#); [Wald and colleagues, 1998](#)). This has been done for both nuchal fold thickening and choroid plexus cysts ([Fig. 41-6](#), p. 1121). [Gupta and colleagues \(1997\)](#) used data from 200,000 ultrasound examinations and concluded that isolated choroid plexus cysts in women over age 32 carried a significant enough risk of trisomy 18 to justify fetal karyotyping.

Another technique undergoing testing is revision of risk estimate of biochemical analytes by ultrasound findings. For example, it may be possible that combining dysmorphisms with AFP screening may provide a more accurate risk assessment for Down syndrome.

DIAGNOSTIC TECHNIQUES

SECOND-TRIMESTER AMNIOCENTESIS

Amniocentesis for genetic diagnosis is usually performed between 15 and 20 weeks. A number of multicenter studies have confirmed its safety as well as its more than 99 percent diagnostic accuracy ([Canadian Early and Mid-Trimester Amniocentesis Trial Group, 1998](#); [NICHD National Registry for Amniocentesis Study Group, 1976](#)). Typically, ultrasound guidance is used to pass a 20- to 22-gauge spinal needle into the amniotic sac while avoiding the placenta, umbilical cord, and fetus. The initial aspirate of 1 or 2 mL of fluid is discarded to decrease the chance of maternal cell contamination, and then after approximately 20 mL of fluid is collected, the needle is removed. The puncture site is observed for bleeding, and the patient is shown the beating fetal heart and remaining amniotic fluid at the conclusion of the procedure. Several studies have confirmed that the incidence of bloody taps, amniotic fluid leakage, and multiple punctures are inversely related to the operator experience ([Leschot and co-workers, 1985](#); [Romero and colleagues, 1985](#)).

Minor complications are infrequent and include transient vaginal spotting or amniotic fluid leakage in 1 to 2 percent and chorioamnionitis in fewer than 1 in 1000. Needle injuries to the fetus are rare when ultrasound guidance is used. Cell culture failure is also rare, but is more likely if the fetus is abnormal ([Persutte and Lenke, 1995](#)). The fetal loss rate is 0.5 percent or less (1 in 200), and it does not appear possible to reduce this further ([Simpson, 1990](#); [Wilson and colleagues, 1984](#)). It may be that some losses result from preexisting abnormalities and were destined to occur whether or not amniocentesis was performed. These might include placental abruption, abnormal placental implantation, uterine anomalies, and infection. [Wenstrom and colleagues \(1996\)](#) analyzed 66 postamniocentesis losses following nearly 12,000 second-trimester procedures, and found that 12 percent were caused by preexisting intrauterine infection.

EARLY AMNIOCENTESIS

This is performed between 11 and 14 weeks and has been widely studied ([Johnson, 1994](#); [Nicolaidis, 1994](#); [Shulman, 1994](#); [Sundberg, 1997](#), and all of their associates). The technique is the same as for traditional amniocentesis, although lack of membrane fusion to the uterine wall makes puncture of the sac difficult, and less fluid is withdrawn (usually 1 mL for each week of gestation). For reasons that are not yet clear, early amniocentesis results in significantly higher pregnancy loss and complication rates than traditional amniocentesis. In a recent multicenter randomized trial, in which all procedures were performed by skilled operators, the spontaneous pregnancy loss rate following early amniocentesis was 2.5 percent compared with 0.7 percent with traditional amniocentesis ([Canadian Early and Mid-Trimester Amniocentesis Trial Group, 1998](#)). These rates are consistent with those of many other studies.

Early amniocentesis has also been associated with significantly more positional foot deformities than traditional amniocentesis ([Fig. 37-9](#)). Most large studies report an incidence of talipes of 1 to 1.4 percent after the early procedure compared with 0.1 percent (the same as the background rate) after traditional amniocentesis. The Canadian study also found that membrane rupture was more likely after the early procedure, and the incidence of talipes was 15 percent in cases with early postprocedure fluid leak. Because oligohydramnios was transitory, it is likely that the foot deformities resulted from a disruption caused by damage to the vascular supply of the developing leg and foot, rather than a deformation caused by oligohydramnios forcing the foot into one position for a prolonged period. Finally, significantly more cell culture failures occurred after the early procedure, necessitating an additional invasive procedure. For all these reasons, many centers no longer offer amniocentesis before 14 weeks.

CHORIONIC VILLOUS SAMPLING (CVS)

The indications for biopsy of chorionic villi are essentially the same as for amniocentesis, except for a few analyses that require amniotic fluid rather than cells or tissue. The primary advantage of CVS is that results are available earlier in pregnancy, which decreases parental anxiety when results are normal and, allows earlier and safer methods of pregnancy termination when they are abnormal. Chorionic villus sampling is generally performed at 10 to 13 weeks. Placental villi may be obtained through transcervical, transabdominal, or transvaginal access to the placenta ([Fig. 37-10](#)). Later in pregnancy, when a fetal abnormality is associated with severe oligohydramnios, transabdominal CVS may be preferred. Skill in ultrasound-guided procedures and specialized training are required before attempting CVS, and maintenance of skills is essential. Relative contraindications include vaginal bleeding or spotting, extreme ante- or retroversion of the uterus, and patient body habitus precluding easy access to the uterus or clear visualization of its contents with ultrasound. Active infection is a contraindication. Complications of CVS are similar to those of amniocentesis.

A number of randomized and case-control trials have compared the safety of CVS with amniocentesis, and of transabdominal CVS with the transcervical procedure. [Wald and colleagues \(1998\)](#) summarized eight randomized trials and found that transcervical CVS has an excess fetal loss rate of 3.7 percent compared with transabdominal CVS or traditional amniocentesis. This rate is similar to that for early amniocentesis.

There have been small series or case reports that suggest an association between CVS and limb-reduction defects, oromandibular defects, and cavernous hemangiomas ([Burton, 1992](#); [Firth, 1991, 1994](#); [Hsieh, 1995](#), and their colleagues). The accumulated experience, however, of nearly 139,000 CVS cases reported to an International Registry of the World Health Organization refutes this. [Kuliev and colleagues \(1996\)](#) showed that the global 10-year experience with CVS done after 9 weeks had an incidence of limb-reduction defects of 6 per 10,000, which is the same as background. A National Institute of Child Health and Human Development workshop of CVS and limb-reduction defects concluded that the frequency of oromandibular-limb hypogenesis appeared to be more common after CVS only when the procedure was performed before 9 weeks ([Bianchi and associates, 1993](#); [Kalousek and Dill, 1983](#)). Transabdominal CVS performed after 9 weeks appears to be as safe as second-trimester amniocentesis.

LABORATORY RESULTS. Midtrimester amniocentesis is associated with the lowest number of uninformative results (up to 0.8 percent), compared with transcervical CVS (0.8 to 1.5 percent) or transabdominal CVS (1 percent) ([Canadian Collaborative CVS-Amniocentesis Clinical Trial Group, 1989](#); [Rhoads and colleagues, 1989](#)). Uninformative results are primarily due to a failure to obtain a sample or the detection of apparent mosaicism. The latter is the finding of more than one distinct cell line obtained from a single chorionic villus sample. Mosaicism may (rarely) represent true fetal mosaicism, but usually indicates *confined placental mosaicism*, or

pseudomosaicism ([Chap. 36, p. 949](#)).

PERCUTANEOUS UMBILICAL CORD BLOOD SAMPLING (PUBS)

Umbilical cord blood was first obtained under direct visualization by [Valenti in 1973](#) who used a surgical endoamioscope and general anesthesia. Fetal blood sampling in the second trimester by placental aspiration using fetoscopy was subsequently described, but was not ideal ([Cao and associates, 1982](#); [Rodeck and Campbell, 1978](#)). [Daffos and colleagues \(1983\)](#) then described the technique now known as percutaneous umbilical cord blood sampling (PUBS) or cordocentesis. After evaluation by [Hobbins \(1985\)](#), [Daffos \(1985\)](#), [Nicolaidis \(1986b\)](#), [Hogge \(1988\)](#), [Weiner \(1988\)](#), and others, cordocentesis became a routine procedure for specific fetal indications. Some of these include evaluation of fetal abnormalities, severe growth restriction, congenital infection, thrombocytopenia, hydrops, twin-to-twin transfusion syndrome, and certain genetic diseases.

The umbilical vein is punctured under direct ultrasound guidance, usually at or near its placental origin, and blood is withdrawn ([Fig. 37-11](#)). Currently, and as discussed in [Chapter 39](#), it is performed primarily for assessment and treatment of confirmed red cell or platelet alloimmunization, and for the analysis of nonimmune hydrops ([Fisk and Bower, 1993](#)). It can also be used to obtain fetal blood cells for genetic analysis when CVS or amniocentesis results are confusing or when rapid diagnosis is necessary. For example, cord blood sampling can be performed when a fetal malformation or severe growth restriction is detected late in pregnancy, and when fetal diagnosis might change management of labor and delivery. Karyotype analysis of fetal blood can usually be accomplished within 24 to 48 hours. The fetal blood sample can also be sent as necessary for metabolic and hematological studies, acid-base analysis, viral cultures, and immunological studies.

COMPLICATIONS. Many complications are similar to those for amniocentesis. [Ghidini and colleagues \(1993\)](#) reviewed unique complications and the most common were umbilical cord vessel bleeding (50 percent), hematoma (17 percent), fetal-maternal hemorrhage (66 percent with an anterior placenta and 17 percent with a posterior placenta), and fetal bradycardia (3 to 12 percent). Most complications were transitory, with complete fetal recovery; however, fetal death does occur. [Ghidini and associates \(1993\)](#) estimated that the procedure-related loss rate was 2.7 percent. This rate appears to be strongly related to the indication for the procedure. It was lower with evaluation of possible isoimmunization in a healthy fetus and higher for evaluation of a severely compromised growth-restricted fetus or a fetus with an anomaly ([Maxwell and colleagues, 1991](#)).

FETAL TISSUE BIOPSY

Some genetic conditions affecting the fetus cannot be diagnosed by molecular genetic techniques. Linkage analysis has been used for diagnosis, but is helpful only if there are other living, informative, affected family members ([Chap. 36, p. 965](#)). In some of these conditions, prenatal diagnosis can sometimes be performed by direct analysis of fetal tissue obtained by sonographically guided skin or muscle biopsy. As with other invasive procedures, biopsy requires specific training, and the outcome appears to be directly related to operator skill and experience.

The technique has been used by [Evans and colleagues \(1994\)](#) for muscle biopsy to diagnose muscular dystrophy and mitochondrial myopathy in 12 high-risk fetuses. [Elias and co-workers \(1994\)](#) used skin biopsy in 17 fetuses at high-risk for epidermolysis bullosa.

PREIMPLANTATION DIAGNOSIS

The identification of genes responsible for certain severe hereditary diseases and the development of techniques for in vitro fertilization have provided access to the early embryo and the means to perform preimplantation diagnosis. It is hoped that preimplantation diagnosis will allow selection of only healthy embryos to avoid pregnancy termination. Applications include diagnosis of single-gene disorders such as cystic fibrosis or sickle cell disease, sex determination in X-linked diseases, and identification of aneuploidy with advanced maternal age or parental chromosome rearrangements.

Several variations in technique have been reported. Some clinicians favor *polar body analysis*, reasoning that the first polar body is expelled anyway and its removal should not affect fetal development. A second technique utilizes the 3-day embryo (6- to 10-cell stage), and involves *blastomere biopsy* through a hole made in the zone pellucida. Loss of one totipotent cell at this stage supposedly has little or no effect on the developing embryo, although too few children have been followed to be certain of this. Genetic testing of the removed cell is performed and unaffected embryos are transferred. This technique is still under development. Prenatal diagnosis using only one isolated cell can be very difficult and fraught with errors ([Simpson and Carson, 1992](#); [Viville and associates, 1996](#)).

FETAL CELLS IN THE MATERNAL CIRCULATION

Since the 1950s, various types of fetal cells have been identified in the maternal circulation ([Douglas and colleagues, 1959](#); [Kleihauer and associates, 1957](#)). It is now known that virtually all women have at least a small number of fetal cells in their bloodstream ([Goldberg, 1997](#)). If these fetal cells could be analyzed for prenatal diagnosis, it would obviate the need for invasive procedures. [Walnowska and co-workers \(1969\)](#) used cumbersome cytogenetic techniques to correctly determine fetal sex in 19 of 22 women carrying a male fetus. Fetal cell isolation was advanced by the development of cell-sorting techniques in the late 1970s ([Steele and associates, 1996](#)). These take advantage of unique cell surface proteins and other characteristics that distinguish fetal from maternal cells. These can be separated by density-gradient or protein separation techniques, fluorescence-activated cell sorting, or magnetic-activated cell sorting. Nucleated red blood cells are most easily isolated.

Isolated fetal cells have been evaluated for autosomal recessive diseases such as β -thalassemia ([Camaschella and associates, 1990](#)). It has also been used for fetal red cell D antigen typing ([Geifman-Holtzman and colleagues, 1996](#)). Fetal cells can be karyotyped using fluorescence in situ hybridization (FISH) ([Poon and co-workers, 2000](#); [Price and colleagues, 1991](#)). [Bianchi and colleagues \(1997\)](#) have reported a sixfold increase in fetal cells in the maternal blood if the fetus is aneuploid.

A number of problems must be resolved before these techniques can be used clinically for fetal diagnosis. Currently, an ongoing multicenter trial sponsored by the National Institutes of Health promises to perfect the technique for widespread application ([Simpson and Elias, 1998](#)). Even if all limitations are not overcome, fetal cell isolation may be useful as a screening test for aneuploidy.

FETAL THERAPY

PREGNANCY TERMINATION

Unfortunately, there is no antenatal therapy available for most congenital anomalies. Despite this, the patient and her family still benefit from prenatal diagnosis because it allows an informed decision about pregnancy continuation and psychological preparation. In addition to maternal-fetal medicine or genetics referral, consultation with a pediatric neurosurgeon, gastrointestinal surgeon, cardiologist, or urologist may be helpful. In some cases, only one of twin fetuses is involved. In cases of high-order multiple fetuses, selective reduction results in better outcomes ([Chap. 30, p. 777](#)). A complete summary of the counseling session is placed in the medical record. Techniques for pregnancy termination are discussed in [Chapter 33 \(p. 870\)](#).

TWIN-TO-TWIN TRANSFUSION SYNDROME

This is a unique complication of monochorionic twin pregnancies that is discussed in detail in [Chapter 30 \(p. 785\)](#). All monochorionic twins share a placenta which contains vascular anastomoses potentially connecting the two circulations. [Schatz recognized as early as 1875](#) that a small proportion of such twins have unequal blood flow as the result of unbalanced anastomoses, and they have varying degrees of discordancy of weight, intravascular volume, hemoglobin concentration, and amniotic fluid volume. In the extreme case, one twin is severely growth restricted with no amniotic fluid—giving it the sonographic appearance of being "stuck" to one spot in the uterus—while the co-twin is larger, often plethoric, and has hydramnios ([Mahony and associates, 1985](#)). Approximately 15 percent of monozygotic twin pregnancies develop some degree of this complication ([Nicolaidis and Petterson, 1994](#)).

Therapeutic options for twin-to-twin transfusion are limited. It has been shown that removal of fluid from the sac with hydramnios somehow improves the pressure differential between the two fetal circulations and occasionally may even reverse the unequal fluid balance between the twins ([Elliott and co-workers, 1991](#); [Mahony and colleagues, 1990](#); [Pinette and associates, 1993](#)). Others have reported intentional creation of an opening in the amnion separating the fetuses, allowing fluid to interchange and supposedly equalizing pressure differences ([Vetter and Schneider, 1988](#)). A more invasive therapy is endoscopic laser ablation of placental vascular anastomoses, literally separating the surface of the placenta into two halves ([De Lia and collaborators, 1995](#)). Because many offending anastomoses are deep in the placenta, this procedure is not always successful and has a high complication rate ([Fisk and associates, 1990](#)). The most aggressive therapy is selective feticide of the donor twin, usually considered for early severe cases that would otherwise result in the death of both twins ([Arabin and associates, 1998](#); [Weiner, 1987](#)). When

severe twin-to-twin transfusion occurs before 24 weeks, the prognosis is poor regardless of therapy ([Bebington and Wittmann, 1989](#)).

FETAL TRANSFUSION

ISOIMMUNIZATION. Intraperitoneal red blood cell transfusion for treatment of fetal anemia from red cell isoimmunization was the first invasive fetal therapy accepted into routine practice ([Berkowitz and Hobbins, 1981](#); [Bowman, 1976](#); [Frigoletto and colleagues, 1981](#)). Using fluoroscopic guidance and a large-bore trocar and needle, blood placed into the fetal abdominal cavity is gradually absorbed by the subdiaphragmatic lymphatics. Severely affected fetuses, especially those with ascites or hydrops, often were not able to absorb enough blood to survive. In addition, the procedure entailed significant risk. Subsequently, [Rodeck and colleagues \(1981, 1984\)](#) described fetoscopically guided intraumbilical blood transfusion, using a 2.4- to 3.0-mm cannula. This was followed by accounts of ultrasonically guided transfusion directly into the hepatic portion of the umbilical vein or the fetal heart ([Bang and associates, 1982](#); [deCrespigny and colleagues, 1985](#); [Westgren and co-workers, 1988](#)).

[Grannum and colleagues \(1986\)](#) described the currently used technique of sonographically directed transfusion into the umbilical cord vein using a 22-gauge needle. With a few modifications, this technique has proved efficacious and safe ([Berkowitz, 1986](#); [Nicolaidis, 1986a](#); [Weiner, 1991](#), and their colleagues). The large fetal-placental volume allows infusion of a relatively large quantity of blood over a short period, and direct sonographic guidance allows direct fetal monitoring. Furosemide can also be administered directly along with the blood, to relax the capacitance vessels and facilitate the clearance of excess plasma. In [Table 37-11](#), the outcomes of 44 isoimmunized women managed with intraumbilical transfusion are compared with the outcomes of 44 women managed by intraperitoneal transfusion. These groups were matched for severity of disease, gestational age, and placental site. The results highlight the greater efficacy and lower morbidity of the intraumbilical procedure.

PARVOVIRUS INFECTION. A small number of fetuses affected by parvovirus B19 infection will develop severe transient aplastic anemia ([Chap. 56, p. 1466](#)). Fetuses infected before 20 weeks are most likely to develop severe anemia with heart failure and subsequent hydrops. While an unknown number spontaneously recover and survive, others that are severely compromised will die. Some of these moribund fetuses can be rescued with blood transfusion ([Peters and Nicolaidis, 1990](#); [Sahakian and colleagues, 1991](#)). In a fetus with nonimmune hydrops, cord blood sampling can be performed to confirm anemia. Fetal and maternal blood is used to identify parvovirus DNA by polymerase chain reaction ([Dieck and associates, 1999](#)). Transfusions are not always lifesaving, probably because some infections include lethal viral myocarditis which cannot be diagnosed antenatally.

OTHER INDICATIONS. Transfusion may also be considered after a severe, but not ongoing fetal-maternal hemorrhage. It has also been described in a case of fetal hemoglobin Bart disease ([Chap. 49, p. 1319](#)). [Copel and co-workers \(1991\)](#) have administered platelet transfusion for severe alloimmune thrombocytopenia using the same technique ([Chap. 39, p. 1072](#)).

FETAL MEDICAL THERAPY

In a unique number of instances, fetal therapy is accomplished by maternal treatment with the desired medication. In other cases, medication is administered directly to the fetus by intramuscular injection or intravenous infusion through the umbilical vein. There are many examples of fetal treatment with maternally administered medications. The obvious example is that treatment of many infections is directed at both patients, for example, syphilis. In other cases, only the fetus is affected, such as the woman with Graves disease who has been rendered euthyroid by radioiodine ablation. The IgG thyroid-stimulating antibody crosses the placenta and causes fetal thyrotoxicosis with up to 25 percent mortality ([Bruinse and colleagues, 1988](#)). In fetuses with suspected compromise, thyroid status can be assessed by cordocentesis, and maternal treatment given with propylthiouracil that crosses the placenta to suppress the fetal thyroid ([Wenstrom and associates, 1990](#)). Also, [David and Forest \(1984\)](#) reported that maternally administered corticosteroids resulted in fetal adrenal suppression and thus prevented fetal masculinization in congenital adrenal hyperplasia.

Up to 1 percent of fetuses have a cardiac arrhythmia, however, only a small number are hemodynamically significant ([Copel and associates, 2000](#)). Most arrhythmias are tolerated without compromise or the arrhythmia resolves spontaneously ([Simpson and colleagues, 1997](#)). When there is sustained tachyarrhythmia, the fetus may begin to show cardiac decompensation, which can progress to hydrops. Maternally administered antiarrhythmic agents cross the placenta in therapeutic doses. Digoxin, verapamil, propranolol, procainamide, quinidine, flecainide, sotalol, and amiodarone have all been given for fetal arrhythmias with reasonable results in nonhydropic fetuses ([Edwards and colleagues, 1999](#); [Sonesson and associates, 1998](#)). With fetal hydrops, however, these drugs do not enter the fetal circulation as well ([Younis and Granat, 1987](#)). In these cases, medication is administered directly to the fetus through the umbilical cord or by intramuscular injection in the buttock ([Mangione and co-workers, 1999](#); [Parilla and colleagues, 1996](#)).

CONGENITAL INFECTION. Several infectious agents can cross the placenta and cause fetal infection with serious consequences. Because effective antenatal treatment can ameliorate some or all of the most severe associated fetal morbidity, treatment of maternal infections constitutes fetal therapy. Diagnosis and treatment of syphilis, gonorrhea, toxoplasmosis, and a number of sexually transmitted or other infectious diseases are discussed in [Chapters 56 and 57](#).

FETAL SURGERY

With only a few exceptions, fetal surgery is still in the pioneering stages. There are a few in utero surgical procedures that are commonplace, but most are considered experimental. Fetal surgery is performed in only a few centers by teams trained in multidisciplinary techniques required for complete care of both mother and fetus. Some of these procedures are discussed in greater detail in the second edition of *Operative Obstetrics* ([Gilstrap and colleagues, 2001](#)).

Recent technical advances, especially in ultrasound and laparoscopic surgical techniques, make it possible to consider surgical correction of structural fetal malformation. There are a number of requisites that are necessary before surgical intervention is considered. Importantly, the natural history of the condition, both with and without therapy, must be known. Because intervention entails substantial fetal and maternal risks, as well as risk to subsequent pregnancies, it should not be considered unless withholding such intervention is absolutely certain to be catastrophic. There must be certainty that the surgical treatment, barring unforeseen complications, will improve outcome. The importance of this criterion is underscored by early experiences with antenatal ventriculoamniotic shunt placement to correct fetal obstructive hydrocephalus. The results of the first 44 procedures reported to the International Fetal Surgery Registry were discouraging ([Manning and colleagues, 1986](#)). The procedure-related fetal death rate was 10 percent, and 18 of the 34 survivors had serious neurological handicaps. It eventually became clear that the natural history of the condition without (and with) shunting was unknown, and appropriate selection criteria for the procedure could not be determined. A third criteria is that the procedure has been perfected and tested successfully in experimental animals, preferably a primate ([Harrison and colleagues, 1980](#); [Moise and associates, 1995](#)). The surgery, usually considered experimental, must be performed by an experienced operator. Rigorous evaluation of the efficacy of these techniques should be expected prior to their widespread use.

While early enthusiasm for fetal surgery has waned somewhat, there is progress concerning the complex influences on fetal development and the unique features of various defects. Along with this understanding, there are a few fetal lesions for which antenatal surgical intervention is considered.

URINARY SHUNTS. As discussed, in many cases the presence of a major urinary tract malformation indicates aneuploidy or another genetic syndrome usually associated with a poor prognosis. An isolated malformation, however, may have the potential for a good prognosis with correction. This is not possible with malformations such as cystic dysplasia or renal agenesis in which associated oligohydramnios has prevented development of the fetal lungs. This mechanism is considered in [Chapter 31 \(p. 822\)](#).

Because fetal urine is the major source of amniotic fluid after 16 weeks, any urinary obstruction can be lethal ([Fig. 37-12](#)). Such lesions include posterior urethral valves, urethral atresia, and ureteropelvic junction obstruction. Outflow obstruction increases intrarenal pressure and produces dysplastic renal changes ([Adzick and Harrison, 1994](#)). Almost 20 years ago, it was theorized that, if fetal urine could somehow be shunted into the uterine cavity, then pulmonary hypoplasia and related problems could be avoided. In the early 1980s, a double-pigtail catheter was placed to reduce pressure and restore amniotic fluid volume ([Berkowitz and colleagues, 1982](#); [Harrison and associates, 1982](#)). It was positioned under ultrasound guidance as shown in [Figure 37-13](#). In experienced hands, fetal survival after such surgery was 70 percent ([Holzgreve and Evans, 1993](#)).

Because most of the poor outcomes are related to serious renal pathology in survivors, the biggest problem is selecting appropriate fetuses for treatment. It has become clear that many fetuses with bladder outlet obstruction already have significant renal dysfunction ([Johnson and associates, 1995](#)). Because correct determination of the cause of the obstruction is important for prognosis, [Quintero and associates \(1995\)](#) have investigated the use of percutaneous fetal cystoscopy.

THORACIC SHUNTS. Accumulation of thoracic fluid can also cause pulmonary hypoplasia by compressing developing lung structures. Some causes include chylothorax, infection, and chest tumors. While successful outcomes after thoracic shunt placement for isolated fetal hydrothorax have been reported, a review by

[Hagay and colleagues \(1993\)](#) suggested that the procedure may not significantly change perinatal outcomes. Of 82 cases, 54 were managed conservatively and 24 were treated either with a thoracic shunt or serial thoracentesis. About a third of fetuses died in each group.

Intrathoracic masses leading to pulmonary hypoplasia include pulmonary sequestration, congenital cystic adenomatoid malformation, and nonspecific cysts ([Harrison and co-workers, 1998](#)). Their diagnosis is considered in [Chapter 41 \(p. 1123\)](#). Fetal goiter or tracheal atresia also may prevent egress of pulmonary fluid. Thoracic shunt placement has been described for all these entities, with variable success. Although fluid drainage immediately following the procedure is usually good, obstruction or displacement of the shunt leads to rapid reaccumulation. Shunt placement in the presence of hydrops is generally not curative, probably because the fetus has already suffered damage, is moribund at the time of the procedure, or because the hydrops itself indicates a more serious abnormality with a poor prognosis ([Adzick and co-workers, 1993](#); [Weiner and colleagues, 1986](#)).

CONGENITAL DIAPHRAGMATIC HERNIA. This is one of the first malformations for which ex utero fetal surgery was performed. The incidence of this defect in the general population is about 1 in 3700 ([Wenstrom and colleagues, 1991](#)). Up to half of these fetuses have genetic syndromes or other associated defects that may be lethal ([Powers and Phillips, 1990](#)). In those with isolated malformations, some survive intact. [Harrison and associates \(1990b\)](#) postulated that antenatal surgical correction of the diaphragmatic defect might restore normal intrathoracic anatomy to allow pulmonary development and prevent pulmonary hypoplasia ([Fig. 37-14](#)). Fetal surgery was justified by data suggesting perinatal mortality of up to 80 percent ([Adzick and co-workers, 1985](#)), however, this rate was challenged ([Wenstrom and colleagues, 1991](#)). Early attempts had survival rates of 25 percent with antenatal intervention. Unfortunately, complication rates, including prematurely ruptured membranes and preterm labor were common. It now seems clear that fetuses with late or intermittent left-sided herniation do well after neonatal surgery, while fetuses with early herniation, mediastinal shift, and dilated intrathoracic stomach or liver do poorly despite repair ([Harrison, 1996](#)).

Another approach to prevent pulmonary hypoplasia has been evaluated by [Harrison and colleagues \(1998\)](#). They reasoned that if normal pulmonary efflux could be prevented, the lungs would inflate with fluid and fill the thorax. This would mechanically keep bowel out of the chest, and thus pulmonary growth would continue. They also took advantage of fetal endoscopic surgical techniques, collectively called *Fetendo* ([Deprest and colleagues, 1997](#); [Vanderwall and co-workers, 1996](#)). They used these techniques to band or plug the trachea in fetuses with congenital diaphragmatic hernia—this protocol is called *Plug the Lung Until it Grows*, or *PLUG*. This procedure was offered only to women whose fetus had a poor prognosis due to liver herniation diagnosed before 25 weeks. In 34 fetuses with poor prognoses, parents chose postnatal treatment with extracorporeal membrane oxygenation in 13, open fetal surgery for tracheal occlusion in 13, or fetoscopic tracheal occlusion in eight ([Harrison and colleagues, 1998](#)). The survival rate in the fetoscopic surgery group was 75 percent compared with only 15 percent in the open surgery group and 40 percent in the neonatal therapy group.

SACROCOCCYGEAL TERATOMA. This is a congenital germ cell tumor composed of tissues representing all three germ layers. It arises from totipotent cells in Hensen node or from ectopic primordial germ cells in the sacral area. In addition to a malignant potential of 10 to 20 percent, perinatal morbidity is high because teratomas are very vascular with numerous arteriovenous shunts. Vascular steal syndromes or hemorrhage result in fetal anemia, heart failure, and hydrops ([Altman and colleagues, 1974](#)). Early detection usually indicates an aggressive tumor. Survival is less than 10 percent in fetuses whose tumors are identified before 30 weeks, compared with 75 percent in those discovered later ([Malone and co-workers, 1990](#)).

In view of the very poor prognosis for early aggressive lesions, prenatal surgical excision has been attempted, but largely without success ([Langer and colleagues, 1989](#)). An alternative approach is to attempt palliative surgery (debulking) in order to prevent hydrops, and to reserve the definitive repair until after birth. [Graf and colleagues \(1998\)](#) reported good results with debulking in four of five fetuses. [Harrison \(1996\)](#) has suggested the possibility to debulk or reduce the blood supply to the tumor endoscopically.

CONGENITAL CYSTIC ADENOMATOID MALFORMATION AND PULMONARY SEQUESTRATION. These two pulmonary lesions may be amenable to fetal surgical therapy. Congenital cystic adenomatoid malformations (CCAMs) are pulmonary hamartomas consisting of overgrown terminal bronchioles. Type I has large cysts, type II has multiple small cysts less than 1.2 cm, and type III is essentially solid. Type III lesions have the worst prognosis. Pulmonary sequestration is a tissue mass that becomes completely separated from normal lung, which receives its blood supply from the systemic circulation. The intralobar variety is located inside the pleura adjacent to normal lung, while the extralobar variety has its own separate pleura, like an accessory lobe.

Both of these may enlarge, eventually leading to mediastinal shift, pleural effusions, hydramnios, and perinatal death from hydrops or pulmonary hypoplasia. Alternatively either may regress spontaneously. [Adzick and colleagues \(1993\)](#) found that 28 of 39 (72 percent) sequestrations regressed before delivery compared with only 15 of 120 (13 percent) of CCAMs. While half of the latter continued to grow, they did not cause hydrops, and fetuses without hydrops did well after neonatal surgery.

There is a subgroup of fetuses with either lesion who are good candidates for fetal surgery because the natural history of the lesions are known, and those with a poor prognosis can be readily identified. Those whose lesions rapidly enlarge leading to early hydropic changes usually do not survive, even with aggressive neonatal therapy. Thus, early or fully hydropic fetuses are candidates for serial cyst drainage or antenatal surgical resection. [Adzick and colleagues \(1993\)](#) offered fetal surgery only to fetuses with a poor prognosis. All 25 fetuses with large cystic CCAMs and hydrops died with expectant management. Conversely, there were eight survivors of 13 hydropic fetuses managed with open fetal lobectomy. There were 5 of 6 survivors with thoracoamniotic shunting. Fetuses with a large cyst do well with such shunting ([Adzick and Nance, 2000](#)).

NEURAL-TUBE DEFECTS. Isolated open spine defects that are not part of a genetic syndrome or associated with other anomalies, often result in permanent neurological damage ([Chap. 36, p. 958](#)). Observations are consistent with a *two-hit hypothesis* in these fetuses. The first "hit" is the defect itself, and the second comes from continued exposure to amniotic fluid ([Heffez and colleagues, 1990](#)). Several investigators have theorized that antenatal closure or coverage of the spine defect might avert some of the neurological damage. Currently, both open surgical closure and laparoscopic techniques are being evaluated.

With the fetal sheep model, Harrison's group has shown that repair of induced fetal spine defects prevents tissue damage and "rescues" neurological function ([Meuli and co-workers, 1995, 1996](#)). [Bruner and colleagues \(1999a\)](#) described four human fetuses whose open lower-spine defects were covered endoscopically with a maternal skin graft at 22 to 24 weeks. It was hoped that this would prevent herniation of the hindbrain into the foramen magnum with obstruction and ventriculomegaly—the *Arnold-Chiari malformation*. The two survivors were delivered at 28 and 35 weeks had only mild somatosensory deficit. [Bruner and co-workers \(1999b\)](#) also compared 10 fetuses who underwent open surgical repair at 26 to 30 weeks with 20 fetuses without antenatal repair. The surgically treated fetuses had a significantly decreased need for ventriculoperitoneal shunt placement after delivery. Unfortunately, the open surgical procedure was associated with serious complications, including preterm delivery and even extrusion of fetal small parts through the uterine incision. Because only very preliminary observations of these procedures have thus far been reported, and most of the children are still too young to assess mobility or control of bodily functions, the procedure remains experimental ([Adzick and Nance, 2000](#)). It also remains controversial because spina bifida is not a lethal defect.

STEM CELL TRANSPLANTATION

This is a therapeutic option for several hematological diseases. Because immunocompetence in the human fetus does not develop until 18 weeks, it would appear possible that the fetus would be tolerant to foreign antigens before that time. Hematopoietic stem cells might also serve as a delivery vehicle for gene transfer. A number of animal models have been developed to study fetal bone marrow transplantation. [Crombleholme \(1989\)](#), [Harrison \(1989\)](#), and others have identified the optimal time interval for transplantation in primate models, and have investigated sources of hematopoietic stem cells including fetal liver, umbilical cord blood, and adult bone marrow. Therapeutic fetal bone marrow transplantation has been attempted in the human fetus for such diseases as bare lymphocyte syndrome, severe combined immunodeficiency syndrome, thalassemia, metachromatic leukodystrophy, and group D isoimmunization. Unfortunately, there has been very limited success; however, research efforts are ongoing ([Crombleholme and Bianchi, 1994](#); [Westgren and co-workers, 1996](#)).

GENE TRANSFER

With advances in genetic technologies and progress in the identification of genes responsible for inherited disease, the possibility of gene transfer for definitive therapy is being explored. Fetal gene transfer is appealing for several reasons, which are summarized in an excellent review by [Pergament and Fiddler \(1995\)](#). First, certain inherited metabolic conditions are particularly devastating because tissue damage begins shortly after or even before birth. In Tay-Sachs disease, for example, central nervous system cells exhibit the characteristic pathology as early as 9 weeks after conception ([Grabowski and colleagues, 1984](#)). Second, early therapy holds out the prospect of being administered only one time, definitive, and having a lifetime impact. Third, parents could be assured of healthy children without having to choose termination of affected pregnancies.

A number of criteria are considered requisite for the development of therapeutic gene transfer. These criteria, which have not been met, include:

1. That the normal gene can be inserted into the target cells and remain there long enough to have the desired effect.
2. That the level of gene expression in the new gene will be appropriate.
3. That the new gene will not harm the cell or the individual ([Anderson, 1984](#)).

Other unresolved issues include the timing of the procedure, viz., preconceptional, at the time of fertilization, prior to implantation, or during embryogenesis or fetal development; the best DNA vectors to use; the ideal recipient or target cells; and the safest methods. Efficient techniques for in vivo gene targeting have yet to be developed, and the possibility of ex vivo gene transfer raises ethical considerations. Ethical questions remaining to be resolved include whether or not to target fetal gonadal tissues—which would affect future generations—and how to prevent gene transfer from being used for enhancement of phenotype rather than disease prevention (eugenics). Gene transfer is still in its earliest experimental stages, and it must be thoroughly investigated in animals and adult humans before it can be extended to fetuses.

TABLE 37-2. Women with Risk of Fetal Aneuploidy High Enough to Justify Risk of Amniocentesis

Singleton pregnancy with age = 35 at delivery
Dizygotic twin pregnancy with age \geq 31 at delivery
Previous autosomal trisomy birth
Previous 47,XXX or 47,XXY birth
Patient or partner is carrier of chromosome translocation
Patient or partner is carrier of chromosomal inversion
History of triploidy
Some cases with repetitive early pregnancy losses
Patient or partner has aneuploidy
Major fetal structural defect by ultrasound

**TABLE 37-4. High-Resolution
Ultrasonography for Detection of Fetal
Anomalies**

Head

Anencephaly
Ventriculomegaly/hydrocephaly
Encephalocele
Intracranial lesions

Gastrointestinal

Duodenal atresia
Omphalocele
Gastroschisis

Neck

Cystic hygroma
Branchial cleft cysts
Teratomas

Urinary Tract

Bilateral renal agenesis
Polycystic kidneys
Multicystic kidneys

Spinal

Myelomeningocele
Sacrococcygeal teratomas

Skeletal

Achondroplasia
Agenesis or hypoplasia of bones
Osteogenesis imperfecta
Camptomelic dysplasia

Chest

Diaphragmatic hernia
Pleural effusion

Cardiac^a

^a Frequently requires echocardiography.

TABLE 37-7. Some Conditions Associated with Abnormal Maternal Serum Alpha-fetoprotein Concentrations

Elevated Levels

Neural-tube defects
Pilonidal cysts
Esophageal or intestinal obstruction
Liver necrosis
Cystic hygroma
Sacrococcygeal teratoma
Abdominal wall defects—omphalocele, gastroschisis
Urinary obstruction
Renal anomalies—polycystic or absent kidneys
Congenital nephrosis
Osteogenesis imperfecta
Congenital skin defects
Cloacal exstrophy
Chorioangioma of placenta
Low birthweight
Oligohydramnios
Multifetal gestation
Decreased maternal weight
Underestimated gestational age
Maternal hepatoma or teratoma

Low Levels

Chromosomal trisomies
Gestational trophoblastic disease
Fetal death
Increased maternal weight
Overestimated gestational age

TABLE 37-9. Aneuploidy Risk Associated with Major Structural Fetal Malformations

Defect	Population Incidence	Aneuploidy Risk	Most Common Aneuploidy (Trisomy)
Cystic hygroma	1/120 EU-1/6000 B	60-75%	45 X (80%), 21, 18, 13, XXY
Hydrops	1/1500-4000 B	30-80% ^a	13, 21, 18, 45, X
Hydrocephalus	3-8/10,000 LB	3-8%	13, 18, triploidy
Hydranencephaly	2/1000 IA	Minimal	
Holoprosencephaly	1/16,000 LB	40-60%	13, 18, 18p-
Cardiac defects	7-9/1000 LB	5-30%	21, 18, 13, 22, 8, 9
Diaphragmatic hernia	1/3500-4000 LB	20-25%	13, 18, 21, 45, X
Omphalocele	1/5800 LB	30-40%	13, 18
Gastroschisis	1/10,000-15,000 LB	Minimal	
Duodenal atresia	1/10,000 LB	20-30%	21
Bowel obstruction	1/2500-5000 LB	Minimal	
Bladder outlet obstruction	1-2/1000 B	20-25%	13, 18
Facial cleft	1/700 LB	1%	13, 18, deletions
Limb reduction	4-6/10,000 LB	8%	18
Club foot	1.2/1000 LB	20-30%	18, 13, 4p-, 18q-
Single umbilical artery	1/100 LB	Minimal	

B = birth; EU = early ultrasound; IA = infant autopsy; LB = live birth.

^a 30% if diagnosed =24 weeks; 80% if diagnosed =17 weeks.

Data from Marchese (1985); Nyberg (1990); Wald (1998); Wladimiroff (1998); Williamson (1987), and all their colleagues.

TABLE 37-10. Down Syndrome Risk Associated with Minor Fetal Abnormalities and Dysmorphic Features

Ultrasound Marker	Risk (%)	False-Positives (%)
Nuchal fold = 6 mm	38	1.3
Femur length (O/E)	34	5.9
Femur length (BPD/FL)	22	5.9
Humerus length (O/E)	37	5.3
Femur plus humerus (O/E)	36	3.7
Pyelectasis	19	2.4
Hyperechogenic bowel	11	0.7
Ventricular dilatation	6	0
Choroid plexus cyst	0	1.8
Ear length	78	8.0
Fifth midphalanx hypoplasia	75	18
Increased iliac length	50	2
Short frontal lobe	21	4.8

BPD = biparietal diameter; FL = fetal length; O/E = observed compared with expected.

38. Teratology, Drugs, and Medications

A birth defect is defined as a major deviation from normal morphology or function that is congenital in origin. Birth defects are common, and 3 percent of all children born in the United States have a major structural malformation detectable at birth. In addition, by 1 year of age, 7 percent have developmental disorders identified, 12 to 14 percent by the time they enter school, and 17 percent before age 18 ([Boyle and associates, 1994](#); [Kimmel and colleagues, 1993](#)). Less than a third of all patients seeking genetic counseling for birth defects have a primarily genetic condition ([Hanson, 1996](#)). The majority of congenital abnormalities are due to nonheritable factors. Only about 10 percent of malformations identified at birth are caused by teratogens ([Shepard, 1998](#)). Only a small number of the latter have been positively identified.

TERATOLOGY

A teratogen is any agent that acts during embryonic or fetal development to produce a permanent alteration of form or function ([Shepard, 1998](#)). Teratology is the study of all environmental contributions to abnormal development. Currently recognized teratogens include chemicals, viruses, environmental agents, physical factors, and drugs. Women commonly ingest medications or drugs while pregnant. In a study of almost 9000 Medicaid prenatal patients in Michigan, [Piper and colleagues \(1987\)](#) reported that each woman received an average of 3.1 prescriptions for drugs other than vitamins. Commonly used drugs include antiemetics, antacids, antihistamines, analgesics, antimicrobials, antihypertensives, tranquilizers, hypnotics, and diuretics. A substantial number of pregnant women also abuse recreational drugs during pregnancy. A study by [Vega and colleagues \(1993\)](#) found that 5.2 percent of 29,494 women presenting for delivery in 202 California hospitals were using one or more illicit drugs, including amphetamines, barbiturates, benzodiazepines, cannabinoid, cocaine, methadone, opiates, or phencyclidine. Another 6.7 percent were using alcohol, and 8.8 percent smoked cigarettes prior to delivery.

The word *teratogen* is derived from the Greek *teras*, meaning monster. Because this derivation implies obvious, visible defects, a teratogen is most properly defined as an agent that produces structural abnormalities. Since recognition of a structural anomaly at birth is often straightforward, its association with a specific agent is more likely to be suspected. Some congenital abnormalities, however, do not become apparent until later. A *hadegen*—after Hades, the god who possessed a helmet conferring invisibility—is an agent that interferes with normal maturation and function of an organ. A *trophogen* is an agent that alters growth. Hadegens and trophogens generally affect processes occurring after organogenesis or even after birth. Chemical or physical exposures that act as hadegens or trophogens are much harder to document. For simplification, most authors use the word teratogen to refer to all three types of agents.

EVALUATION OF POTENTIAL TERATOGENS

A birth defect in a child exposed prenatally to a certain drug, chemical, or environmental agent naturally arouses concern that the agent was a teratogen. Before such culpability is established, and as shown in [Table 38-1](#) and described next, certain criteria must be met.

THE DEFECT MUST BE COMPLETELY CHARACTERIZED. This should be done preferably by a geneticist or dysmorphologist. A wide variety of genetic and environmental factors can often produce the same anomaly. For example, although cleft lip and palate are associated with antenatal hydantoin exposure, there are also more than 300 known genetic causes ([Murray, 1995](#)). Identical defects with different etiologies are called *phenocopies* ([Chap. 36, p. 940](#)). In general, it is easiest to prove causation when a rare drug exposure produces a rare defect, when at least three cases have been identified, and when the defect is relatively severe. For example, it has not been difficult to show that isotretinoin is a teratogen because relatively few pregnant women have taken it during pregnancy, and one associated defect—agenesis of the ears—is an otherwise rare and severe abnormality.

THE AGENT MUST CROSS THE PLACENTA. The drug or chemical must cross in sufficient doses to directly influence fetal development, or alter maternal or placental metabolism to exert an indirect fetal effect. Placental transfer depends on maternal metabolism, protein binding and storage, molecular size, electrical charge, and lipid solubility. Additionally, placental tissue contains an array of enzymes including cytochrome P-450, which may metabolize offending substances, and in the first trimester has a relatively thick membrane which slows diffusion ([Leppik and Rask, 1988](#)). These requirements are illustrated by the vitamin A analogs. *Isotretinoin* given for cystic acne readily crosses the placenta and produces severe fetal defects, while its topical form, *tretinoin*, is not absorbed in appreciable amounts and thus has no apparent fetal effects ([Shepard, 1998](#)).

EXPOSURE MUST OCCUR DURING A CRITICAL DEVELOPMENTAL PERIOD. Gestation is divided into the following periods:

1. Preimplantation period, the 2 weeks from fertilization to implantation.
2. Embryonic period, from the second through the eighth week.
3. Fetal period, from 9 weeks until term.

Syndromes from drug exposure are named accordingly—major effects occurring within the first 8 weeks result in an *embryopathy*; after 8 weeks, a *fetopathy*.

The **preimplantation period** has been called the "all or none" period. The zygote undergoes cleavage and cells divide into an outer and inner cell mass. An insult damaging a large number of cells usually causes death of the embryo. If only a few cells are injured, compensation is usually possible with continued normal development ([Clayton-Smith and Donnai, 1996](#)). Some animal research studies have challenged this concept by showing that an insult that diminishes the number of cells in the inner cell mass can produce a dose-dependent diminution in body length or size ([lahnaccone and co-workers, 1987](#)).

The **embryonic period** is the most crucial with regard to structural malformations because it encompasses organogenesis. [Figure 38-1](#) illustrates the critical structural development period for each organ system. For example, the heart undergoes major structural development between 3.5 and 6 weeks, and is completely formed by the eighth week. Drugs associated with cardiac malformations can only exert an effect if ingested during this time. It follows that if pregnancy is diagnosed at 10 weeks in a woman ingesting a known cardiac teratogen, there is no advantage to discontinuing the drug.

Throughout the **fetal period** maturation that is important for functional development continues but the fetus remains vulnerable. For example, the brain remains susceptible throughout pregnancy to environmental influences such as alcohol exposure. Alteration in cardiac blood flow during the fetal period can result in deformations such as hypoplastic left heart or aortic coarctation ([Clark, 1984](#)). Any agent that reduces amniotic fluid volume between 20 to 25 weeks can cause pulmonary hypoplasia.

CAUSE AND EFFECT MUST BE BIOLOGICALLY PLAUSIBLE. After consideration of the pharmacology of the drug and maternal and fetal metabolism, is it biologically plausible that the suspected agent caused the defect? Because both birth defects and drug or environmental exposures are common, it is always possible that an exposure and a defect are temporally but not causally related. For example, pregnant women often express concern over ingesting food or drinks containing aspartame (Nutrasweet). However, aspartame is metabolized to aspartic acid, which does not cross the placenta; phenylalanine, which is normally metabolized; and methanol, which is produced in levels lower than are found in an equivalent amount of fruit juice.

EPIDEMIOLOGICAL STUDIES MUST BE CONSISTENT. Recurrent findings of characteristic abnormalities in association with a possible environmental exposure should prompt suspicion. Abnormalities include fetal wastage, fetal growth restriction, structural abnormalities, and altered neurological function ([Hanson, 1996](#)). The initial evaluation of teratogen exposure is usually retrospective, and is likely to be hampered by recall bias, inadequate reporting, and incomplete assessment of the exposed population. This is further confounded by a variety of doses, concomitant drug therapy, and maternal disease(s). Familial and environmental factors can also influence development of birth defects. Thus, an important criterion for proving teratogenicity is that two or more high-quality epidemiological studies report similar findings.

Epidemiological studies can be **descriptive**, monitoring the change in frequency of a certain birth defect in a specified population over time; **analytic**, looking for an association between certain exposures and specific outcomes; or **experimental**, in which the exposure occurs as the result of the study. Optimally, epidemiological studies are controlled for confounding factors, exclude positive and negative biases, include a sufficient number of cases, and are carried out prospectively. Additionally, a relative risk greater than three is generally necessary to support the hypothesis; a lesser risk should be interpreted with caution ([Khouri and colleagues, 1992](#)).

An illustration of the advantages of prospective evaluation is the Canadian multicenter study of lithium exposure during pregnancy ([Jacobson and colleagues, 1992](#)).

Case reports had linked lithium to the rare cardiac malformation, *Ebstein anomaly*. In the study, 138 women taking lithium were monitored prospectively, with confounding factors carefully detailed. A control group was monitored identically, and children born to both groups were evaluated by echocardiography. There was no difference in the incidence of birth defects between the two groups, nor was there an association between lithium and any cardiac malformation.

Suspected teratogens are rarely evaluated epidemiologically, and as a result drug safety information is derived from case reports and small series. Nonscientific and biased reporting has contributed to subsequently proved false assertions that such widely used drugs as benzodiazepines and spermicides were teratogenic. In many cases this prompted litigation and cessation of manufacture of some very useful drugs. An example is Bendectin, a drug that was safe and effective for the treatment of nausea and vomiting in early pregnancy. More than 30 million women used this drug worldwide and the 3 percent congenital anomaly rate among exposed fetuses was not different from the background rate ([McKeague and associates, 1994](#)). Despite scientific evidence that Bendectin did not cause birth defects, it was the subject of numerous lawsuits. The financial burden of defending these suits forced its withdrawal, after which hospitalizations for hyperemesis gravidarum increased ([Koren and co-workers, 1998](#)). [Brent \(1985\)](#), concluded that although a drug may not be a teratogen, it may be a *litogen*!

THE SUSPECTED TERATOGEN CAUSES A DEFECT IN AN ANIMAL. If a suspected teratogen causes birth defects in experimental animals, the agent may be harmful to the human fetus ([Jelovsek and colleagues, 1989](#)). The more species in which a drug produces an effect, especially if testing includes subhuman primates, the more likely it is to have an effect on humans. However, drugs under development are often tested in animals at the equivalent of toxic human doses, making fetal outcomes difficult to interpret. Additionally, different species of animals often have different responses to the same drug. Reliance solely on animal data is imperfect as illustrated by thalidomide. This drug is one of the most potent teratogens ever prescribed, but this was not immediately recognized because it produced no defects in mice and rats ([Shepard, 1998](#)). Conversely, corticosteroids have been withheld in pregnancy because they cause cleft lip in rodents, although, there is no evidence that they cause human structural malformations ([Czeizel and Rockenbauer, 1997](#)).

FOOD AND DRUG ADMINISTRATION CLASSIFICATIONS

The rating system developed to provide therapeutic guidance based on potential benefits and maternal and fetal risks is shown in [Table 38-2](#). However, it may be based on case reports or limited animal data, and updates of these ratings are sometimes slow—for example, oral contraceptives were listed as category X for many years after their teratogenicity was disproved. [Friedman and colleagues \(1990\)](#) concluded that these categories have no correlation with teratogenic risk. The [Teratology Society Public Affairs Committee \(1994\)](#) has proposed that the current rating system be abandoned in favor of an evidence-based rating system which is currently under development. The most current information can be obtained from a drug information service (offered by many academic centers) or an on-line reproductive toxicity service such as reprotox.

GENETIC AND PHYSIOLOGICAL MECHANISMS OF TERATOGENICITY

Teratogens likely act by disturbing specific pathogenetic processes, leading to cell death, altered tissue growth, abnormal cellular differentiation, or disruption of normal development. The mechanism by which most teratogens disturb these processes is unknown. Presumed mechanisms of several agents have been inferred from clinical observations and animal research. Some teratogens disrupt one or more of these processes, and combinations of drugs may be additive. Two established mechanisms of teratogenesis are disruption of folic acid metabolism and production of oxidative intermediates.

DISRUPTION OF FOLIC ACID METABOLISM

Several congenital anomalies, including neural-tube defects, cardiac defects, and cleft lip and palate are thought to arise from disturbance of folic acid metabolic pathways. Folic acid is essential for the production of methionine, which is a co-factor in RNA and DNA synthesis, and is required for methylation of proteins, lipids, and myelin ([Scott and associates, 1994](#)). Hydantoin, carbamazepine, valproic acid, and phenobarbital all impair folate absorption or act as antagonists ([Donaldson, 1989](#)). There may be a relationship between decreased preconceptional folate levels in epileptic women and fetal malformations ([Dansky and colleagues, 1987](#); [Hiilesmaa and co-workers, 1983](#)). Periconceptional folate supplementation decreases malformations in offspring exposed to maternal anticonvulsant therapy ([Biale and Lewenthal, 1984](#); [Zhu and Zhou, 1989](#)).

OXIDATIVE INTERMEDIATES

Hydantoin, carbamazepine, and phenobarbital are metabolized by microsomes to arene oxides or epoxides. These oxidative intermediates are detoxified by cytoplasmic *epoxide hydrolase*. The fetus produces arene oxides from anticonvulsants, but because fetal epoxide hydrolase activity is weak, oxidative intermediates accumulate in fetal tissue ([Horning and colleagues, 1974](#)). These free oxide radicals have carcinogenic, mutagenic, and other toxic effects ([Buehler and associates, 1990](#)). These effects are dose related and increase with multidrug therapy ([Lindhout and co-workers, 1984](#)). Damage resulting from toxic intermediates may be common to other teratogens.

Because abnormal physiological processes are induced in many different cells or tissues, teratogen exposure commonly results in multiple effects. Conversely, different drugs that disturb similar pathophysiological processes can produce similar phenotypes. The **fetal hydantoin syndrome** illustrates these concepts (p. 1013). Exposure may cause any combination of growth deficiency, borderline mental deficiency, craniofacial abnormalities, hypoplasia of the distal phalanges, and widely spaced nipples. This phenotype also results from prenatal exposure to carbamazepine, and it is similar to fetal alcohol syndrome ([Vorhees and associates, 1988](#)).

EFFECTS OF MATERNAL DISEASES

The interaction of maternal disease and maternal and fetal genetic makeup will determine some drug effects. For example, alcoholic women often have poor nutrition and abuse other drugs. Fetuses exposed to these combined adverse influences are at higher risk for malformation than those exposed to alcohol alone. Heredity and socioeconomic factors appear to influence the development of birth defects in offspring of epileptic women. Even untreated epileptic women have an increased risk of fetal anomalies ([American Academy of Neurology, 1998](#)).

FETAL GENETIC COMPOSITION

It is likely that many anomalies now categorized as multifactorial are caused by the interaction of environment and certain altered genes. For example, fetuses exposed to hydantoin are most likely to develop anomalies if they are homozygous for a gene mutation resulting in abnormally low levels of epoxide hydrolase ([Buehler and associates, 1990](#)). Another example is a reported association between cigarette smoking and isolated cleft palate, but observed only in individuals with an uncommon polymorphism in the gene for transforming growth factor α -1. The risk of clefts in individuals with this allele is increased two- to sevenfold ([Hwang and colleagues, 1995](#); [Shaw and co-workers, 1996](#)).

HOMEBOX GENES

Certain genes are found in all humans and confer equal susceptibility to specific agents. For example, all vertebrates carry groups of highly conserved genes which share a region of homology and are called **homeobox genes**. These regulatory genes encode nuclear proteins that act as transcription factors to control the expression of other developmentally important genes ([Boncinelli, 1997](#)). They are essential for establishing positional identity of various structures along the body axis from the branchial area to the coccyx. The arrangement of the genes along the chromosome corresponds to the arrangement of the body areas they control, and the order in which they are activated. Genes at the 3' end control the cranial region and are expressed before those at the 5' end, which control the caudal region ([Faiella and collaborators, 1994](#)). During normal embryogenesis, retinoids such as vitamin A activate some of these genes essential for normal growth and tissue differentiation. The potent teratogen, retinoic acid, can activate these genes prematurely, resulting in chaotic gene expression at sensitive stages of development ([Soprano and Soprano, 1995](#)). This mechanism has been linked to abnormalities in the hindbrain and limb buds. Valproic acid may preferentially activate a homeobox gene near the 5' end that regulates axial skeletal patterning. This corresponds with clinical observations that most neural-tube defects caused by valproic acid are in the lumbosacral area.

PATERNAL EXPOSURES

It is possible that paternal exposures to drugs or environmental influences may increase the risk of adverse fetal outcome ([Robaire and Hales, 1993](#)). Several mechanisms have been postulated. One is the induction of a gene mutation or chromosome abnormality in sperm. Because the process by which germ cells mature into functional spermatogonia takes 64 days, drug exposure at any time during the 2 months prior to conception could result in a mutation. A second possibility is that a drug in seminal fluid could gain exposure to the fetus during intercourse. Third, male germ cell exposure to drugs or environmental agents may alter genomic imprinting or cause other changes in gene expression ([Trasler and Doerksen, 1999](#)).

Some studies support these hypotheses. Ethyl alcohol, cyclophosphamide, lead, and certain opiates have been associated with an increased risk of behavioral defects in the offspring of exposed male rodents ([Nelson and colleagues, 1996](#)). In humans, paternal environmental exposure to mercury, lead, solvents, pesticides, anesthetic gases, or hydrocarbons has been associated with early pregnancy loss although the data is of varying quality ([Savitz and associates, 1994](#)). Offspring of men employed in the art or textile industries have been reported to be at increased risk for stillbirth, preterm delivery, and growth restriction. Others who may have an increased risk of congenital fetal anomalies include janitors, woodworkers, firemen, printers, and painters ([Olshan and co-workers, 1991](#); [Schnitzer and associates, 1995](#)). There have been no adverse outcomes associated with paternal therapeutic or recreational drug exposure, atomic radiation exposure, or Agent Orange ([Centers for Disease Control, 1998](#), [Trasler and Doerksen, 1999](#)).

COUNSELING FOR TERATOGEN EXPOSURE

Women who request genetic counseling for drug exposure during pregnancy often have misconceptions regarding their risk. [Koren and colleagues \(1989\)](#) reported that a fourth of pregnant women seeking counseling because of exposure to nonteratogenic drugs thought they had a 25 percent risk of fetal anomalies, equivalent to thalidomide exposure. These women may also underestimate the background risk of birth defects in the general population. Such misconceptions can be amplified by the referral source, who may exaggerate risk—and even offer pregnancy termination—or by inaccurate articles in the lay press. Counseling should include discussion of possible teratogenic risks of the condition for which the drug was prescribed as well as its genetic implications, in addition to any fetal risks from drug exposure. Ideally, women should be counseled preconceptionally ([Chap. 9](#)). In reality, however, patients often report such exposure after conception.

With a few notable exceptions, most commonly prescribed drugs and medications can be used with relative safety during pregnancy. For the few believed to be teratogenic, counseling should emphasize *relative risk*. All women have about a 3 percent chance of having a child with a birth defect, and although exposure to a confirmed teratogen may increase this risk, it is usually increased by only 1 or 2 percent or at most doubled or tripled. The concept of *risk versus benefit* should also be introduced. Some untreated diseases pose a more serious threat to both mother and fetus than any theoretical risks from medication exposure.

KNOWN TERATOGENS

The number of drugs or medications strongly suspected or proven to be human teratogens is small ([Table 38-3](#)). New or infrequently used drugs should be considered to have possible teratogenic potential, and given in pregnancy only if benefits outweigh any theoretical risks.

ALCOHOL

Ethyl alcohol is one of the most potent teratogens. As many as 70 percent of Americans imbibe alcohol socially. During pregnancy, alcohol use varies by population, but its prevalence has been reported to be 1 to 2 percent ([Chasnoff and associates, 1990](#); [Little and colleagues, 1989a](#)). The fetal effects of alcohol abuse have been recognized at least since the 1800s, and the consequences of antenatal exposure were first described in a medical journal in 1900 by Sullivan. In 1968, Lemoine and associates reported the wide spectrum of alcohol-related fetal defects culminating in what is now called *fetal alcohol syndrome* ([Table 38-4](#)). According to data from the Birth Defects Monitoring Program, the reported rate of the syndrome has increased from 1 per 10,000 births in 1979 to more than 6 per 10,000 births in 1993 ([Centers for Disease Control and Prevention, 1995](#)). It is one of the most frequent recognizable causes of mental retardation in the United States, a tragedy that could be avoided ([Hanson, 1996](#)). The affected child typically has hyperactivity and persistent irritability in the early years. This is followed by developmental delay, growth deficiency, a variable degree of mental retardation, hyperactivity, poor coordination, and distinctive facial features listed in [Table 38-4](#) and shown in [Figure 38-2](#). Congenital heart and joint defects are common. The affected child is typically recognized because of failure to thrive and persistent irritability in early years.

EXPOSURE DOSE. A safe threshold dose for alcohol use during pregnancy has never been established. Women at highest risk to have affected children are those who chronically ingest large quantities and those who engage in binge drinking. Although some studies indicate that fetal injury can result from consuming as little as 1 to 2 drinks per day, the effects of binge drinking may have been obscured by computing a daily average alcohol consumption. For example, [Jacobson and co-workers \(1993\)](#) reported that the threshold below which no alcohol-related effects occurred was 0.5 oz of absolute alcohol per day, however, also stated that most women with affected children actually drank 4 to 6 drinks per occasion, which averaged out to lower daily doses. Subsequently, [Jacobson and associates \(1998\)](#) found that 80 percent of functionally impaired infants were born to women who drank more than five drinks per occasion, on several occasions weekly.

The effects of alcohol thus appear to be biphasic, with a linear dose-response observed only once a threshold of six drinks per occasion is met ([Abel, 1999](#)). Alcoholic women ingesting eight or more drinks daily throughout pregnancy have a 30 to 50 percent risk of having a child with all features of the alcohol syndrome.

Early cessation of alcohol consumption may result in amelioration of some effects. In a prospective study of 60 fetuses exposed to heavy alcohol consumption, [Autti-Ramo and colleagues \(1992\)](#) did not identify any abnormalities of language or mental development in children exposed to heavy drinking only in the first trimester. Those exposed to heavy drinking throughout pregnancy, however, had significantly lower scores in these two areas. Prenatal alcohol exposure also increases the risk of pregnancy complications such as intraventricular hemorrhage and white-matter brain damage in preterm neonates ([Holzman and colleagues, 1995](#)). Maternal age may contribute independently to increased fetal risk. [Jacobson and co-workers \(1998\)](#) have speculated that susceptibility may be the result of age-related increases in the body fat-to-water ratio and a faster rate of alcohol metabolism in older women.

Fetal alcohol syndrome cannot be diagnosed prenatally. [Persutte and associates \(1996\)](#) reported no correlation between alcohol use and ultrasonically detectable facial and intracranial biometrical measurements in 167 high-risk women compared with controls. While cardiac defects or cleft lip can be diagnosed sonographically, failure to identify major organ defects does not preclude other alcohol effects.

Despite the preceding data, even low levels of alcohol consumption cannot be recommended during pregnancy. Besides individual variation of "threshold dose," there are confounding effects of maternal age, other drug and environmental exposures, and pregnancy complications. However, the data can be used to reassure women who have inadvertently exposed their fetuses to low levels of alcohol.

ANTICONVULSANT MEDICATIONS

It is well established that women with epilepsy have an increased risk of fetal malformations even without exposure to anticonvulsant medication (Yerby, 1997, [1993](#)). In a review of over 750,000 pregnancies from 13 cohort studies, [Kelly \(1984\)](#) calculated a malformation rate of 70 per 1000 for infants of epileptic mothers compared with 30 per 1000 for controls. The most frequently reported defects, whether or not the mother takes medication, include orofacial clefts and congenital heart disease ([Table 38-5](#)). Clefts occur almost 10 times more frequently than in the general population (Yerby, 1997, [1993](#)).

The association of minor facial anomalies with drug exposure was first reported by [Meadow \(1968\)](#). Most studies since then have supported that anticonvulsant use is directly related to adverse fetal outcome, with risk increasing directly with the number of drugs. Malformations are more prevalent with high serum anticonvulsant concentrations, and polytherapy imposes a higher risk than monotherapy ([Dansky and associates, 1980](#); [Omtzigt and colleagues, 1992](#)). A Japanese collaborative study reported that the rate of fetal malformations was 1.9 percent if the epileptic mother took no anticonvulsants during pregnancy, 5.5 percent if two drugs were taken, 11 percent if three were taken, and 23 percent if four were taken ([Nakane and colleagues, 1980](#); [Okuma and associates, 1980](#)). Because the need for drug therapy, high serum levels, and multiple medications also reflect severity of maternal disease, it is possible that at least part of the increased risk is related to epilepsy itself.

PHENYTOIN. [Hanson and Smith \(1975\)](#) were the first to report that this commonly prescribed anticonvulsant caused craniofacial defects, limb abnormalities, and mental deficiency ([Table 38-6](#) and [Fig. 38-3](#)). [Hanson and colleagues \(1976\)](#) estimated that 7 to 10 percent of exposed infants have sufficient features of this **fetal hydantoin syndrome** to be recognizable in infancy, while a third display minor craniofacial and digital anomalies. [Kelly \(1984\)](#) confirmed these estimates, and [Scolnik and colleagues \(1994\)](#) also described lower global intelligence quotient (IQ) scores in phenytoin-exposed children compared with controls. Teratogenicity is strongly influenced by the fetal genetic makeup, with inability to produce normal levels of epoxide hydrolase increasing risk as discussed earlier. This in part explains observations by [Van Dyke and co-workers \(1988\)](#) that some families include many exposed but normal offspring while other families include multiple affected children.

CARBAMAZEPINE. This commonly prescribed anticonvulsant was considered for years to be the drug of choice in pregnancy. [Jones and co-workers \(1989\)](#), however, subsequently described a significant excess of carbamazepine-exposed children with three or more of the minor malformations shown in [Table 38-6](#), similar to the fetal hydantoin syndrome. These were primarily craniofacial defects (11 percent), fingernail hypoplasia (26 percent), and developmental delay (20 percent). This study was subsequently criticized because of methodological flaws, including the fact that a large proportion of the subjects were taking multiple medications and the proportion of children with developmental delay was not different than that expected based on the normal distribution of test scores ([Bortnichak and Wetter, 1989](#); [Keller, 1989](#); [Scialli and Lione, 1989](#)). Thus, the teratogenic potential of carbamazepine is unclear. Because it is metabolized through the arene oxide pathway, there

is potential for accumulation of toxic intermediates and alteration of the phenotype in susceptible individuals with some enzyme deficiencies.

TRIMETHADIONE AND PARAMETHADIONE. These are used infrequently to treat petit mal seizures. A characteristic pattern of severe malformations including those in [Table 38-6](#) was found to be associated with their use ([German and associates, 1970](#); [Zackai and co-workers, 1975](#)). Because of their high potential for teratogenicity, they are avoided.

VALPROIC ACID. Fetuses exposed to this drug in the first trimester have a 1 to 2 percent—20 times background—risk of spina bifida ([Robert and colleagues, 1983](#)). Because these defects are located almost exclusively in the lumbosacral region, it is likely that this agent acts directly on a homeobox gene governing the development of caudal structures (see earlier discussion). Valproic acid has also been associated with several minor facial features ([Clayton-Smith and Donnai, 1995](#)). Reported cardiac malformations and oral clefts probably are related to the epilepsy itself ([Lammer and colleagues, 1987](#)).

WARFARIN COMPOUNDS

These drugs have a low molecular weight, readily cross the placenta, and can cause significant adverse teratogenic and fetal effects. [Hall and co-workers \(1980\)](#) estimated that a sixth of exposed pregnancies result in an abnormal live-born infant, and a sixth will result in abortion or stillbirth. [Ginsberg and Hirsh \(1989\)](#) reviewed 186 studies including 1325 exposed pregnancies and reported that 9 percent of exposed fetuses suffered permanent deformity or disability, and 17 percent of these died.

Distinct defects with two different etiologies result from exposure during two different developmental periods. If exposure occurs between the sixth and ninth week, the fetus is at increased risk for **warfarin embryopathy** characterized by nasal hypoplasia ([Fig. 38-4](#)) and stippled vertebral and femoral epiphyses. It is doubtful that this embryopathy results from fetal hemorrhage because vitamin K clotting factors are not demonstrable in the embryo at this age. Instead, these derivatives are thought to exert their teratogenic effect by inhibiting post-translational carboxylation of coagulation proteins ([Hall and associates, 1980](#)). These proteins are called *osteocalcins* because of their role in embryonic control of calcification, and their deficiency could result in many features of warfarin embryopathy. The syndrome is a phenocopy of *chondrodysplasia punctata*, a group of genetic diseases thought to be caused by inherited defects in osteocalcin.

During the second and third trimester, the defects associated with fetal exposure to warfarin likely result from hemorrhage leading to subsequent dysharmonic growth and deformation from scarring in any of several organs ([Warkany, 1976](#)). Defects may be regionally extensive and include dorsal midline central nervous system dysplasia such as agenesis of the corpus callosum, Dandy-Walker malformation, and midline cerebellar atrophy; ventral midline dysplasia such as microphthalmia, optic atrophy, and blindness; and developmental delay and mental retardation ([Hall and colleagues, 1980](#)).

ANGIOTENSIN-CONVERTING ENZYME (ACE) INHIBITORS

These antihypertensive agents have been associated with many reports of fetal damage. The most frequently associated agent is *enalapril*, although *captopril* and *lisinopril* have been implicated. No structural malformations from first-trimester exposure have been documented, although animals given doses comparable to those used in humans have an increased incidence of fetal wastage (fetotoxicity). Most commonly, there is late-onset growth restriction and oligohydramnios, followed by prolonged and profound neonatal hypotension and anuria. The most severe consequence is renal tubular dysgenesis, which causes early-onset oligohydramnios, pulmonary hypoplasia and limb contractures, and perinatal death ([Table 38-7](#)). Hypocalvaria—hypoplasia of the membranous skull bones—is strongly linked to [ACE¹](#) inhibitor exposure ([Barr and Cohen, 1991](#)). Relative limb shortening has also been described ([Pryde and co-workers, 1993](#)).

All of these abnormalities are believed to result from prolonged fetal hypotension and hypoperfusion that causes renal ischemia, renal tubular dysgenesis, and then anuria ([Pryde and colleagues, 1993](#); [Schubiger and associates, 1988](#)). The resulting oligohydramnios prevents normal lung development and causes limb contractures. Reduced perfusion also causes growth restriction. Hypotension also explains maldevelopment of the calvarium because it is formed from membranous bone which requires extensive vascularity and high oxygen tension for growth. Because these changes occur during the fetal period they are termed **ACE inhibitor fetopathy**.¹ This is not a syndrome, but instead is a classical example of a *sequence* in which one initial insult leads to a cascade of other problems ([Chap. 36, p. 940](#)).

Not all fetuses are affected, and the lack of epidemiological data prevents estimation of risk. However, the variable fetal response may be due to genetic variation in the [ACE¹](#) gene. Individuals homozygous for a 50-bp deletion in this gene have high serum ACE activity, while those homozygous for an insertion of the same fragment have low activity ([Lee, 1994](#); [Rigat and associates, 1990](#)). The relationship between ACE exposure and the fetal ACE gene has yet to be explored.

RETINOIDS

Retinoids, especially vitamin A, are essential for normal growth, tissue differentiation, reproduction, and vision ([Gudas, 1994](#)). As discussed earlier, retinoids are believed to activate four clusters of homeobox genes during embryogenesis ([Soprano and Soprano, 1995](#)). While vitamin A deficiency is a health problem worldwide, it is rare in the United States.

VITAMIN A. There are two forms of vitamin A in nature. **Beta-carotene** is a precursor of provitamin A. It is found in fruits and vegetables and has never been shown to cause birth defects ([Oakley and Erickson, 1995](#)). **Retinol** is preformed vitamin A. Many foods contain vitamin A, but only livers from animals raised in Europe and polar bear liver contain toxic doses. Levels found in animal liver available in markets in the United States are not dangerous ([American College of Obstetricians and Gynecologists, 1998](#)). Likewise, the 5000-IU dose of vitamin A contained in common prenatal vitamins is not harmful.

It is uncertain whether high doses of vitamin A are teratogenic. Several case reports and small series have associated high doses with congenital anomalies. These reports concern vitamin A supplements, and in general have been hampered by small numbers, unknown daily dose, and absence of any recognizable pattern in the small number of observed defects. Two cohort studies have also been inconclusive. [Conway \(1958\)](#) gave 12,500 IU of vitamin A daily prior to and through 3 months' gestation as an experimental therapy to prevent recurrence in 59 women who had a child with cleft lip or palate. They observed no defects. [Rothman and co-workers \(1995\)](#) evaluated outcomes of 317 women ingesting at least 10,000 IU of vitamin A daily during the first 12 weeks of pregnancy. Only 1 in 57 of these, the same incidence as in the general population, had a child with a congenital anomaly.

The largest prospective series evaluated a cohort of 423 women who ingested from 10,000 to 300,000 IU of vitamin A daily during the first 9 weeks and who contacted one of 13 European Teratology Services ([Mastroiacovo and associates, 1999](#)). Only three children had birth defects, and there was no relationship between vitamin dose and outcome. Their conclusion supports the opinion that in developed countries there is no scientific basis for vitamin A supplementation and doses higher than the daily allowance should be avoided ([American College of Obstetricians and Gynecologists, 1995](#)).

ISOTRETINOIN. Some isomers display the biological activity of vitamin A, and because they stimulate epithelial cell differentiation, are used chiefly for dermatological disorders ([Chap. 54, p. 1435](#)). Isotretinoin is 13-*cis*-retinoic acid and is highly effective for treatment of cystic acne. It is also considered one of the most potent teratogens in common use. First-trimester exposure is associated with a high rate of fetal loss and malformations in survivors at a rate similar to that for thalidomide ([Lammer and co-workers, 1985](#)). Abnormalities have been described only with first-trimester use. Its mean serum half-life is 12 hours, and anomalies are not increased in women who discontinue therapy before conception ([Dai and colleagues, 1989](#)).

Malformations typically involve the cranium and face, heart, central nervous system, and thymus. The craniofacial malformation most strongly associated with isotretinoin is bilateral but often asymmetrical microtia or anotia, frequently with agenesis or stenoses of the external ear canal ([Fig. 38-5](#)). Other defects include maldevelopment of the facial bones and cranium, and cleft palate. The most frequent cardiac defects are conotruncal, and hydrocephalus is the most common central nervous system defect. Thymic abnormalities include aplasia, hypoplasia, or malposition.

[Dai and colleagues \(1992\)](#) summarized 433 exposed pregnancies reported to the manufacturer. Elective abortion was chosen in half. Of the others exposed before 12 weeks, a third spontaneously aborted and a third had an infant with at least one major malformation. There did not appear to be any safe first-trimester exposure period or dose. The incidence was unaffected by the length of exposure, and a third of women who used the drug for less than 1 week had malformed infants.

Despite that isotretinoin has been listed as a category X drug since its introduction, and there have been at least three packaging changes to highlight reproductive risks, exposures continue to be reported. In the aforementioned report, almost 30 percent of women were pregnant when they started the drug, and 65 percent conceived while taking the drug because of improper contraceptive use. A pregnancy test before initiating the drug and a mistake-proof method of birth control such as Norplant are now required by many clinics prior to beginning therapy.

ETRETINATE. This orally administered retinoid is used to treat psoriasis. It is associated with severe anomalies similar to those with isotretinoin. In contrast to isotretinoin, however, anomalies are observed even when conception is after discontinuation of therapy. Etretinate is lipophilic and has a half-life of 120 days. It has been detected in serum almost 3 years after cessation of therapy ([DiGiovanna and colleagues, 1984](#); [Thomson and Cordero, 1989](#)). It is unknown how long the teratogenic effects persist, but malformations have been described up to 51 weeks after its discontinuation ([Lammer, 1988](#)). If possible, women who have not completed their child bearing should not use this drug. If etretinate use cannot be avoided, [Geiger and associates \(1994\)](#) suggest that the woman wait at least 2 years after treatment before conceiving.

TRETINOIN. This is all-*trans*-retinoic acid and is prescribed for treatment of acne vulgaris. It is available only as a topical gel. The skin metabolizes most of the drug without apparent absorption. [Jick and colleagues \(1993\)](#) found no increase in congenital anomalies in 212 infants born to women who used tretinoin during early pregnancy.

HORMONES

The primordial structures that will become the external genitalia are bipotential for the first 9 weeks ([Chap. 7, p. 157](#)). Between 9 and 14 weeks, the testis secretes androgen and the male fetus develops a male perineal phenotype. Because the ovaries do not secrete androgens, the female fetus continues to develop a female phenotype which is completed by 20 weeks ([Speroff and colleagues, 1994](#)). Exposure to exogenous sex hormones before 7 completed weeks generally has no effect on external structures. Between 7 and 12 weeks, however, female genital tissue is very responsive to exogenous androgens and exposure can result in full masculinization. The tissue continues to exhibit some response until 20 weeks, and up to then partial masculinization or genital ambiguity can develop.

Those areas of the brain with high concentrations of estrogen and androgen receptors are also influenced by hormone exposure, which programs the central nervous system for gender identity, sexual behavior, levels of aggression and gender-specific play behaviors. The critical period for hormonal influence on behavior is much later than that for the external genitalia, with the degree of behavioral alteration proportional to dose and length of exposure.

ANDROGENS. An example of the effects of early androgen exposure is autosomal recessive *congenital adrenal hyperplasia*. Fetal adrenal glands ordinarily begin functioning by 12 weeks, but because of certain enzyme deficiencies, the glands are unable to hydroxylate cortisol precursors. Androgenic intermediates accumulate, masculinizing female external genitalia and producing abnormal male genital growth ([Chrousos and associates, 1985](#)). Early androgen exposure may also result in a more masculine orientation with stronger homosexual and/or weaker heterosexual interests, as well as increased male gender identity ([Dittman and co-workers, 1990, 1992](#); [Meyer-Bahlburg and collaborators, 1996](#); [Zucker and associates, 1996](#)). Maternal exposure to androgens can induce similar fetal effects; however, in contrast to congenital adrenal hyperplasia, masculinization does not progress after birth ([Stevenson, 1993b](#)).

TESTOSTERONE AND ANABOLIC STEROIDS. Androgen exposure in reproductive-age women occurs primarily as the result of anabolic steroid use by athletes wishing to increase lean body mass and muscular strength. The most effective agents are synthetic testosterone, which are taken in doses 10 to 40 times higher than those used therapeutically. These cause extreme and irreversible virilization, liver dysfunction, and mood and libido disorders in women. Exposure of a female fetus results in varying degrees of virilization, including labioscrotal fusion after first-trimester exposure and phallic enlargement later ([Grumbach and Ducharme, 1960](#); [Schardein, 1985](#)). Normal female maturation can be anticipated at puberty, although surgical correction may be necessary for genital defects.

ANDROGENIC PROGESTINS. These agents are currently used as contraceptives. Antenatal exposure to *medroxyprogesterone acetate*, an intramuscular depot contraceptive, has been associated with virilization of the female fetus and a small increase in heart defects ([Barlow and Knight, 1983](#); [Prahallada and associates, 1985](#)). *Norethindrone*, a progesterone-only contraceptive, is estimated to cause female fetus masculinization in 1 percent of exposures ([Schardein, 1985](#)).

DANOCRINE. This ethinyltestosterone derivative has weak androgenic activity that inhibits the pituitary-ovarian axis. It is primarily prescribed for endometriosis but is also used to treat immune thrombocytopenic purpura, migraine headaches, premenstrual syndrome, and some breast diseases. In a review of its inadvertent use during early pregnancy, [Brunskill \(1992\)](#) reported that 40 percent of 57 exposed female fetuses were virilized. There was a dose-related pattern of clitoromegaly, fused labia, and urogenital sinus malformation, most of which required surgical correction.

ESTROGENS. Of many compounds, most estrogenic substances do not affect fetal development. Oral contraceptives are discussed on page 1029.

DIETHYLSTILBESTROL (DES). From 1940 to 1971, between 2 and 10 million pregnant women took DES^2 to "support" high-risk pregnancies ([Giusti and co-workers, 1995](#); [Smith, 1948](#)). The drug later was shown to have no salutary effects, and its use for this purpose was abandoned. [Herbst and colleagues \(1971\)](#) subsequently presented their classical study showing that vaginal adenocarcinoma developed between ages 15 and 22 in eight prenatally exposed women. These observations were subsequently confirmed. Moreover, when ingested before 18 weeks, the drug affects normal development of both female and male reproductive structures. DES is thus a carcinogen and teratogen.

The most striking associated malignancy is clear-cell adenocarcinoma of the cervix and/or vagina ([Herbst and Anderson, 1990](#)). The absolute risk is substantially increased to about 1 per 1000 DES-exposed daughters. The Registry for Research on Hormonal Transplacental Carcinogenesis reported that half of 384 cancer patients were exposed before 12 weeks and 70 percent before 17 weeks ([Melnick and colleagues, 1987](#)). Malignancy was not dose related and there was no relationship between location of the tumor and timing of exposure. For these reasons and because its absolute risk is low, some categorize DES^2 as an *incomplete carcinogen*.

DES^2 produces both structural and functional abnormalities ([Salle and colleagues, 1996](#)). One is interruption of normal vaginal development. By 18 weeks, the müllerian-derived cuboidal-columnar epithelium lining the vagina should be replaced by squamous epithelium originating from the urogenital sinus. DES interrupts this transition in up to half of exposed female fetuses, resulting in excess cervical eversion (ectropion) and ectopic vaginal glandular epithelium (adenosis). The Diethylstilbestrol Adenosis (DESAD) Project showed that these lesions have malignant potential, as DES-exposed women have a twofold increase in vaginal and cervical intraepithelial neoplasia ([Vessey, 1989](#)).

There are structural abnormalities of the cervix or vagina in a fourth of exposed females ([Robboy and associates, 1984](#)). As many as two thirds have uterine abnormalities and their embryological mechanism is unknown ([Kaufman and co-workers, 1980](#)). The most commonly reported abnormalities include hypoplastic T-shaped uterine cavity; cervical collars, hoods, septa, and coxcombs; and "withered" fallopian tubes (Falcone, 1999). As discussed in [Chapter 35 \(p. 918\)](#), these exposed women are at increased risk for poor pregnancy outcomes related to the uterine malformation, decreased endometrial thickness, and reduced uterine perfusion ([Kaufman and colleagues, 2000](#)). Exposed men have normal sexual function and fertility, but are at increased risk for epididymal cysts, microphallus, cryptorchidism, and testicular hypoplasia ([Stillman, 1982](#)).

ANTINEOPLASTIC DRUGS

By their mechanisms of action, many anticancer drugs intuitively would be thought to be teratogenic or carcinogenic. Fortunately, this is not the case for most, as discussed in [Chapter 55](#). There are notable exceptions, as follows.

CYCLOPHOSPHAMIDE. This alkylating agent inflicts a chemical insult on developing fetal tissues, resulting in cell death and heritable DNA alterations in surviving cells. Fetal anomalies have been described after exposure during early pregnancy. The most commonly reported are missing and hypoplastic digits on hands and feet. These defects are believed to be caused by necrosis of limb buds and DNA damage in surviving cells ([Manson and associates, 1982](#)). Other defects include cleft palate, single coronary artery, imperforate anus, and fetal growth restriction with microcephaly ([Kirshon and colleagues, 1988](#)). It has been reported that nurses who administer cyclophosphamide may be at increased risk for fetal loss, but the data are hard to interpret and there are no adequate epidemiological studies ([Glantz, 1994](#)). Alkylating agents should be avoided during early pregnancy if possible, but can be given during the second and third trimester.

METHOTREXATE/AMINOPTERIN. Closely related, both are associated with a rare but strikingly similar pattern of anomalies. Teratogenic potential is from alteration of folic acid metabolism essential for cell replication ([Sutton and co-workers, 1998](#)). Methotrexate is commonly prescribed as an abortifacient, for ectopic pregnancy, and for psoriasis and some connective-tissue diseases. Principal features of fetal methotrexate/aminopterin syndrome are growth restriction, failure of calvarial ossification, craniosynostosis, hypoplastic supraorbital ridges, small posteriorly rotated ears, micrognathia, and severe limb abnormalities ([Del Campo and associates, 1999](#)). [Feldcamp and Carey \(1993\)](#) reviewed 20 first-trimester exposures and calculated that a dose of 10 mg per week is necessary to produce abnormalities. This dose is exceeded during standard therapy for ectopic pregnancy or elective abortion. Ongoing pregnancies after methotrexate treatment require immediate follow-up ([Creinin and Vittinghoff, 1994](#)).

ANTIMICROBIALS

TETRACYCLINES. These drugs, including doxycycline and minocycline, may cause yellow-brown discoloration of deciduous teeth or be deposited in fetal long bones (Kutscher and associates, 1966). Tetracycline causes acute fatty liver changes in pregnant women with renal insufficiency (Whalley and colleagues, 1964). One acceptable use is treatment of maternal syphilis in penicillin-allergic women for whom desensitization is impractical (Chap. 57, p. 1489).

AMINOGLYCOSIDES. Maternal administration results in significant fetal blood levels (Gilstrap and co-workers, 1988). *Streptomycin* is associated with fetal cranial nerve VIII damage when given for protracted periods (Conway and Birt, 1965). The risk of ototoxicity with any aminoglycoside is approximately 1 to 2 percent.

SULFONAMIDES. While these agents readily cross the placenta, fetal blood levels are lower than maternal levels. These drugs compete for bilirubin-binding sites, and may be associated with hyperbilirubinemia if used near delivery in the preterm infant (Landers and colleagues, 1983). There have been no studies exploring a possible association of sulfa drugs with congenital anomalies. *Trimethoprim* is used in conjunction with a sulfonamide, and because it is a folate antagonist, some authors caution against its use; however, congenital anomalies are not reportedly increased (Brumfitt and Pursell, 1973).

GRISEOFULVIN. This oral fungicide is used for treatment of mycotic infections of the skin, nails, and scalp. There is one report of possible association with conjoined twins (Rosa and associates, 1987a, 1987b). Animal studies indicate increased anomalies of the central nervous system and skeleton.

RIBAVIRIN. This antiviral is given by aerosol inhalation to treat respiratory syncytial virus infections in infants and young children. Pregnant women may be exposed to the drug while working in intensive care nurseries. Based on animal studies, the drug has significant teratogenic potential. It consistently produces hydrocephalus and limb abnormalities in rodent models.

TOBACCO

Cigarette smoke contains a number of potential teratogens, including nicotine, cotinine, cyanide, thiocyanate, carbon monoxide, cadmium, lead, and a variety of hydrocarbons. In addition to being fetotoxic, many of these substances have vasoactive effects or reduce oxygen levels. The best documented reproductive outcome related to smoking is fetal growth restriction. Smoking has a direct dose-response effect on fetal growth. Infants of mothers who smoke are on average 200 g lighter than those of nonsmokers, and heavy smoking results in more severe weight reduction (D'Souza and associates, 1981). The risk of low birthweight is doubled, and that of a small-for-gestational age infant is increased 2.5-fold (Werler, 1997). Women who stop smoking early in pregnancy generally have infants with normal birthweights (Cliver and co-workers, 1995). Smoking also may cause slightly increased incidence of subfertility, spontaneous abortion, placenta previa and abruption, and preterm delivery (Werler, 1997).

While it is plausible that vasoactive properties of smoking would produce defects related to vascular disturbances, most studies indicate no increased risk of congenital malformations involving the cardiac or central nervous systems, or of gastroschisis. A twofold increased risk of Poland sequence—caused by an interruption in the vascular supply to the chest and arm—was reported by Martinez-Frias and colleagues (1999). Smoking has been associated with cleft lip and palate, but only in individuals heterozygous or homozygous for an uncommon polymorphism in the gene for transforming growth factor- α (Shaw and colleagues, 1996). In individuals carrying this allele, the risk of cleft lip and palate is doubled and the risk of cleft palate is increased four- to sevenfold (Hwang and associates, 1995; Shaw and co-workers, 1996).

COCAINE

This alkaloid is derived from the leaves of the South American tree, *Erythroxylon coca*. It is a highly effective topical anesthetic and local vasoconstrictor, and through sympathomimetic action via dopamine, it is also a central nervous system stimulant. Cocaine is currently one of the most widely abused drugs in the United States. In a 1994 Georgia study, the Centers for Disease Control and Prevention (1996) determined that 1 in 20 pregnancies was associated with cocaine use. A population-based study of over 29,000 racially and socioeconomically diverse obstetrical patients from 202 California hospitals found that 1.1 percent had a positive urine test for cocaine (Vega and colleagues, 1993).

Many adverse outcomes associated with cocaine are from its vasoconstrictive and hypertensive effects. Although an impressive number of adverse sequelae have been reported, placental abruption is the most frequently cited (Chasnoff and colleagues, 1985). In their review, Shiono and colleagues (1995) found that cocaine use was associated with a fourfold increase in placental abruption. Cocaine use has been associated with myocardial infarction, arrhythmias, aortic rupture, strokes, seizures, bowel ischemia, hyperthermia, and sudden death.

Risk of vascular disruption within the embryo, fetus, or placenta is highest after the first trimester, and likely accounts for the increased incidence of stillbirth (Hoyme and associates, 1990). A number of cocaine-related congenital anomalies due to vascular-based disruptions have been described. They include skull defects, cutis aplasia, porencephaly, ileal atresia, cardiac anomalies, and visceral infarcts (Little and colleagues, 1989b; Stevenson, 1993a). Cohen and associates (1994b) have identified subependymal and periventricular cysts in term infants. One mechanism by which brain defects may develop after cocaine exposure is shown in Figure 38-6.

Reports of increased limb-reduction defects are disputed (Hume and co-workers, 1997). However, cocaine is especially likely to disrupt urinary tract development separate from genital organ development. Chavez and colleagues (1988) utilized the population-based Atlanta Birth Defects Case-Control Study and concluded that cocaine use increased the risk of urinary tract defects by 4.39. Finally, prune-belly anomaly has been reported (Bingol and co-workers, 1986; Chasnoff and colleagues, 1985, 1988).

THALIDOMIDE

This is an anxiolytic and sedative drug that is a notorious human teratogen. It produces malformations in approximately 20 percent of exposed pregnancies, primarily limited to structures derived from the mesodermal layer such as limbs, ears, cardiovascular system, and bowel musculature. A wide variety of limb-reduction defects have been associated with thalidomide, with upper limbs usually more severely affected. Bone defects range from abnormal shape or size to total absence of a bone or limb segment.

Thalidomide was available from 1956 to 1960 before its teratogenicity, along with several teratological principles, were forcefully demonstrated. Prior to this, the placenta was believed to be a perfect barrier that was impervious to toxic substances unless given in such high doses that the mother was killed (Dally, 1998). The extreme variability in species susceptibility to drugs and chemicals also was not appreciated. Thalidomide produced no defects in experimental mice and rats and thus was assumed safe in humans. The thalidomide experience also demonstrated the very close relationship between time of exposure and the presence and type of defect produced (Knapp and co-workers, 1962). For example, upper limb phocomelia occurred after ingestion during days 27 to 30, coincidental with appearance of the upper limb buds at 27 days. Lower limb phocomelia was associated with treatment during days 30 to 33 at the time of lower limb bud development.

Recently, thalidomide has again become available in the United States. It is used for refractory cutaneous lupus erythematosus, chronic graft-versus-host disease with bone marrow transplantation, and for treatment of leprosy (Cole and colleagues, 1994; Duna and Cash, 1995). Reproductive-age women taking thalidomide need excellent birth control, as thalidomide-affected children continue to be born in countries where the drug is available, and despite ample warnings (Castilla and co-investigators, 1996).

DRUGS COMMONLY USED IN PREGNANCY

INFECTIONS

A number of bacterial, viral, fungal, and parasitic infections are commonly encountered during pregnancy. Some of the agents used to treat them are listed in Table 38-8. Virtually all antimicrobial and chemotherapeutic medications readily cross the placenta.

ANTIBACTERIAL AGENTS. As a group, **penicillins** are probably the safest antimicrobial to use during pregnancy. They include agents with broad-spectrum activity such as piperacillin and mezlocillin, as well as those combined with the β -lactamase inhibitors, clavulanic acid, sulbactam, and tazobactam.

Erythromycin is a macrolide often given to penicillin-allergic patients, especially for community-acquired pneumonia (Chap. 46, p. 1225). The fetus is not always treated effectively when erythromycin is given for maternal syphilis because only small amounts of the drug gain fetal access (Chap. 57, p. 1489). **Azithromycin** has proven efficacy for treatment of community-acquired pneumonias and for treatment of chlamydial cervicitis. It is listed as a category B drug.

There are numerous oral and parenteral **cephalosporins**. When given during pregnancy, all cross the placenta, although their half-life is likely shorter during pregnancy because of increased renal clearance ([Gilstrap and colleagues, 1988](#)). Limited data suggest no adverse embryo-fetal effects and as a group they are listed in category B.

Aztreonam is a monobactam used primarily as an aminoglycoside alternative. It is not associated with either renal or ototoxicity, and although there are no well-controlled human studies, it is not teratogenic for rodents.

Imipenem is a carbapenem that is effective against aerobic and anaerobic organisms commonly isolated from intra-abdominal and female pelvic infections. Although there are no available human data regarding its safety during pregnancy, there are few specific indications for its use.

Clindamycin readily crosses the placenta and may result in significant fetal blood levels ([Gilstrap and associates, 1988](#)). There have been no studies of potential adverse embryo-fetal effects from its use during pregnancy, although clinical experience suggests that this drug is relatively safe.

Chloramphenicol readily crosses the placenta and results in significant fetal blood levels. In almost 100 infants exposed to this antimicrobial in early pregnancy, congenital anomalies were not increased ([Heinonen and associates, 1977](#)). The *gray baby syndrome*, manifested by cyanosis, vascular collapse, and death, has been reported with large doses of chloramphenicol given to the preterm neonate. It seems unlikely that fetal levels obtained from maternal administration would cause this syndrome.

Nitrofurantoin is commonly used for urinary infections during pregnancy. In a prospective study of 100 women treated with this drug, congenital anomalies were not increased ([Lenke and colleagues, 1983](#)). Nitrofurantoin has been associated with hemolytic anemia in women with glucose-6-phosphate dehydrogenase deficiency. In our experiences with more than 20,000 pregnant women given this drug for asymptomatic bacteriuria, hemolytic anemia has not been observed in either the mother or the fetus.

Vancomycin is used primarily for bacterial endocarditis prophylaxis in penicillin-allergic patients or as the drug of choice for *Clostridium difficile* pseudomembranous colitis. While there are no available human reproductive studies, vancomycin is associated with maternal nephrotoxicity and ototoxicity, and theoretically could cause these in the embryo or fetus ([Hermans and Wilhelm, 1987](#)).

Quinolones—ciprofloxacin, norfloxacin, ofloxacin, and enoxacin—are especially useful for treatment of urinary infections. Although there are no well-controlled studies in pregnant women, [Berkovitch and colleagues \(1994\)](#) observed no congenital anomalies among 10 fetuses exposed to ciprofloxacin. No teratogenic effects have been demonstrated in animal studies. Fluoroquinolones are reported by their manufacturer to be associated with irreversible arthropathy in immature dogs and are not recommended during pregnancy except for resistant infections.

Commonly used tuberculostatic drugs include **rifampicin**, **isoniazid**, and **ethambutol** ([Chap. 46, p. 1241](#)). [Snyder and co-workers \(1980\)](#) reviewed studies of several hundred pregnant women given these drugs, and reported no increase in congenital anomalies. **Rifabutin**, a category C drug, is used to treat *Mycobacterium avium* complex (MAC) disease in patients with human immunodeficiency infection.

ANTIFUNGAL AGENTS. Vaginal candidiasis is common during pregnancy. Three commonly used agents for its treatment are **clotrimazole**, **miconazole**, and **nystatin**. In one report there was no increase in congenital malformations reported with their use ([Rosa and associates, 1987b](#)). **Fluconazole** and **itraconazole** are category C antifungal agents commonly used in immunocompromised patients. There are no human studies of **butoconazole** use during early pregnancy; however, it is not teratogenic in rodents.

Amphotericin B is used primarily to treat systemic histoplasmosis, coccidioidomycosis, cryptococcosis, and candidiasis. In more than 30 fetuses exposed to this agent, there was no evidence for congenital anomalies ([Dean and associates, 1994](#)).

ANTIVIRAL AGENTS. Experience with use of antiviral medications during pregnancy is limited. There is ample reason for concern because they inhibit host-intracellular viral replication through their action on RNA or DNA substrates. A great deal of emphasis has been placed on these agents in light of the epidemic of human immunodeficiency virus (HIV) infection that began in the 1980s.

Zidovudine, previously called azidothymidine or AZT, is a thymidine analog that decreases DNA synthesis by reverse transcriptase inhibition. It is used specifically to treat HIV infections. It has been given to delay the onset of clinical disease in asymptomatic seropositive persons and prophylactically following accidental HIV exposure. Transplacental passage of the drug has been documented ([Pons and colleagues, 1991](#)). In 1994, the Centers for Disease Control reported data from the Zidovudine in Pregnancy Registry which was established in 1989 by the Glaxo Wellcome Company as discussed in [Chapter 57 \(p. 1501\)](#), and later renamed the [Antiretroviral Pregnancy Registry \(1996\)](#). Both registers indicate that birth defects are not increased with first-trimester zidovudine exposure ([Briggs and colleagues, 1998](#)).

Zalcitabine (ddC), **didanosine** (ddI), **stavudine** (d4T), and **lamivudine** (3TC) are similar to zidovudine. They are nucleoside analogs that inhibit reverse transcriptase. These nucleoside analogs are combined with protease inhibitors and given along with zidovudine because combination therapy dramatically lowers viral titers and reverses HIV-related complications. Although currently recommended for use in pregnant women, their efficacy in preventing vertical transmission is unknown ([Public Health Service Task Force, 2000](#)). While there is limited information of use during pregnancy, reports from the manufacturers indicate that these agents do not cause malformations in animals, and there are no reports of associated defects in human fetuses ([Antiretroviral Pregnancy Registry, 1996](#); [Briggs and colleagues, 1998](#)).

Acyclovir and **ganciclovir** are purine nucleoside analogs that are effective for treating primary herpes and possibly varicella infections. Both drugs are category B. The [Acyclovir Pregnancy Registry \(1998\)](#) reported the outcome of 739 pregnancies in which this agent was given during the first trimester. There were nine infants with anomalies but with no distinctive pattern. Topical administration of acyclovir results in minimal systemic absorption. There is limited information on ganciclovir, with only 25 first-trimester exposures reported by the [Valacyclovir Pregnancy Registry \(1998\)](#).

Amantadine is used to prevent or modify influenza infections ([Chap. 46, p. 1227](#)). This drug has not been studied in human pregnancy, but it is embryotoxic and teratogenic in animals in high doses. Experience with 51 pregnancies in which amantadine was given during the first trimester resulted in five major anomalies ([Briggs and colleagues, 1998](#)).

Oseltamivir, a viral neuraminidase inhibitor, is used to treat influenza ([Chap. 56, p. 1464](#)). No data on safety in humans is available. In animals, doses producing blood levels 50 to 100 times higher than achieved therapeutically caused maternal toxicity and minor skeletal malformations ([Reprotox, 2000e](#)).

Interferons are a family of proteins and glycoproteins with antiviral, antineoplastic, and immunomodulating actions. Interferon- α is approved for treating hairy cell leukemia, and it is effective for some viral infections. Interferons β 1b and γ 1b are also used therapeutically. Animal studies indicate that interferons have a very low potential for toxicity. Experience in pregnant women is very limited but it appears safe ([Briggs and associates, 1998](#)).

Idoxuridine is effective against adenovirus, cytomegalovirus, varicella, and vaccinia viral infections. **Trifluridine** is effective in treating herpes virus infections, and **vidarabine** is effective against herpesvirus and poxvirus infections. **Idoxuridine** has not been investigated in human pregnancy, and may have the same potential for damage as other cytotoxic drugs such as trifluridine and vidarabine, which were developed originally as antineoplastics.

ANTIPARASITIC AGENTS. Parasitic infections during pregnancy are quite common, are usually asymptomatic, and in general do not need to be treated until after delivery. **Metronidazole** is a nitroimidazole that is effective for treatment of vaginal trichomoniasis and bacterial vaginosis. Although carcinogenic in rodents and mutagenic in certain bacteria, there was no increase in congenital anomalies in over 1700 fetuses exposed to metronidazole during the first trimester ([Piper and associates, 1993](#); [Rosa and colleagues, 1987a](#)). In a meta-analysis of seven studies, [Burtin and colleagues \(1995\)](#) found no association with increased teratogenic risk. It is classified as category B and is recommended by the [Centers for Disease Control and Prevention \(1998\)](#) for treatment of trichomoniasis in pregnancy ([Chap. 57, p. 1506](#)).

Lindane, used topically for the treatment of pediculosis pubis and scabies, was not teratogenic for a variety of animals. In adults, a significant amount of lindane is absorbed systemically, but rarely it causes central nervous system toxicity ([Orkin and Maibach, 1983](#)). Because of this, some recommend a combination of **pyrethrins** and **piperonyl butoxide** as initial treatment of pediculosis pubis during pregnancy, with lindane reserved for resistant infections. Crothamiton in 10 percent lotion or

cream or 6 percent sulfur in petrolatum can also be used as first-line treatment for scabies during pregnancy.

Chloroquine is a valuable first-line antimalarial. There was no increase in congenital anomalies in over 150 offspring of mothers who received this drug during pregnancy ([Wolfe and Cordero, 1985](#)). It is also used at much lower doses for chemoprophylaxis against malaria in pregnant women who must travel to or live in countries in which malaria is endemic. **Mefloquine** has been used more recently for chloroquine-resistant falciparum malaria. Accumulated evidence supports its safety ([Briggs and colleagues, 1998](#)). **Quinine** and **quinidine** are reserved for severely ill women with chloroquine-resistant malaria. Malformations primarily involving the central nervous system, hearing, limb, and urogenital structures were reported during the 1930s when large doses of quinine were used to induce abortion. Defects have not been reported at therapeutic doses. It should be avoided if possible during pregnancy, but should not be withheld from severely ill women because of fetal concerns.

Pyrimethamine is an antiparasitic folic acid antagonist used to treat malaria and toxoplasmosis. [Hengst \(1972\)](#) reported no increased frequency of malformations in 64 newborns exposed in early pregnancy. **Spiramycin** has been used to treat toxoplasmosis; there is no evidence of adverse embryo-fetal effects. Sulfadiazine plus pyrimethamine also has been used for toxoplasmosis. The efficacy of all of these agents for either the prevention or amelioration of embryo-fetal effects of toxoplasmosis is uncertain. Despite therapy, newborns may have chorioretinitis, hydrocephalus, and intracranial calcifications ([Chap. 56, p. 1476](#)).

Mebendazole is effective for treatment of a variety of helminths, including enterobiasis (pinworm), trichuriasis (whipworm), ascariasis (roundworm), and uncinariasis (hookworm). It is teratogenic for animals given several times the human adult dose. In a number of studies, there did not appear to be increased teratogenic risks ([Briggs and co-workers, 1998](#)). **Thiabendazole** is a similar anthelmintic used primarily to treat strongyloidiasis, trichinosis, and cutaneous larval migrans. It is also used as second-line therapy to treat pinworm, whipworm, roundworm, and hookworm infections. It has not been reported to be teratogenic for animals, but there are no adequate human studies. **Pyrantel pamoate** is primarily used for the treatment of ascariasis and enterobiasis. It has not been reported as teratogenic for animals, and there are no human studies.

CARDIOVASCULAR DISEASES

Almost 1 percent of pregnant women have some form of heart disease. They are often given a myriad of drugs and medications, the majority of which are safe during pregnancy ([Table 38-9](#)).

HEART FAILURE AND ARRHYTHMIAS. Cardiac glycosides are prescribed for heart failure, atrial fibrillation or flutter, and other supraventricular tachycardias. **Digoxin** is the most commonly used preparation, and although it rapidly crosses the placenta, there is no convincing evidence that it causes adverse fetal effects. Antiarrhythmic drugs have been administered both maternally and directly to the fetus in attempts to control fetal tachycardias ([Harrigan and associates, 1981](#); [Kerenyi and colleagues, 1980](#); [Weiner and Thompson, 1988](#)). This is discussed in [Chapter 37 \(p. 994\)](#).

Quinidine, discussed earlier for malaria treatment, is commonly used to treat supraventricular tachycardias and some ventricular arrhythmias. The drug readily crosses the placenta, and has been given to the mother to treat fetal supraventricular tachycardias ([Killeen and Bowers, 1987](#)). There are no epidemiological studies of congenital anomalies following its use during the first trimester, but it is relatively safe during later pregnancy ([Rotmensch and colleagues, 1987](#)).

A number of **β-adrenergic blocking** drugs are used to treat supraventricular and ventricular tachycardias, as well as chronic hypertension and hyperthyroidism. Propranolol has been used widely in pregnancy now for several decades and is not teratogenic ([Briggs and associates, 1998](#)). Earlier it was associated with fetal growth restriction; however, in a review of five prospective studies, such complications were identified in only 4 percent of pregnancies ([Rotmensch and colleagues, 1983](#)). Other β-blockers may be associated with fetal growth restriction ([Chap. 45, p. 1216](#)).

Some **antiarrhythmic drugs** include disopyramide, amiodarone, adenosine, bretylium, diltiazem, local anesthetics (procainamide, lidocaine, and tocainide), and calcium antagonists (nifedipine and verapamil). All cross the placenta, and many have been used to treat fetal arrhythmias without adverse effects ([Dumesic and colleagues, 1982](#); [Rey and associates, 1985](#)). Amiodarone is structurally similar to thyroxine but readily crosses the placenta at levels 10 to 30 percent of maternal serum levels. Fetal and neonatal hypothyroidism after exposure has been reported ([De Catte and co-workers, 1994](#); [Grosso and colleagues, 1998](#)). Although most exposed fetuses have no drug-related abnormalities, amiodarone use in pregnancy should be avoided.

ANTIHYPERTENSIVE DRUGS. Undoubtedly **methyldopa** is the most widely used of these agents during pregnancy for the treatment of chronic hypertension ([Chap. 45, p. 1217](#)). There are no large epidemiological studies in early pregnancy, but its many years of use attest to its safety. **Hydralazine** is commonly utilized to treat hypertension in women in the latter half of pregnancy without apparent adverse fetal effects. There are no human reproduction studies of **sodium nitroprusside**; however, this drug readily crosses the placenta ([Lewis and colleagues, 1977](#)). Theoretically its use may result in the accumulation of cyanide in fetal liver. **Clonidine** is an α-adrenergic blocker that has been used to treat hypertension in pregnant women without apparent adverse fetal effects ([Horvath and co-workers, 1985](#)).

A number of **β-adrenergic blocking agents** are used primarily for the treatment of chronic hypertension. These include propranolol, labetalol, atenolol, metoprolol, nadolol, and timolol. Several are also useful for the chronic treatment of angina pectoris, certain cardiac arrhythmias, and for treatment of hyperthyroidism. There is little information regarding their use in early gestation; however, increasing numbers of reports indicate no apparent adverse effects in pregnant women in the United Kingdom. In two studies, [Sibai and associates \(1987, 1990\)](#) reported that infants of women given labetalol were more likely to be growth restricted than those born to chronically hypertensive women not given the drug ([Chap. 45, p. 1218](#)). There are now a number of studies that have not found an association with growth restriction, bradycardia, or neonatal hypoglycemia, and some have reported a beneficial effect of labetalol on birthweight ([Reprotox, 2000c](#)).

Calcium-channel antagonists are also commonly used to treat chronic hypertension. **Verapamil** is used to treat hypertension, angina, and supraventricular tachycardias. Although it is commonly employed to treat hypertension in pregnant women without apparent adverse effects, it may cause decreased uterine blood flow ([Murad and colleagues, 1985](#)). First-trimester use has been associated with limb defects ([Magee and associates, 1996](#)). Although cause and effect have not been proven, many embryogenic processes are calcium dependent and could theoretically be blocked by calcium-channel blockers ([Bilozur and colleagues, 1982](#); [Lee and Nagel, 1986](#)). Verapamil has also been associated with fetal cardiac depression and arrest when used transplacentally in combination with digoxin for treatment of fetal supraventricular tachycardias ([Owen and associates, 1988](#)). Whether **nifedipine** is associated with similar adverse effects is unclear at this time. [Sibai and associates \(1992\)](#) used nifedipine to treat women with preeclampsia remote from term. Although no adverse fetal effects were noted, there was also no improvement in perinatal outcome. Other calcium antagonists include **diltiazem** and **nicardipine**.

DIURETICS. These drugs are prescribed during pregnancy for some women with chronic hypertension, and are also given acutely or chronically to treat pulmonary edema. Congenital anomalies were not increased among over 60 women who took **chlorothiazide** in the first trimester, or among over 5000 who took it later ([Heinonen and co-workers, 1977](#)). Similarly, **hydrochlorothiazide** use during early pregnancy was not associated with increased congenital anomalies ([Jick and colleagues, 1981](#)). Thiazides have been associated with neonatal thrombocytopenia, bleeding, and electrolyte disturbances when given near the time of delivery.

Acetazolamide is a carbonic anhydrase inhibitor used as a diuretic and to treat glaucoma and epilepsy. Although the drug has been consistently reported to be associated with an unusual type of limb abnormality in rodents, similar defects could not be induced in primates and have not been observed in humans ([Heinonen and co-workers, 1977](#); [Hirsch and colleagues, 1983](#)). **Spirolactone** is a commonly used potassium-sparing diuretic that has not been widely studied in human pregnancy. It causes feminization of male rat fetuses and delayed sexual maturation of female rat fetuses, but these effects have not been observed in humans ([Messina and colleagues, 1979](#)).

Ethacrynic acid and **furosemide** are loop diuretics that are usually not used chronically during pregnancy. Furosemide crosses the placenta and increases fetal urine production. There is some evidence that it stimulates the renal synthesis of prostaglandin E₂, which increases the incidence of patent ductus arteriosus in preterm infants ([Green and colleagues, 1983](#)). No adverse fetal effects have been associated with its acute administration. Ethacrynic acid has ototoxic effects in vitro, but only one report has been made of associated ototoxicity in vivo ([Jones, 1973](#)).

ANTICOAGULANTS. Deep vein thrombosis or pulmonary embolus is estimated to complicate about 1 in 2500 pregnancies ([Chap. 46, p. 1237](#)). **Coumarin** derivatives cause embryo-fetal defects and should not be used in pregnancy (p. 1014). **Heparin** is the anticoagulant of choice. Unfractionated heparin is a group of large (m.w. 4000 to 30,000) highly polar molecules that do not cross the placenta and are not associated with congenital anomalies. It may be given intravenously, either continuously or intermittently, or by subcutaneous injection. Its protracted use may cause maternal osteopenia, osteoporosis, and thrombocytopenia ([Chap. 46, p. 1239](#)). The newer low-molecular weight (4000 to 6000) heparins such as **enoxaparin** have been used for anticoagulation. In a review by [Fejgin and Lourwood \(1994\)](#), low-molecular weight heparin was not found to cross the placenta. Although [Nelson-Piercy and co-workers \(1997\)](#) reported five miscarriages, four midtrimester losses, and seven preterm deliveries in 69 pregnancies treated with enoxaparin, they attributed the poor outcomes to the antiphospholipid antibody syndrome. In another study of 108 pregnant women, [Schneider and colleagues \(1997\)](#) found no adverse fetal effects associated with either preparation.

Thrombolytic agents have been used during pregnancy. Examples of these agents include **streptokinase, urokinase, and tissue plasminogen activator (t-PA)**. Urokinase is normally produced by the ovary and cytotrophoblast, and case reports suggest it can be used safely in pregnancy ([Kramer, 1995](#); [La Valleur, 1996](#); [Turrentine, 1995](#), and their associates). In two reports of 166 pregnancies, streptokinase was not associated with adverse fetal effects ([Ludwig, 1973](#)). The few reports of use of tissue plasminogen activator during pregnancy do not support a teratogenic risk ([Briggs and colleagues, 1998](#)).

ASTHMA

Most medications for treatment of asthma can be used with apparent safety during pregnancy ([Chap. 46, p. 1230](#)). For acute asthma, **epinephrine and terbutaline** may be given subcutaneously as there is little evidence that these agents cause adverse fetal effects. In one long-term study of exposed fetuses, [Wallace and colleagues \(1978\)](#) reported no increase in complications. **Metaproterenol** and **albuterol** are self-administered by inhalation. There is little information regarding their possible teratogenicity following first-trimester use.

Theophylline salts are commonly used bronchodilators. **Aminopylline** is the only salt available for parenteral use, but there are numerous oral forms of which many contain other bronchodilators such as **ephedrine**.

Cromolyn inhibits mast cell histamine release and is given chronically for asthma prophylaxis. There are no large studies in pregnant women, nor are there reports of congenital anomalies after first-trimester use.

Inhaled corticosteroids, including beclomethasone and triamcinolone acetonide, are now used commonly for asthma. Oral prednisone may be given as a dose pack or methylprednisolone given intravenously. Similar to other corticosteroids, beclomethasone has been associated with fetal resorption and cleft lip and palate in mice and rabbits ([Esaki and associates, 1976](#); [Oguro and co-workers, 1970](#)). However, two clinical studies including 101 pregnant women treated with beclomethasone and/or prednisone for severe asthma showed no increase in congenital malformation ([Fitzsimons and colleagues, 1986](#); [Greenberger and Patterson, 1983](#)). Triamcinolone is a more potent teratogen in animals than either hydrocortisone or cortisone, but has not been associated with adverse fetal effects in humans ([Dombrowski and co-investigators, 1996](#)).

SEIZURE DISORDERS

The most commonly used anticonvulsants are teratogenic, as discussed earlier (p. 1012). **Phenobarbital** has been used frequently in combination with these other anticonvulsants. Over 1000 mother-infant pairs with first-trimester exposure to phenobarbital were included in the Collaborative Perinatal Project database, and no increased frequency of either minor or major birth defects was observed compared with unexposed controls ([Heinonen and associates, 1977](#)). The effects of phenobarbital on fetal development have been obscured by the co-administration of hydantoin and the increased risk of anomalies due to epilepsy itself ([Briggs and associates, 1998](#)). [Reinisch and colleagues \(1995\)](#) studied over 9000 offspring in the Danish perinatal cohort, and reported that 114 phenobarbital-exposed men tested at age 22 or older had decreased cognitive performance compared with nonexposed controls.

Ethosuximide and **methsuximide** are succinimide anticonvulsants used for petit mal seizures. There are no human reproduction studies available or reports of malformations attributed solely to either of these agents. They are classified as category C drugs.

Newer anticonvulsants include **felbamate, gabapentin, lamotrigine, oxcarbazepine, tiagabine, topiramate, and vigabatrin**. Information about the safety of these agents in pregnancy is limited, as relatively few exposed pregnancies have been reported ([Briggs and associates, 1998](#)). Based on what is known about the likely mechanisms of teratogenesis in the more traditional anticonvulsants, several of these new drugs may actually be safer for the fetus. For example, none of these agents has antifolate effects; none except tiagabine results in the production of arene oxide metabolites; and most have minimal or no effect on the cytochrome p450 system ([Morrell, 1996](#)). Whether they are as efficacious as older drugs for management of epilepsy in pregnancy remains to be seen.

PSYCHIATRIC CONDITIONS

Medications used to treat psychiatric illness include sedatives, hypnotics, tranquilizers, antidepressants, and antipsychotics ([Table 38-10](#)). Some of these treatments are discussed in [Chapter 53](#).

BENZODIAZEPINES. These minor tranquilizers may be required for women who have severe and debilitating anxiety disorders or who are psychotic and assaultive or agitated. **Diazepam** is the most widely used and it has been associated with an increased risk of cleft palate and limb malformations in rodents. Although some studies have associated high doses of benzodiazepines with multiple defects, determination of cause and effect has been complicated by frequent concomitant alcohol and substance abuse ([Bergman and associates, 1992](#); [Laegrid and colleagues, 1989](#)). More recent studies have not found an association between diazepam alone and fetal anomalies ([Czeizel, 1987/88](#)). Likewise, lorazepam and midazolam have not been linked to adverse fetal outcomes other than transient sedation at birth. Alprazolam is commonly used for panic disorder. It has been available for less time than other benzodiazepines and thus the data are not conclusive. There have been few reports associating alprazolam with congenital abnormalities, although one study found that the rate of malformations following over 400 first-trimester exposures was 4.7 percent ([St. Clair and Schirmer, 1992](#)). Exposed neonates should be watched for signs of hypotonia.

ANTIDEPRESSANT DRUGS. Commonly used antidepressants are listed in [Table 38-10](#). The most commonly used antidepressants are the **selective serotonin reuptake inhibitors (SSRIs)**. The older compounds, **fluoxetine** and **sertraline**, have not been reported to cause birth defects in animals or humans. A summary of 796 fluoxetine-exposed pregnancies reported to the manufacturer described rates of early pregnancy loss and congenital abnormalities not different from those in historical controls (3.5 percent). This report and others also failed to identify a specific pattern of defects or a predilection for any particular organ system in the small number of affected offspring ([Goldstein and associates, 1993, 1997](#)). In a study comparing first-trimester treatment with fluoxetine, standard tricyclic antidepressants, or another nonteratogen, there were no differences in malformations or fetal losses ([Pastuszak and colleagues, 1993](#)). Because these agents have few side effects compared with other antidepressants, they are a good therapeutic choice for pregnant women requiring treatment.

Some malformations, particularly those affecting limbs, have been reported in conjunction with first-trimester use of **tricyclic antidepressants** ([Elia and colleagues, 1987](#)). In the largest study investigating the rate of malformations in over 1 million women exposed to these antidepressants during pregnancy, however, no increase in fetal malformations was found ([Rowe, 1973](#)). These agents are unlikely to be potent teratogens ([Briggs and colleagues, 1998](#)).

Lithium salts, especially lithium carbonate, are used for treatment of affective mental illness. In an early study, [Weinstein \(1980\)](#) reported that 8 percent of 225 lithium-exposed infants in an international registry had serious congenital cardiovascular abnormalities. Six of these affected infants—2.7 percent of those exposed—had the otherwise rare defect *Ebstein anomaly*. Because of this, lithium was presumed to be a teratogen. However, methodological problems with this study clouded interpretation. In a subsequent prospective study, [Jacobson and colleagues \(1992\)](#) followed 148 women given lithium in the first trimester and reported a 2.8 percent major congenital malformation rate (one fetus had *Ebstein anomaly*), similar to the 2.4 percent observed in controls. They concluded that lithium is not a major teratogen. Epidemiological data would indicate that the risk of *Ebstein anomaly* from first-trimester lithium exposure is much lower than previously estimated ([Cohen and associates, 1994a](#)). Considering these data, lithium can be taken throughout pregnancy if necessary, or it may be discontinued at least until 6 to 8 weeks, when cardiac structures have formed ([Briggs and colleagues, 1998](#)).

Monoamine oxidase (MAO) inhibitors are used less frequently today because patients must follow a low tyramine diet and hypertensive crises can occur after dietary indiscretion. Administration of meperidine and some anesthetic agents coincident with **MAO³** inhibitor use can stimulate a life-threatening hyperthermic crisis. Such severe adverse reactions are especially undesirable in pregnant women, and this class of medication is generally avoided ([Mortola, 1989](#)).

ANTIPSYCHOTIC MEDICATIONS. Many of these agents are **phenothiazines**, which have been used in pregnancy to treat both psychotic disorders and hyperemesis, although most safety information has been derived from their use as antiemetics. Most information concerns chlorpromazine, and the largest study of this and other phenothiazines from the Collaborative Perinatal Project reported no increased risk of fetal malformations after prenatal exposure ([Slone and colleagues, 1977](#)). When used for hyperemesis, these drugs are ingested intermittently at low doses, and their safety when taken at high continuous doses for antipsychotic therapy is generally difficult to assess. Infants born to mothers with certain psychiatric illnesses such as schizophrenia are independently at greater risk for malformations ([Elia and colleagues, 1987](#)). Also, affected women often take a number of other prescription medications as well as known teratogens such as alcohol. Because of widespread use without serious fetal effects, the teratogenic potential of most antipsychotic agents is considered to be minimal ([Briggs and associates, 1998](#)).

ANALGESICS

SALICYLATES AND ACETAMINOPHEN. In one review of over 1000 women, [Streissguth and colleagues \(1987\)](#) reported that almost half of pregnant women used salicylates and acetaminophen. Most investigators have found no association between maternal salicylate ingestion and fetal anomalies ([Heinonen, 1977](#); [Slone, 1976](#); [Turner, 1975](#), and their associates). Because **aspirin** is a potent prostaglandin inhibitor, there is a theoretical concern that antenatal exposure could lead to premature closure of the ductus arteriosus and associated cardiac and pulmonary abnormalities. Although the fetal effects of chronic high-dose aspirin ingestion are not known, no adverse outcomes have been reported after low-dose exposure. [DiSessa and colleagues \(1994\)](#) performed echocardiograms from 15 to 40 weeks in 63 fetuses exposed to 60 mg aspirin given daily to prevent preeclampsia. They found consistently normal ductus flow velocity, and normal output from both ventricles. **Acetaminophen** was not found to be associated with an increased risk of anomalies in over 500 exposed offspring ([Aselton and colleagues, 1985](#); [Heinonen and associates, 1977](#)). Liver toxicity may result from maternal overdose with acetaminophen ([Chap. 48, p. 1294](#)).

OTHER NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDs). There are a variety of nonsteroidal anti-inflammatory drugs with analgesic action, but **ibuprofen**, **naproxen**, and **ketoprofen** are used most often. **Indomethacin** has also been employed as a tocolytic agent ([Niebyl and colleagues, 1980](#)). These drugs are not considered to be teratogenic but may have reversible fetal effects when used in the third trimester. Indomethacin and other prostaglandin inhibitors have been associated with constriction of the fetal ductus arteriosus and subsequent persistent fetal circulation (pulmonary hypertension) in the neonate ([Csaba and associates, 1978](#)). It also causes decreased urine output and reduced amniotic fluid volume after prolonged usage ([Hickok and colleagues, 1989](#)). For these reasons, the drug is used to treat hydramnios ([Chap. 31, p. 820](#)). Most studies have shown that these effects are reversible as long as the drug is not given after 34 weeks ([Dudley and Hardie, 1985](#); [Niebyl, 1991](#)). Case reports have associated indomethacin with other adverse fetal effects such as intraventricular hemorrhage, bronchopulmonary dysplasia, and necrotizing enterocolitis. Infants are at highest risk if delivery occurs within 48 hours of instituting therapy ([Major and associates, 1994](#); [Norton and co-workers, 1993](#)). Doppler studies in neonates suggest that these problems may be related to hypotension and decreased blood flow in blood vessels supplying the bowel and brain ([Van Bel and co-workers, 1990](#)).

NARCOTIC ANALGESICS. Commonly used opioids include **meperidine** and **morphine**. [Heinonen and colleagues \(1977\)](#) found no association between either of these agents and congenital anomalies. As with all narcotics, chronic maternal ingestion may be associated with a neonatal withdrawal syndrome ([Chap. 29, p. 751](#)). **Codeine**, **propoxyphene**, **oxycodone**, and **hydrocodone** have not been found to be associated with congenital anomalies ([Bracken and Holford, 1981](#); [Heinonen and colleagues, 1977](#)). **Butorphanol** has been associated with neonatal respiratory depression and withdrawal, and 20 percent of fetuses exposed to it exhibit a sinusoidal heart rate pattern ([Hatjis and Meis, 1986](#); [Welt, 1985](#)).

LOCAL ANALGESIA AND ANESTHESIA

GENERAL ANESTHESIA. As discussed in [Chapter 42 \(p. 1144\)](#), nonobstetrical surgery is occasionally performed during pregnancy. All general anesthetic agents cross the placenta to some degree, and some local analgesics have the potential for systemic absorption. Although risk-benefit analysis during a surgical emergency in pregnancy usually clearly supports surgery, it is appropriate to counsel the woman about any potential fetal risks. None of the currently used anesthetic agents is a known teratogen, and the exposures during pregnancy are generally brief and not at toxic levels. However, data supporting this conclusion is imperfect. It is difficult to clearly differentiate any adverse fetal effects from anesthetic exposure from any harmful sequelae of the conditions leading to surgery. Other confounding factors include maternal hypotension, hypoxia, metabolic disturbances, and the interaction of multiple drugs. The Collaborative Perinatal Project did not identify any anesthesia-related teratogenic effects in the first 4 months of pregnancy, even though the analysis was not controlled for confounding factors ([Heinonen and colleagues, 1977](#)). Because halothane appears to interfere with normal fetal cardiovascular homeostasis in animals (fetal lambs), it is not recommended for fetal surgery ([Sabik and colleagues, 1993](#)). A large Swedish study likewise failed to find an association between anesthesia exposure and adverse fetal outcome ([Mazze and Kallen, 1989](#)). This 8-year study included 720,000 pregnant women who underwent 5405 nonobstetrical operations. In a case-control study, [Czeizel and associates \(1998\)](#) also found no increased malformations from anesthesia exposure.

Of 152 women given **thiopental** in early pregnancy, the frequency of congenital malformations was not increased ([Heinonen and colleagues, 1977](#)). Thiopental also does not increase the rate of malformations in rodents at three times the usual dose ([Tanimura and colleagues, 1967](#)). Although none has been examined in a large study, **ketamine**, **methohexital**, **thiamylal**, **etomidate**, **alphaxalone**, **sodium oxylate**, and **thialbarbitone** have not been associated with fetal malformations when used in pregnant women. The two most commonly used muscle relaxants, **curare** and **succinylcholine**, have not been associated with teratogenic effects in humans.

A wide variety of inhalation agents are employed for general anesthesia, but the most commonly used is **nitrous oxide**. The frequency of malformations was not increased in offspring of mothers exposed to nitrous oxide during the first 4 months of pregnancy ([Friedman, 1988](#); [Heinonen and co-workers, 1977](#)). **Halogenated agents** are commonly used to supplement nitrous oxide. **Halothane** has been reported to be teratogenic in some animal studies, but not in others ([Friedman, 1988](#)). It was not associated with increased malformations in the offspring of 25 women who were given this agent during the first 4 months of pregnancy ([Heinonen and colleagues, 1977](#)). There have been no epidemiological studies regarding the use of either **isoflurane**, **enflurane**, or **methoxyflurane** during pregnancy. Chronic exposure of mouse and rabbit embryos to isoflurane and enflurane at doses causing maternal toxicity has caused impaired development, but similar effects have not been seen in humans ([Reprotox, 2000a, 2000b](#)).

Older reports suggested that women with an occupational exposure to inhalation agents—**anesthesiologists**, **surgeons**, **nurse anesthetists**, **operating room nurses**, **dental hygienists**—had an increased risk of pregnancy loss or decreased fertility. In general, however, these studies are marred by their retrospective designs, recall bias among subjects, inadequate documentation of the dose or timing of exposure, and failure to show a dose-response relationship ([Friedman, 1988](#); [Shnider and Levinson, 1987](#)). Most of these also concerned exposures which occurred before nitrous oxide scavenging equipment was routinely utilized ([Rowland and associates, 1992](#)). Epidemiological studies did not find significantly increased risk of either pregnancy loss or fetal malformations in women exposed when scavenging equipment is used. Current safety guidelines require stringent ventilation and scavenging equipment in areas where inhalation agents are used.

LOCAL ANESTHESIA. A variety of local anesthetic agents may be employed for spinal or epidural analgesia. **Lidocaine** is used frequently, and in one review of almost 300 children whose mothers were given lidocaine in early pregnancy, the frequency of congenital malformations was not increased ([Heinonen and colleagues, 1977](#)). The frequency of malformations in offspring exposed to the other "caine" anesthetics also was not greater than expected in the general population. The main concern with these agents is the possibility of associated fetal bradycardia or hyperthermia, both of which could be detrimental to the fetus, but would likely not produce structural anomalies ([Macaulay and co-workers, 1992](#); [Stavrou and colleagues, 1990](#)).

ANTIEMETICS

Bendectin, a combination of doxylamine and pyridoxine, is no longer available in the United States because of the litigation it engendered as discussed earlier (p. 1008). It can essentially be reconstituted by ingesting **vitamin B₆** along with an over-the-counter sleep aid, **doxylamine**, neither of which is considered to have teratogenic potential ([Niebyl, 2000](#)). A variety of other antiemetics are used during pregnancy such as the piperazines (**meclizine**, **cyclizine**) and phenothiazines (**chlorpromazine**, **prochlorperazine**, **promethazine**). Teratogenic effects of **metoclopramide** have not been seen in a variety of experimental animals, and no adverse effects in humans have been reported ([Berkovitch and associates, 2000](#); [Reprotox, 2000d](#)). There is no evidence that any antiemetics are associated with an increased risk of congenital anomalies ([Farkas and Farkas, 1971](#); [Heinonen and colleagues, 1977](#)).

Ondansetron hydrochloride is used primarily for nausea associated with cancer chemotherapy. There are no large human studies with the drug. It is given by intravenous infusion and is especially helpful in pregnant women with hyperemesis refractory to other medications. This antiemetic is often reserved for use after 12 weeks.

IMMUNOSUPPRESSIVE DRUGS

Immunosuppressants are given primarily for the treatment of autoimmune disease and for organ transplantation maintenance. **Corticosteroids** such as prednisone and dexamethasone are most commonly used and are discussed on page 1025.

Azathioprine is primarily used to prevent organ transplant rejection or to treat inflammatory bowel disease. Although teratogenic for animals, most investigators have found the drug safe for use during human pregnancy ([Briggs and colleagues, 1998](#)). Neonatal hematological abnormalities, including fatal pancytopenia, have been described in association with maternal therapy ([Davidson and co-workers, 1985](#); [DeWitte and associates, 1984](#)).

Cyclosporine is an antibiotic used as an immunosuppressant to prevent organ transplant rejection. It is widely used for liver and heart allografts, and has recently also been used for renal transplantation. The drug causes significant maternal toxicity, especially nephrotoxicity. There are no large epidemiological reports regarding its use in pregnancy, but it appears to be safe for the fetus ([Briggs and co-workers, 1998](#)). Moreover, the benefits appear to outweigh any theoretical risks.

Cyclophosphamide, often prescribed for immune suppression after organ transplant or for systemic lupus erythematosus, is a suspected teratogen (p. 1018).

HORMONES

Some hormones are teratogenic as discussed on page 1017. Initial findings from the Collaborative Perinatal Project indicated that high-dose **oral contraceptives** were associated with an increased risk for cardiovascular and limb-reduction defects. Subsequent analysis, however, has shown no difference when compared with control women (Wiseman and Dodds-Smith, 1984). In 1988, the Food and Drug Administration approved the removal of the package insert rejoinder that warned against birth defects. In a meta-analysis of first-trimester sex hormone exposure, including oral contraceptives, [Raman-Wilms and colleagues \(1995\)](#) found no association between exposure and fetal genital malformations.

Gonadotropin-releasing hormone agonists (GnRH) have been used to treat infertility as well as other gynecological conditions. There is little information regarding their use during pregnancy. In a review of five women who were exposed to GnRH⁴ agonists during the first trimester, [Young and colleagues \(1993\)](#) reported three term pregnancies without complications and two abortions.

NATURAL (HERBAL) REMEDIES

It is difficult to estimate the risk or safety of various herbal remedies because they are not regulated as prescription or over-the-counter drugs. Often, the identity and quantity of all ingredients are unknown. Virtually no human or animal studies of their teratogenic potential have been reported, and knowledge of complications is essentially limited to acute toxicity ([Sheehan, 1998](#)). Because it is not possible to assess the safety of various herbal remedies during pregnancy, pregnant women should be counseled to avoid these substances. Several remedies do contain substances with pharmaceutical properties that could theoretically have adverse fetal effects. **Echinaceae**, which is believed to have anti-inflammatory properties, causes fragmentation of hamster sperm at high concentrations ([Ondrizek and associates, 1999](#)). **Black cohosh**, used to speed labor and treat premenstrual symptoms, contains a chemical that acts like estrogen. **Garlic** and **willow barks** have anticoagulant properties that may intensify the effects of anticoagulant drugs. **Ginkgo**, touted as an aid to memory and mental clarity, can apparently interfere with the effects of MAO-inhibiting drugs and has anticoagulant properties. Real **licorice** contains **glycyrrhizin**, which has hypertensive and potassium wasting effects. **Valerian** intensifies the effects of prescription sleep aids. **Ginseng**, which is ingested to increase energy, interferes with MAO-inhibiting drugs. **Soy** products contain phytoestrogen.

Certain herbal remedies are used as abortifacients, for example, **blue** and **black cohosh** appear to directly stimulate uterine musculature. **Pennyroyal** has been used as an abortifacient, and appears to work by irritating the bladder and uterus and causing strong uterine contractions. The drug can also cause liver damage, renal failure, and disseminated intravascular coagulation, and has been associated with several maternal deaths ([Black, 1985](#)).

ILLICIT DRUGS

The [American College of Obstetricians and Gynecologists \(1994\)](#) estimates that 10 percent is a minimal prevalence for substance abuse in pregnant women. In one survey of 715 pregnant women screened for alcohol, opiates, cocaine, and cannabinoids, 15 percent had positive urine toxicological tests ([Chasnoff and associates, 1990](#)). It has been estimated that from 350,000 to over 700,000 infants may be exposed to illicit substances in utero each year ([Chasnoff, 1991](#); [Gomby and Shiono, 1991](#)). While solid information is lacking for most drugs of abuse, **cocaine** and alcohol are potent and commonly used teratogenic substances (pp. 1019 and 1011).

POLYDRUG ABUSE. Illicit drug users seldom abuse only one drug. In a review of patterns of substance abuse during pregnancy, [Little and colleagues \(1990b\)](#) analyzed the use of methamphetamine, cocaine, heroin, and "t's and blues" in a primarily indigent population. Overall, 75 percent of these women reported that they abused more than one drug during pregnancy. Alcohol is a common co-factor, and appears to increase the risk of congenital anomalies and growth retardation. For example, infants born to women who abuse "t's and blues" are at a 3- to 14-fold risk of alcohol-induced embryo-fetal damage compared with infants born to abusers of other drugs ([Little and co-workers, 1990b](#)). Similarly, in a study of 104,000 pregnant women registered in the Swedish public health insurance system, 10 percent of offspring of women who abused benzodiazepines during pregnancy had birth defects thought to be caused by the additive effects of heavy alcohol use and exposure to other substances ([Bergman and colleagues, 1992](#)).

IMPURITIES AND DILUTANTS. Most illegal substances contain impurities and contaminants. Examples include lead, cyanide, cellulose, herbicides, and pesticides. Many substances are used as dilutants, including fine glass beads, powdered sugar, finely ground sawdust, strychnine, arsenic, and antihistamines. Coumadin has been used to "cut" heroin. Some of these dilutants and impurities may have serious adverse effects on both the mother and her fetus.

SPECIFIC SUBSTANCES. There are not enough data concerning substance use during pregnancy to allow full assessment of risks, especially to the embryo-fetus. Available information is usually confounded by factors that include poor maternal health, malnutrition, infectious diseases, and especially the use of multiple drugs.

Marijuana or **hashish** is used by nearly 15 percent of pregnant women ([Abel and Sokol, 1988](#); [Chasnoff and colleagues, 1990](#)). The active ingredient is **delta-9-tetrahydrocannabinol (THC)** which in high doses is teratogenic for animals; however, there is no evidence that marijuana is associated with human anomalies. In one study, birthweight was lower in exposed infants than controls, however, larger studies failed to corroborate this ([Greenland, 1983](#); [Linn, 1983](#); [Shiono, 1995](#), and their colleagues).

Amphetamines are sympathomimetic agents used as central nervous system stimulants, anorectics, and to treat narcolepsy. Various amphetamines are teratogenic in mice and rabbits, producing cleft palate, exencephaly, and eye defects when given at very high doses ([Reprotox, 2000g](#)). Retrospective human studies and case reports have linked amphetamines to congenital heart disease, biliary atresia, and limb-reduction defects ([Bays, 1991](#); [Nora and colleagues, 1970](#)). In four cohort studies of 818 women who took amphetamines during early pregnancy, however, the frequencies of major and minor congenital anomalies were no greater than controls ([Heinonen and colleagues, 1983](#); [Little and associates, 1988](#); [Milkovich and van den Berg, 1977](#)).

Methamphetamines are used medically to treat narcolepsy and hyperkinetic children, but are largely ineffective in the treatment of obesity. These drugs are often used to dilute other illicit drugs. In one cohort study of medically supervised methamphetamine use, the frequency of congenital anomalies was not increased compared with controls ([Heinonen and co-workers, 1977](#)). In two investigations, symmetrical fetal growth retardation was increased compared with control women, but the frequency of congenital anomalies was not different ([Little and colleagues, 1988](#); [Ramin and associates, 1992](#)). Methamphetamine, known as speed, ice, crank, and crystal meth, is a drug of abuse that produces defects in mice, rats, and rabbits, but has not been associated with defects in humans.

In most studies, the frequency of congenital anomalies is not higher among infants born to mothers addicted to **heroin** ([Little and associates, 1990c](#)). In one cohort study of 830 exposed infants, the frequency of anomalies of 2.4 percent was similar to background risk ([Ostrea and Chavez, 1979](#)). Other morbidity is common, and fetal growth restriction, perinatal death, and several perinatal complications were reported with high frequency in offspring of narcotic-addicted mothers ([Lifschitz and colleagues, 1983](#); [Little and co-workers, 1990c](#)). It is not clear whether these effects are due to fetal heroin exposure or to generally poor maternal health. Postnatal growth of these children appears to be normal in most cases, although the average head circumference is smaller than that of unexposed children ([Lifschitz and co-workers, 1983](#)). In addition, [Chasnoff and colleagues \(1986\)](#), as well as others, have reported mild developmental delay or behavioral disturbances in the children of narcotic-addicted women. Withdrawal symptoms in exposed neonates are common. Tremors, irritability, sneezing, vomiting, fever, diarrhea, and occasionally seizures are observed in 40 to 80 percent of infants born to heroin-addicted women ([Alroomi and colleagues, 1988](#)). Although these symptoms can be of prolonged duration, they usually persist for less than 10 days. Abnormal respiratory function during sleep often persists after withdrawal is complete, and may be a factor in the increased incidence of sudden infant death syndrome seen in exposed infants ([Kandall and associates, 1993](#)).

Methadone is a synthetic opiate narcotic that structurally resembles propoxyphene. Its principal medical use is maintenance therapy for heroin addiction. In large doses, methadone causes exencephaly and central nervous system defects in rodents. However, congenital anomalies were not increased above background in cohort studies and clinical series of infants born to heroin-addicted women treated with methadone ([Stimmel and Adamsons, 1976](#)). Conversely, withdrawal symptoms frequently develop and birthweight is lower than in unexposed infants ([Briggs and colleagues, 1998](#)). [Chasnoff and co-workers \(1987\)](#) compared 52 cocaine-using pregnant women to 73 women who were former heroin addicts maintained on methadone, and found a significantly higher rate of preterm labor, rapid labor, abruptio placentae, and meconium staining among cocaine users. Withdrawal from methadone is more severe than from heroin and more protracted (up to 3 weeks), due to the much longer half-life of methadone.

Lysergic acid amides, classically known as **lysergic acid diethylamide (LSD)**, are amine alkaloids obtained only through chemical synthesis. There is no evidence that this drug is a human teratogen. Some investigators have found increased frequencies of chromosomal breakage in somatic cells of mothers who used lysergic acid as well as their prenatally exposed infants. This also has been observed in human cells incubated in vitro with the drug ([Long, 1972](#)). Such breakage, however, does not appear to correlate with an increased risk for congenital anomalies.

Phencyclidine (PCP), known as angel dust, is no longer manufactured legally, although it is still used illegally. [Wachsman and cohorts \(1989\)](#) described 57 infants whose mothers used phencyclidine throughout pregnancy, including embryogenesis, and reported the frequency of congenital anomalies to be no greater than background. Neonatal withdrawal characterized by tremors, jitteriness, and irritability was observed in more than half of exposed infants. A study of 94 phencyclidine-exposed infants did not identify an increase in structural malformations, but did confirm an increased incidence of newborn behavioral and developmental abnormalities ([Golden and colleagues, 1987](#)).

"**T's and blues**" is a street mixture of the narcotic analgesic *pentazocine* (*Talwin*) and the over-the-counter antihistamine *tripelennamine* (*Pyribenzamine*). Since 1972 this mixture has gained popularity in urban centers among lower socioeconomic groups as a less costly substitute for heroin. Although its abuse by pregnant women has been reported to increase the risk of fetal growth restriction, an increased frequency of congenital anomalies was not found ([Little and co-workers, 1990a](#); [von Almen and Miller, 1984](#)). Exposed infants often suffer from withdrawal symptoms.

TABLE 38-1. Criteria for Proof of Human Teratogenicity

1. Proven exposure to agent at critical time(s) in prenatal development—prescriptions, office records, dates.
2. Consistent findings by two or more epidemiological studies of high quality:
 - a. Control of confounding factors
 - b. Sufficient numbers
 - c. Exclusion of positive and negative bias factors
 - d. Prospective studies, if possible
 - e. Relative risk of six or more (?).
3. Careful delineation of clinical cases—specific defect or syndrome, if present, is very helpful.
4. Rare environmental exposure associated with rare defect. Probably three or more cases—examples: oral anticoagulants and nasal hypoplasia, methimazole and scalp defects (?), and heart block and maternal rheumatism.
5. Teratogenicity in experimental animals important but not essential.
6. The association should make biological sense.
7. Proof in an experimental system that the agent acts in an unaltered state. Important information for prevention.

Note: Items 1, 2, and 3 or 1, 3, and 4 are essential criteria. Items 5, 6, and 7 are helpful but not essential.

From Shepard (1998), with permission.

TABLE 38-2. Food and Drug Administration Categories for Drugs and Medications

Category A

Controlled studies in humans have demonstrated no fetal risks. There are a few category A drugs, and examples include multivitamins or prenatal vitamins, but not "megavitamins."

Category B

Animal studies indicate no fetal risks, but there are no human studies; or adverse effects have been demonstrated in animals, but not in well-controlled human studies. Several classes of commonly used drugs, for example, penicillins, are in this category.

Category C

There are either no adequate studies, either animal or human, or there are adverse fetal effects in animal studies but no available human data. Many drugs or medications commonly taken during pregnancy are in this category.

Category D

There is evidence of fetal risk, but benefits are thought to outweigh these risks. Carbamazepine and phenytoin are examples.

Category X

Proven fetal risks clearly outweigh any benefits. An example is the acne medication isotretinoin, which may cause multiple central nervous system, facial, and cardiovascular anomalies.

39. Diseases and injuries of the Fetus and Newborn

The fetus and newborn are subject to a great variety of diseases. Those that are the direct consequence of maternal disease have been considered in other chapters along with specific maternal illnesses. This chapter provides an introduction to other fetal and neonatal diseases and injuries of major clinical importance.

DISEASES OF THE FETUS AND NEWBORN

HYALINE MEMBRANE DISEASE

To provide blood-gas exchange after birth, the infant's lungs must rapidly fill with air while being cleared of fluid, and the volume of blood that perfuses the lungs must increase remarkably. Some of the fluid is expressed as the chest is compressed during vaginal delivery, and the remainder is absorbed through the pulmonary lymphatics. The presence of sufficient surfactant synthesized by the type II pneumonocytes is essential to stabilize the air-expanded alveoli by lowering surface tension and thereby preventing lung collapse during expiration ([Chap. 7, p. 151](#)). If surfactant is inadequate, respiratory distress develops. This is characterized by the formation of hyaline membranes in the distal bronchioles and alveoli.

Hyaline membrane disease has decreased as a cause of neonatal death in the United States. According to most experts, surfactant therapy and administration of antenatal corticosteroids are responsible for much of this decrease ([Avery, 1995](#); [National Institutes of Health, 1994](#)). Boys are more prone than girls to develop these problems, and white infants appear to be more often and more severely affected than are black infants ([Hulseley and associates, 1993](#)). Neither preeclampsia nor prematurely ruptured membranes appear to accelerate fetal lung maturation ([Hallack and Bottoms, 1993](#); [Schiff and colleagues, 1993](#)).

CLINICAL COURSE. In the typical case, tachypnea develops and the chest wall retracts, while expiration is often accompanied by a whimper and grunt—a combination called "grunting and flaring." Grunting is common in the newborn whenever there is uneven expansion of the lungs or lower airway obstruction. Progressive shunting of blood through nonventilated lung areas contributes to hypoxemia and metabolic and respiratory acidosis. Poor peripheral circulation and systemic hypotension may be evident. The chest x-ray shows a diffuse reticulogranular infiltrate with an air-filled tracheobronchial tree (air bronchogram).

Respiratory insufficiency can also be caused by sepsis, pneumonia, meconium aspiration, pneumothorax, diaphragmatic hernia, persistent fetal circulation, and heart failure. Common causes of cardiac decompensation in the early newborn period are patent ductus arteriosus and congenital cardiac malformations.

PATHOLOGY. Hyaline membrane disease is the consequence of inadequate surfactant production. Without surfactant, the alveoli are not stable and low pressures cause collapse on end expiration. Nutrition of lung cells is compromised by hypoxia and systemic hypotension. There may be only partial maintenance of the fetal circulation (pulmonary hypertension) and a relative right-to-left shunt. Ischemic necrosis of the cells lining the airway eventually occurs. When oxygen therapy is initiated, the pulmonary vascular bed dilates and the shunt (if there is one) reverses. Protein filled fluid leaks into the alveolar ducts, and cells lining the alveolar ducts slough. Hyaline membranes of fibrin-rich protein and cellular debris line the dilated alveoli and terminal bronchioles, and the epithelium underlying the membrane becomes necrotic. In fatal cases, the atelectatic lungs on gross examination resemble liver. Histologically, many alveoli are collapsed while some are dilated widely, and the alveolar duct epithelium appears vacuolated.

TREATMENT. The most important factor influencing survival is admission to a neonatal intensive care unit. This has dramatically reduced the number of deaths from respiratory distress syndrome. An arterial PO₂ below 40 mm Hg is indicative of the need for oxygen therapy. Because excess oxygen can damage the pulmonary epithelium and retina, the oxygen concentration administered should be at the lowest level sufficient to relieve hypoxia and acidosis. Arterial oxygen tensions of 50 to 70 mm Hg are adequate.

Continuous positive airway pressure (CPAP) prevents the collapse of unstable alveoli and has brought about an appreciable reduction in the mortality rate. Successful ventilation usually allows high inspired oxygen concentrations to be reduced and thereby minimizes toxicity. Disadvantages are that venous return is impaired and there is always the possibility of barotrauma. Although positive pressure ventilation has undoubtedly improved survival, it is also an important factor in the genesis of bronchopulmonary dysplasia.

Mechanical ventilation results in repeated alveolar overstretching, which can disturb the integrity of the endothelium and epithelium and cause barotrauma ([Verbrugge and Lachmann, 1999](#)). To obviate this, *high-frequency oscillatory ventilation* is used to maintain an optimal lung volume and to clear CO₂ by using a constant low distending pressure and small variations or oscillations that promote alveolar recruitment. It can be used in combination with inhaled nitric oxide for severe cases of pulmonary hypertension ([Biarent, 1999](#)).

SURFACTANT TREATMENT. Because hyaline membrane disease is caused by lack of surfactant, important preventive therapy is the administration of exogenous surfactant. Following an initial report by [Fujiwara and colleagues \(1980\)](#) that aerosolized surfactant treatment appeared to ameliorate the severity of the respiratory distress syndrome, many clinical trials have confirmed its efficacy. Preparations included biological or animal surfactants such as human, bovine (Survanta), calf lung surfactant extract (CLSE), porcine (Curosurf), or synthetic surfactant (Exosurf).

The introduction of surfactant therapy has been credited by both the Centers for Disease Control and the Surgeon General for the largest drop in infant mortality observed in 20 years. It has been utilized for **prophylaxis** of preterm infants at risk for respiratory distress, as well as for **rescue** of those with established disease. [Long and co-workers \(1995\)](#) summarized the many published clinical trials of surfactant use, and found that it has reduced morbidity substantively with a net savings of over \$8000 per added year of life. Moreover, both early and late follow-up of treated infants over a wide range of birthweights indicate that surfactant does not result in more survivors with impairments.

[Jobe \(1993\)](#) summarized the results of 35 randomized controlled studies of surfactant utilized either as prophylaxis or rescue therapy, and found that it substantially reduced the incidence of pneumothorax and death in the first 28 days ([Table 39-1](#)). There was also a greater reduction in overall death rate and deaths due to respiratory distress syndrome when antenatal corticosteroids and surfactant were given together. These findings were confirmed by [Kari and associates \(1994\)](#). In a report from a large multicenter trial conducted under the auspices of the National Institute of Child Health and Human Development Neonatal Research Network, [Horbar and associates \(1993\)](#) reported a decrease in mortality from 28 to 20 percent from surfactant therapy alone.

Surfactant treatment is also beneficial for the very-low-birthweight infant. [Hamvas and co-workers \(1996\)](#) described a preferential improvement in neonatal mortality for white versus black very-low-birthweight infants. [Ferrara and colleagues \(1994\)](#) demonstrated improved intact survival in a group of infants born between 23 and 26 weeks. These findings were confirmed by a large multicenter trial of infants weighing 500 to 750 g ([Smyth and associates, 1995](#)). The superiority of prophylactic versus rescue surfactant for the very-low-birthweight infant was demonstrated in the large trial conducted by the [OSRIS Collaborative Group \(1992\)](#). For the older preterm infant, prophylactic versus rescue surfactant use continues to be debated ([Dunn, 1993](#)).

COMPLICATIONS. As previously described, persistent hyperoxia injures the lung, especially the alveoli and capillaries. High oxygen concentrations given at high pressures can cause *bronchopulmonary dysplasia*, or *oxygen toxicity lung disease*. This is a chronic condition in which alveolar and bronchiolar epithelial damage leads to hypoxia, hypercarbia, and oxygen dependence, followed by peribronchial and interstitial fibrosis. *Pulmonary hypertension* is another frequent complication. If hyperoxemia is sustained, the infant is also at risk of developing *retinopathy of prematurity*, formerly called *retrolental fibroplasia*. Thus, the oxygen concentration must be reduced appropriately as the arterial PO₂ rises.

PREVENTION. There is no method of diagnosis or treatment of preterm labor that has significantly reduced the incidence of preterm birth or improved any index of neonatal outcome ([American College of Obstetricians and Gynecologists, 1995c](#)). Elective preterm birth, however, can be avoided. It is clearly inexcusable to electively deliver an infant without a certain knowledge of gestational age, or confirmation of pulmonary maturity (see [Table 23-5](#), p. 544). When preterm delivery is indicated, for example in some cases of preeclampsia, it is also important to weigh the relative risks of immaturity and maternal disease ([Wigton and co-workers, 1993](#)).

AMNIOCENTESIS FOR FETAL LUNG MATURITY. Certainly, there are times when the risks to the fetus from a hostile intrauterine environment are greater than the risk of respiratory distress. If the criteria for elective delivery at term are not met, however, then amniocentesis is often utilized to confirm fetal lung maturity. A number of methods are used to determine the relative concentration of surfactant-active phospholipids. The technique is similar to that described for second-trimester amniocentesis in [Chapter 37 \(p. 989\)](#).

LECITHIN-TO-SPHINGOMYELIN (L/S) RATIO. Lecithin (dipalmitoyl phosphatidylcholine) plus phosphatidylinositol and especially phosphatidylglycerol are important in the formation and stabilization of the surface-active layer that prevents alveolar collapse and respiratory distress ([Chap. 7, p. 152](#)). Before 34 weeks, lecithin and sphingomyelin are present in amniotic fluid in similar concentrations. At about 34 weeks, the concentration of lecithin relative to sphingomyelin begins to rise ([Fig. 39-1](#)).

[Gluck and co-workers \(1971\)](#) reported that the risk of neonatal respiratory distress is very slight whenever the concentration of lecithin is at least twice that of sphingomyelin (L/S ratio). Conversely, there is increased risk of respiratory distress when this ratio is below 2. Because lecithin and sphingomyelin are found in blood and meconium, contamination with these substances may confound the results. Blood has an L/S ratio of 1.3 to 1.5 and could thus either raise or lower the true value, whereas meconium usually lowers the L/S ratio ([Bui and Spellacy, 1975](#)). [Harper and Lorenz \(1993\)](#) found an immature L/S ratio to be more predictive of the need for ventilatory support than gestational age or birthweight ([Table 39-2](#)).

Unfortunately, with some pregnancy complications, respiratory distress may develop despite a mature L/S ratio. This outcome has been reported most frequently with diabetes, but this concept is controversial. [Kjos and co-workers \(1990\)](#) presented data to suggest that standard methods of lung assessment are valid in infants of diabetic mothers, and that cases of respiratory distress in infants with "mature" studies are unrelated to surfactant deficiency. [Low and colleagues \(1994\)](#) opined that additional factors causing metabolic compromise, such as acidosis or sepsis, may also adversely impact the development of respiratory distress despite a mature L/S ratio. [Berkowitz and associates \(1996\)](#) reported that 96 percent of 585 diabetic women and 90 percent of 628 nondiabetic women had mature L/S ratios at 39 weeks. They concluded that lung maturation is not delayed. [Piper and Langer \(1996\)](#), however, in a study of 621 diabetic pregnancies, found that delayed pulmonary maturation is associated with poor glucose control.

Ethnic background may also affect the predictive value of the L/S ratio and the likelihood of respiratory distress ([Hulsev and colleagues, 1993](#)). [Richardson and Torday \(1994\)](#) studied 135 black infants and found no case of respiratory distress syndrome when the L/S ratio was greater than 1.5.

PHOSPHATIDYLGlycerol. Because of uncertainty about the predictive value of the L/S ratio, some clinicians consider the presence of phosphatidylglycerol to be mandatory prior to elective delivery of the diabetic mother ([Ojomo and Coustan, 1990](#)). Phosphatidylglycerol is believed to enhance the surface-active properties of lecithin and sphingomyelin ([Chap. 7, p. 152](#)). Its identification in amniotic fluid provides more assurance, but not necessarily an absolute guarantee, that respiratory distress will not develop. Because phosphatidylglycerol is not detected in blood, meconium, or vaginal secretions, these contaminants do not confuse the interpretation. While the presence of phosphatidylglycerol is reassuring, its absence is not necessarily a strong indicator that respiratory distress is likely to develop after delivery.

TDx-FLM. This automated assay measures the surfactant-albumin ratio in uncentrifuged amniotic fluid and gives results in approximately 30 minutes. In a study of 374 consecutive amniotic fluid specimens, [Steinfeld and associates \(1992\)](#) reported that a TDx value of 50 or greater predicted fetal lung maturity in 100 percent of cases. Subsequent investigations by [Hagen and associates \(1993\)](#) and [Herbert and co-workers \(1993\)](#) found the TDx-FLM to be equal or superior to the L/S ratio, foam stability index, or phosphatidylglycerol assessment in predicting both positive and negative tests. [Eriksen and associates \(1996\)](#) reported that the TDx-FLM test has a sensitivity, specificity, and negative-predictive value for evaluating fetal lung maturity in diabetic women comparable to the L/S ratio. Many hospitals use the TDx-FLM as their first-line test of pulmonary maturity, followed by the L/S ratio in indeterminate samples.

OTHER TESTS. The **foam stability** or **shake test** was introduced by [Clements and associates \(1972\)](#) to reduce the time and effort inherent in precise measurement of the L/S ratio. The test depends on the ability of surfactant in amniotic fluid, when mixed appropriately with ethanol, to generate stable foam at the air-liquid interface. There are two problems with the test:

1. Slight contamination of amniotic fluid, reagents, or glassware, as well as errors in measurement may alter the test results.
2. A false-negative test is rather common.

Some laboratories use this as a screening test, and if negative, use another test to better quantify the L/S ratio.

The **Lumadex-FSI test** is based on the principle of foam stability to identify surfactant activity in amniotic fluid. It has also been found to be reliable ([Herbert and associates, 1993](#)). **Fluorescent polarization (microviscometry)** is a test in which the microviscosity of lipid aggregates in amniotic fluid are assayed by mixing the fluid with a specific fluorescent dye that incorporates into hydrocarbons of surfactant lipids. The intensity of the fluorescence induced by polarized light is then measured. The technique is rapid and simple to perform, but expensive ([Barkai and associates, 1982](#)). **Amniotic fluid absorbance at 650-nm** wavelength has been reported to correlate well with the L/S ratio ([Sbarra and co-workers, 1977](#)). [Tsai and associates \(1983\)](#) reported that the test is most informative at low and high absorbance. Between these extremes, however, false-positive and false-negative values proved troublesome. [Kjos and colleagues \(1990\)](#) found this test to be reliable even in infants of diabetic mothers.

[Welsch and colleagues \(1996\)](#) used the **lamellar body count** to study 849 amniotic fluid specimens. They reported that a count of at least 35,000/mL was a reliable predictor of fetal lung maturity and compared favorably with the L/S ratio. They concluded that this assay was rapid, simple, and an accurate method for assessing fetal lung maturity. [Alvarez and Ludmir \(1996\)](#) reported that measurement of the concentration of **dipalmitoylphosphatidylcholine (DPPC test)** in amniotic fluid had a sensitivity and specificity of 100 percent and 96 percent, respectively, for prediction of respiratory distress.

RETINOPATHY OF PREMATURITY

Formally known as retrolental fibroplasia, retinopathy of prematurity had become by 1950 the largest single cause of blindness in this country. After the discovery that the etiology of the disease was hyperoxemia, its frequency decreased remarkably.

PATHOLOGY. The retina vascularizes centrifugally from the optic nerve starting about the fourth month and continuing until shortly after birth. During the time of vascularization, retinal vessels are easily damaged by excessive oxygen. The temporal portion of the retina is most vulnerable. Oxygen induces severe vasoconstriction, endothelial damage, and vessel obliteration. When the oxygen level is reduced, there is neovascularization at the site of previous vascular damage. The new vessels penetrate the retina and extend intravitreally, where they are prone to leak proteinaceous material or burst with subsequent hemorrhage. Adhesions then form, which detach the retina.

PREVENTION. Precise levels of hyperoxemia that can be sustained without causing retinopathy are not known. Retinopathy is unlikely if inhaled air is enriched with oxygen to no more than 40 percent. Unfortunately, very immature infants who develop respiratory distress will most likely require ventilation with high oxygen concentrations to maintain life until respiratory distress clears. Administration of relatively large doses of vitamin E to prevent oxidation has produced conflicting results ([Mino, 1992](#)).

RESPIRATORY DISTRESS IN THE TERM INFANT

Term infants can also have respiratory complications, although much less frequently than those born preterm. Common causes in term infants include sepsis and intrauterine-acquired pneumonia, persistent pulmonary hypertension of the newborn (PPHN), meconium aspiration syndrome, and pulmonary hemorrhage. Septicemia, especially from group B streptococcal disease, is a relatively common cause of respiratory distress in the term infant ([Chap. 56, p. 1471](#)). Persistent pulmonary hypertension is more common after elective cesarean delivery or premature closure of the ductus arteriosus. Meconium aspiration syndrome is frequently associated with oligohydramnios, uteroplacental insufficiency, and fetal stress. Frequently, most of these diagnoses are completely unexpected.

Treatment is similar to that for respiratory distress from surfactant deficiency in preterm neonates, described previously. Advances in neonatal care have improved the survival rate and decreased the morbidity of these conditions. One is high-frequency oscillatory ventilation, discussed earlier, and another is the use of nitric oxide as a pulmonary vasodilator that has no effect on systemic vasculature. [Finer and Barrington \(2000\)](#) performed a meta-analysis of 11 trials of nitric oxide use in term or near-term infants with respiratory failure. When compared with traditional therapy, nitric oxide significantly improved oxygenation and reduced the incidence of death or the need for extracorporeal membrane oxygenation (ECMO). Furthermore, its effects seem to be enhanced when used along with high-frequency oscillatory ventilation. Nitric oxide apparently does not have similar beneficial effects for infants born before 34 weeks ([Kinsella and co-workers, 1999](#)).

MECONIUM ASPIRATION

This is a severe pulmonary disease characterized by chemical pneumonitis and mechanical obstruction of the airways. It results from peripartum inhalation of

meconium-stained amniotic fluid, leading to inflammation of pulmonary tissues and hypoxia. There is also evidence that the free fatty acids in meconium strip away alveolar surfactant ([Clark and colleagues, 1987](#)). In severe cases, the pathological process progresses to persistent pulmonary hypertension, other morbidity, and death. Even with prompt and appropriate therapy, seriously affected infants frequently die or suffer long-term neurological sequelae.

RISK FACTORS. In about 20 percent of pregnancies at term, amniotic fluid is contaminated by the passage of fetal meconium. In the past, this was considered a sign of "fetal distress" occurring only in response to hypoxia. It is now recognized, however, that in the majority of cases meconium passage is a manifestation of a normally maturing gastrointestinal tract, or is the result of vagal stimulation from umbilical cord compression ([Nathan and co-workers, 1994](#)). In a global sense, however, it is still considered a marker for adverse perinatal outcomes ([Chap. 31, p. 814](#)).

Aspiration of meconium-stained amniotic fluid before labor is thus a relatively common occurrence. In healthy, well-oxygenated fetuses with normal amniotic fluid volume, meconium is diluted and is readily cleared from the lungs by normal physiological mechanisms. In some infants, however, the inhaled meconium is not cleared, and meconium aspiration syndrome results. The syndrome may occur after otherwise normal labor, but it is more often encountered in postterm pregnancy or in association with fetal growth restriction. Meconium varies in concentration, and the syndrome is more likely when meconium is thick. Putting these together, pregnancies at highest risk are those in which there is diminished amniotic fluid volume, along with cord compression or uteroplacental insufficiency that may cause meconium passage. In these, meconium remains thick and undiluted, and the compromised fetus cannot clear it. [Leveno and colleagues \(1984\)](#) reported that meconium aspiration syndrome may follow transient episodes of umbilical-cord compression, an event more likely if there is oligohydramnios. In a study by [Davis and co-workers \(1985\)](#), meconium aspiration syndrome was strongly associated with thick meconium and fetal heart rate abnormalities, which mostly were severe variable decelerations from cord compression.

Unfortunately, pathological meconium aspiration cannot be predicted. [Dooley and co-workers \(1985\)](#) studied 272 pregnancies with meconium-stained fluid, and found that the 20 percent of fetuses who had aspirated meconium did not have fetal heart decelerations during labor or any other predictive heart rate pattern. They reported that liberal cesarean delivery (60 percent) for meconium and fetal heart rate abnormalities did not alter the frequency of meconium found beneath the cords. Moreover, the single death was not prevented by aggressive peripartum airway management.

PREVENTION. In 1976, [Carson and colleagues](#) reported that meconium aspiration syndrome could be prevented by **oropharyngeal suctioning** of the infant following delivery of the head, but before delivery of the chest. This maneuver was followed by laryngoscopic visualization of the cords and, when meconium was visualized, additional suctioning of the trachea. In this study, meconium aspiration syndrome was reduced but not eliminated, suggesting that delivery factors were not solely responsible. In the two decades since this report, this combined obstetric-pediatric delivery protocol became common.

In subsequent studies, [Davis and colleagues \(1985\)](#) found that strict adherence to this protocol in 1420 pregnancies failed to reduce the incidence of meconium aspiration syndrome below 2.1 percent. [Wiswell and colleagues \(1990\)](#) found no reduction in the risk of meconium aspiration syndrome with perinatal suctioning maneuvers in a study involving more than 175,000 neonates over a 14-year period. [Linder and associates \(1988\)](#) demonstrated that nondepressed infants with meconium-stained fluid who underwent routine tracheal suctioning actually had increased respiratory morbidity compared with those not suctioned.

During this time, [Murphy and associates \(1984\)](#) presented evidence that development of newborn pulmonary hypertension with this syndrome depended upon a chronic or recurring antenatal insult. This in turn would cause abnormal muscularization of the interacinic arteries beginning well before birth, and thus would be unaffected by maneuvers at delivery. [Cornish and colleagues \(1994\)](#) used a baboon model and found that meconium aspiration, either alone or combined with peripartum asphyxia, did not produce pathophysiological effects which led to long-term damage or death in the human neonate.

[Katz and Bowes \(1992\)](#) concluded from their review that the etiology of the meconium aspiration syndrome is primarily chronic fetal asphyxia rather than simply damage from meconium. They postulated that chronic antepartum asphyxia causes pathophysiological changes leading to pulmonary vascular damage, pulmonary hypertension, and persistent fetal circulation. Affected infants are unable to clear aspirated meconium. Thus, the 2 percent of infants who do not respond to suctioning at delivery are likely to be those who have sustained this type of antenatal damage. These findings agree with those provided by [Richey and colleagues \(1995\)](#) who found no correlation between markers of acute asphyxia—umbilical artery pH, lactate, or hypoxanthine—and meconium. One marker of chronic asphyxia, erythropoietin, was significantly elevated in newborns with meconium-stained fluid. This latter observation was confirmed by [Bloom and associates \(1996\)](#).

AMNIOINFUSION. [Gabbe and co-workers \(1976\)](#) demonstrated the utility of amnioinfusion for relief of variable decelerations in labor in a rhesus monkey model. [Miyazaki and Taylor \(1983\)](#) applied the technique to human fetuses experiencing variable heart rate decelerations in labor. It was then suggested that amnioinfusion might also prevent meconium aspiration because fetal gasping would be less likely with reduced variable decelerations from cord compression. To test this, [Wenstrom and Parsons \(1989\)](#) performed a randomized trial of amnioinfusion in pregnancies complicated by thick meconium. They showed that it significantly decreased the incidence of meconium below the cords and operative delivery, and that no infants receiving amnioinfusion developed meconium aspiration syndrome. At the same time, [Sadovsky and colleagues \(1989\)](#) reported similar results. A number of studies since then have generally confirmed these findings, and in a meta-analysis of 13 studies, [Pierce and co-workers \(2000\)](#) found that amnioinfusion significantly lowered the incidence of meconium beneath the vocal cords (OR 0.18), meconium aspiration syndrome (OR 0.30), and neonatal acidemia (OR 0.42).

Amnioinfusion for meconium may be beneficial only when the meconium is thick and there are recurrent variable decelerations that could provoke aspiration ([Spong and colleagues, 1994](#)). While amnioinfusion appears to be beneficial only for some pregnancies, it probably poses little or no increased risk ([Wenstrom and co-workers, 1995](#)). Finally, it does not benefit fetuses in whom meconium aspiration has occurred well before the onset of labor ([Byrne and Gau, 1987](#); [Manning and colleagues, 1978](#)).

MANAGEMENT. According to guidelines of the [American Academy of Pediatrics and American Heart Association \(1994\)](#), at delivery the infant's mouth and nares should be carefully suctioned before the shoulders are delivered. A suction bulb is usually adequate. The DeLee trap can also be used, but should be connected to wall suction and not suctioned by mouth. [Locus and colleagues \(1990\)](#) studied 80 women whose labors were complicated by moderate to thick meconium-stained amniotic fluid. Fetuses were randomly assigned to undergo suction at delivery of the head by either bulb or DeLee trap. Although both methods were equally efficacious, even with careful suctioning, 5 percent of these infants developed meconium aspiration syndrome.

For infants who are depressed, or those who have passed thick, particulate meconium, the infant is placed on the radiant warmer and residual meconium in the hypopharynx is removed by suctioning under direct visualization. The trachea is then intubated and meconium suctioned from the lower airway. The stomach is emptied to avoid the possibility of further meconium aspiration. It remains controversial whether a vigorous infant with thinly meconium-stained fluid requires tracheal suctioning. These guidelines are followed with the realization that their efficacy in preventing long-term neonatal morbidity or mortality is, as outlined, undocumented. Nevertheless, when skillfully and promptly performed, these procedures carry little risk of harm ([Yoder, 1994](#)).

INTRAVENTRICULAR HEMORRHAGE

There are four major categories of neonatal intracranial hemorrhage: **subdural hemorrhage** is usually due to trauma. **Subarachnoid and intracerebellar hemorrhage** usually result from trauma in term infants, but are commonly due to hypoxia in preterm infants. **Periventricular-intraventricular hemorrhage** results from either trauma or asphyxia in half of term infants, but has no discernible cause in 25 percent of cases ([Volpe, 1995](#)). In preterm neonates, the pathogenesis of periventricular hemorrhage is multifactorial and includes hypoxic-ischemic events, anatomical considerations, coagulopathy, and many others. The prognosis after hemorrhage depends on the location and extent of the bleeding. Subdural and subarachnoid hemorrhage, for example, often results in minimal if any neurological abnormalities. Bleeding into the parenchyma of the brain, however, can cause serious permanent damage.

PERIVENTRICULAR-INTRAVENTRICULAR HEMORRHAGE. When the fragile capillaries in the germinal matrix rupture, this leads to bleeding into surrounding tissues which may extend into the ventricular system and brain parenchyma. Unfortunately, it is a common problem in preterm neonates. Although a variety of external perinatal and postnatal influences undoubtedly alter its incidence and severity, preterm birth before 32 weeks has the greatest impact. These lesions can develop at later gestational ages, and are occasionally seen in term neonates.

Most hemorrhages develop within 72 hours of birth, but they have been observed as late as 24 days ([Perlman and Volpe, 1986](#)). Almost half are clinically silent, and most small germinal matrix hemorrhages and those confined to the cerebral ventricles resolve without impairment ([Weindling, 1995](#)). Large lesions can result in hydrocephalus or *periventricular leukomalacia*, a correlate of cerebral palsy discussed later. Because intraventricular hemorrhages are usually recognized within 3 days of delivery, their genesis is often erroneously attributed to birth events. It is important to realize that prelabor intraventricular hemorrhage is well recognized ([Achiron and associates, 1993](#); [Asakura and co-workers, 1994](#); [Nores and associates, 1996](#)).

PATHOLOGY. The primary pathological process is damage to the germinal matrix capillary network, which predisposes to subsequent extravasation of blood into the

surrounding tissue. This capillary network is especially fragile in preterm infants:

1. The subependymal germinal matrix provides poor support for the vessels coursing through it.
2. Venous anatomy in this region cause venous stasis and congestion susceptible to vessel bursting with increased intravascular pressure.
3. Vascular autoregulation is impaired before 32 weeks ([Volpe and Hill, 1987](#)).

If extensive hemorrhage or other complications of preterm birth do not cause death, survivors can have major neurodevelopmental handicaps ([Papile and co-workers, 1983](#)).

[DeVries and colleagues \(1985\)](#) attribute most long-term sequelae of intraventricular-periventricular hemorrhage to cystic areas called *periventricular leukomalacia*. These areas develop more commonly as a result of ischemia and less commonly in direct response to hemorrhage, and are discussed subsequently.

INCIDENCE AND SEVERITY. The incidence of ventricular hemorrhage undoubtedly depends on gestational age at birth ([Fig. 39-2](#)). About half of all neonates born before 34 weeks will have evidence of some hemorrhage, and this incidence decreases to 4 percent at term ([Hayden and associates, 1985](#)). [Perlman and Volpe \(1986\)](#) have shown that very-low-birthweight infants have the earliest onset of hemorrhage, the greatest likelihood for progression into parenchymal tissue, and thus the highest mortality rate.

The severity of intraventricular hemorrhage can be assessed by ultrasound and computed tomography, and various grading schemes are used to quantify the extent of the lesion. The scheme proposed by [Papile and colleagues \(1978\)](#) is commonly used:

- *Grade I*—Hemorrhage limited to the germinal matrix
- *Grade II*—Intraventricular hemorrhage
- *Grade III*—Hemorrhage with ventricular dilatation
- *Grade IV*—Parenchymal extension of hemorrhage

The severity of the hemorrhage strongly influences prognosis. [Jakobi and colleagues \(1992\)](#) showed that infants with grades I or II intraventricular hemorrhage had over 90 percent survival with 3.2 percent handicap. This was the same as for control infants of the same age but without hemorrhage. The survival rate for infants with grades III or IV hemorrhage, however, was only 50 percent. [Vergani and co-workers \(1996\)](#) also correlated the degree of hemorrhage with outcome. Very preterm infants are at increased risk of sustaining severe intracranial hemorrhage. In a report of 1765 very-low-birthweight infants studied by the National Institute of Child Health and Development (NICHD)-sponsored Neonatal Intensive Care Network, the incidence of intraventricular hemorrhage was 45 percent, and about 20 percent of these infants had grade III or IV hemorrhage ([Hack and colleagues, 1991](#)).

CONTRIBUTING FACTORS. Events that predispose to germinal matrix hemorrhage and subsequent periventricular leukomalacia are multifactorial and complex. Most recognized risk factors relate to immaturity characterized by fragile intracranial blood vessels. Associated complications of preterm birth, which for example is frequently associated with infection, predispose to tissue ischemia. [Luthy and co-workers \(1987\)](#) reported a threefold increased risk for grade III or IV hemorrhage when the cord arterial pH was less than 7.2. Respiratory distress syndrome and mechanical ventilation are commonly associated factors. [Lesko and colleagues \(1986\)](#) reported that heparin, often used to maintain vascular catheter patency in intensive care units, was associated with a fourfold increased risk of germinal matrix hemorrhage. In a review of 232 infants who weighed less than 1500 g, [Wallin and co-workers \(1990\)](#) reported that associated postnatal factors include respiratory distress, ventilator therapy, a PCO₂ of 60 mm Hg or greater, a PO₂ less than 40 mm Hg at 2 hours of life or greater, and pneumothorax.

PREVENTION AND TREATMENT. Administration of corticosteroids before delivery appears to prevent intraventricular hemorrhage. Based in part on the data of [Garite and associates \(1992\)](#) and the March of Dimes Multicenter Study Group ([Maher and colleagues, 1994](#)), a consensus statement was developed by a panel of the National Institutes of Health (1994). The advisory panel concluded that antenatal corticosteroid therapy reduced mortality, respiratory distress, and intraventricular hemorrhage in preterm infants born between 24 and 32 weeks' gestation. These benefits are additive with those from surfactant therapy. Even though the original Consensus Conference concluded that benefits of antenatal steroid therapy probably extended to preterm premature membrane rupture, the [American College of Obstetricians and Gynecologists \(1994\)](#) concluded that further research was needed in this area.

[Silver and associates \(1996\)](#) reported that antenatal dexamethasone administered to surfactant-treated infants born before 30 weeks' gestation resulted in fewer grade III and IV hemorrhages than placebo plus surfactant. Conversely, [Cox and associates \(1996\)](#) found no benefits of dexamethasone with regard to grade III or IV hemorrhage in preterm infants delivered at Parkland Hospital. The type of corticosteroid administered may be important. [Baud and colleagues \(1999\)](#) found that *betamethasone* decreased the incidence of periventricular leukomalacia but *dexamethasone* did not. [Canterino and associates \(1996\)](#), in a study of 716 consecutive newborns less than 34 weeks' gestation, reported that antenatal corticosteroid therapy decreased the risk of periventricular leukomalacia.

The efficacy of phenobarbital or vitamin K in diminishing the frequency and severity of intracranial hemorrhage, when administered either to the neonate or to the mother during labor, remains controversial ([Thorp and colleagues, 1995](#)). While vitamin E given to high-risk neonates reportedly decreases the incidence and severity of hemorrhage, it did not affect mortality ([Chiswick and colleagues, 1991](#)). Indomethacin given to neonates weighing less than 1000 g was associated with a similar incidence of hemorrhage, but a higher mortality rate than untreated controls ([Hanigan and colleagues, 1988](#)). Data from a variety of sources suggest that magnesium sulfate may prevent the sequelae of periventricular hemorrhage (see later discussion).

It is generally agreed that avoiding significant hypoxia both before and after preterm delivery is of paramount importance ([Low and co-workers, 1995](#)). There is presently no convincing evidence, however, that routine cesarean delivery for the preterm fetus presenting cephalic will decrease the incidence of periventricular hemorrhage ([Tejani and co-workers, 1987](#); [Welch and Bottoms, 1986](#)). [Strauss and colleagues \(1985\)](#) found no association with presence of labor or its duration. In a study of 106 preterm infants weighing less than 1750 g, [Anderson and associates \(1992\)](#) found no significant difference in the overall frequency of hemorrhage in infants whose mothers were not in labor compared with those in latent or active labor. There was, however, an increased frequency of grade III or IV hemorrhage in infants of women in active labor. In contrast, data presented by [Ment and associates \(1995\)](#) suggested a reduction in early intracranial hemorrhage with cesarean delivery.

OUTCOME IN EXTREME PREMATURITY. All of the concerns described are amplified as the limits of viability are reached in the 22- to 25-week age group ([Holtrop and co-workers, 1994](#); [Wood and colleagues, 2000](#)). Not only is the mortality rate in this age group high, but survivors frequently have devastating neurological, ophthalmological, or pulmonary injury due to immaturity. [Allen and associates \(1993\)](#) provided outcome data for 142 infants born at 22 to 25 weeks in whom surfactant therapy was routinely administered ([Table 39-3](#)). No infant born prior to 23 weeks survived. Although survival increased at or beyond 23 weeks, severe abnormalities seen on cranial ultrasonography, which usually lead to major neurological impairment, were inversely associated with age. In all, 98 percent of infants born at 23 weeks, 79 percent at 24 weeks, and 31 percent at 25 weeks either died or had severe neurological abnormalities. [Wood and associates \(2000\)](#) provided follow-up of 283 of 308 survivors born at 25 or fewer completed weeks. Formal assessment at a median of 30 months showed that half had neurological disability and half of these (25 percent of the total group) had severe disability.

BRAIN DISORDERS

The etiology of cerebral palsy has been debated since 1862 when a London orthopedist, William Little, described 47 children with spastic rigidity and concluded that abnormalities of birth could cause this clinical picture. Sigmund Freud questioned this over 100 years ago because abnormal birth processes frequently produced no effects. It is now recognized that cerebral palsy is caused by a combination of genetic, physiological, environmental, and obstetrical factors. Although it inarguably is a complex multifactorial disease, [Paneth \(1986\)](#) emphasized that the presumed birth-injury etiology for cerebral palsy has endured and has influenced the opinions and practices of countless obstetricians and pediatricians. This myth likely is one of the major reasons that at least one in four infants in the United States is currently born by cesarean delivery. Unfortunately, despite the substantive increase in cesarean delivery over 50 years, there has not been any significant decline in the rate of cerebral palsy.

In 1985, the National Institutes of Health convened a panel of experts to set some guidelines crucial to resolving issues that often surround cerebral palsy, mental retardation, learning disabilities, and seizures ([Freeman, 1985](#)). Progress has been made and understanding improved as to what antepartum, intrapartum, and

neonatal factors are, and—possibly more important—are not associated with neurological abnormalities and cerebral palsy. Despite this, some obstetricians, pediatricians, and neurologists—and most if not all plaintiff attorneys—still erroneously attribute many cases of cerebral palsy to intrapartum or perinatal asphyxia.

Unfortunately, although "asphyxia" has been clearly defined, the term is still widely misused. According to the [American College of Obstetricians and Gynecologists \(1998\)](#), birth asphyxia is defined by (1) *profound metabolic or mixed acidemia (pH < 7.00) determined on an umbilical cord arterial blood sample*, (2) *persistent Apgar score of 0 to 3 for longer than 5 minutes*; and (3) *evidence of neonatal neurological sequelae such as seizures, coma, or hypotonia, or dysfunction of one or more of the following systems: cardiovascular, gastrointestinal, hematological, pulmonary, or renal*. Despite this precise definition, the diagnosis is frequently based on low Apgar scores alone, which may be caused by other factors such as preterm birth, maternal sedation, anesthesia, vigorous suctioning or intubation, congenital malformations, and newborn musculoskeletal, neurological, or cardiorespiratory disease ([Gilstrap and Crosby, 1994](#)).

CEREBRAL PALSY

The National Institutes of Health defines cerebral palsy as a nonprogressive motor disorder of early infant onset involving one or more limbs, with resulting muscular spasticity or paralysis. Epilepsy and mental retardation may also be associated with cerebral palsy, but are usually not associated with perinatal asphyxia in the absence of cerebral palsy ([American College of Obstetricians and Gynecologists, 1992](#); [Freeman and Nelson, 1988](#)). Cerebral palsy may be categorized by the type of neurological dysfunction (spastic, dyskinetic, or ataxic) and by the number and distribution of limbs involved (quadriplegia, diplegia, hemiplegia, or monoplegia).

The major types of cerebral palsy are:

1. *Spastic quadriplegia*—which has an increased association with mental retardation and seizure disorders.
2. *Diplegia*—which is common in preterm or low-birthweight infants.
3. *Hemiplegia*.
4. *Choreoathetoid types*.
5. *Mixed varieties* ([Freeman and Nelson, 1988](#)).

From their review, [Rosen and Dickinson \(1992\)](#) reported that approximately 35 percent of cases were of the diplegic type, 30 percent were hemiplegic, 20 percent quadriplegic, and 15 percent were of the extrapyramidal type. Significant mental retardation, defined as an intelligence quotient (IQ) less than 50, was associated with 25 percent of cerebral palsy cases.

INCIDENCE AND EPIDEMIOLOGICAL CORRELATES. The incidence of cerebral palsy is approximately 1 to 2 per 1000 livebirths ([American College of Obstetricians and Gynecologists, 1992](#)). Importantly, as emphasized by many groups, the incidence has remained essentially unchanged since the 1950s, and it may actually have increased in some countries ([Freeman and Nelson, 1988](#); [Torfs and colleagues, 1990](#)). As perhaps expected, cerebral palsy has increased coincidentally with an increase in survival of low-birthweight babies ([Stanley and Blair, 1991](#)). Advances in the care of very preterm infants has improved their survival, but not without significant handicaps, as discussed earlier. In their review of 11 studies published from 1985 through 1990, [Rosen and Dickinson \(1992\)](#) reported that the average cumulative rate for cerebral palsy at ages 5 to 7 years was 2.7 per 1000 livebirths. The rate for infants born weighing less than 2500 g was 15 per 1000, and for survivors weighing 500 to 1500 g at birth, the rate was 13 to 90 per 1000. In the study by [Wood and co-workers \(2000\)](#), half of all surviving infants born before 25 completed weeks had a neurological disability.

[Nelson and Ellenberg \(1984, 1985, 1986a, 1986b\)](#) have made important contributions to our understanding of cerebral palsy. They analyzed data from the Collaborative Perinatal Project, which followed offspring of 54,000 pregnancies regularly until age 7. They determined that important antecedents and most commonly associated risk factors of cerebral palsy were:

1. Evidence of genetic abnormalities such as maternal mental retardation, microcephaly, and congenital malformations.
2. Birthweight less than 2000 g.
3. Gestational age less than 32 weeks.
4. Infection.

They further found that obstetrical complications were not strongly predictive of cerebral palsy. Indeed, only about 20 percent of affected children had markers of perinatal asphyxia, whereas over half had associated congenital malformations, low birthweight, microcephaly, or another explanation for the brain disorder. They concluded that the causes of most cases of cerebral palsy are unknown and that no foreseeable single intervention is likely to prevent a large proportion of cases.

[Torfs and associates \(1990\)](#) presented data that confirm these observations. They reported an incidence of cerebral palsy of 0.3 percent among 19,044 live-born children from the California Child Health and Development Studies database. Of the 55 children with cerebral palsy, 14 (25 percent) had neural-tube defects or obvious postnatal causes, such as infection or injury. There were only nine infants (22 percent) with cerebral palsy who had "perinatal asphyxia"—defined erroneously as a time-to-cry interval longer than 5 minutes. Importantly, all nine had birth defects, gestational risk factors, or both. The strongest predictors for cerebral palsy were the presence of a major or minor congenital anomaly, low birthweight, low placental weight, or abnormal fetal position (which is often associated with neurological abnormality) such as face, breech, or transverse lie. These factors were similar to those identified in the Collaborative Perinatal Project ([Table 39-4](#)). Interestingly, instrumental delivery—including low, mid, or even high forceps—or cesarean delivery did not correlate with cerebral palsy. More recent observations from the Maternal Fetal Medicine Network of nearly 800 infants weighing less than 1000 g were that only low birthweight and early gestational age correlated with neonatal neurological morbidity ([Goepfert and associates, 1996](#)).

INTRAPARTUM EVENTS. Obstetricians and the legal system naturally want to know whether cerebral palsy is related to intrapartum events—the mismanagement of labor—which could be prevented or avoided. Data from several studies indicate that this usually is not the case. [Stanley and Blair \(1991\)](#) performed a case-control study of all cases of cerebral palsy in western Australia from 1975 to 1980. Antepartum, intrapartum, and neonatal events were carefully reviewed. They found that in 92 percent of cases, intrapartum injury as the cause of cerebral palsy was not likely; in 3.3 percent, intrapartum injury was possible; and in only 4.9 percent was it likely. [Phelan and associates \(1996\)](#) reviewed fetal monitor tracings of 209 neurologically impaired neonates and classified 75 percent as nonpreventable.

The role of continuous electronic fetal monitoring in predicting or allowing prevention of cerebral palsy has been studied. Data from a variety of sources indicate that such monitoring neither predicts nor reduces the risk of cerebral palsy when compared with intermittent auscultation ([American College of Obstetricians and Gynecologists, 1992](#); [Freeman, 1990](#); [Thacker and colleagues, 1995](#)). [MacDonald and associates \(1985\)](#) performed a randomized, prospective study of over 13,000 pregnancies comparing continuous electronic monitoring with intermittent auscultation. In a later analysis, [Grant and associates \(1989\)](#) found an equal number of cases of cerebral palsy (3) in each group. The [American College of Obstetricians and Gynecologists \(1995a\)](#) concluded that "a substantial body of evidence disproves the hypothesis that electronic fetal monitoring would reduce long-term neurological impairment and cerebral palsy in newborns so monitored."

Importantly, there does not appear to be any specific fetal heart rate pattern that predicts cerebral palsy. Furthermore, the recognition of abnormal patterns, usually leading to cesarean delivery, has not decreased the incidence of cerebral palsy. In fact, in cases that ultimately result in cerebral palsy, the abnormal heart rate pattern may reflect preexisting neurological abnormality and not ongoing, remedial injury ([Phelan and Ahn, 1994](#)). This in part accounts for the unchanged incidence of cerebral palsy in the United States, despite a fivefold increase in the cesarean delivery rate since 1965. A number of studies found no relationship between an appropriate response to abnormal fetal heart rate patterns and neurological outcome ([Melone and associates, 1991](#); [Nelson and co-workers, 1996](#); [Niswander and colleagues, 1984](#)). Indeed, [Shy and co-workers \(1990\)](#) found a significant increase in cerebral palsy among a group of preterm infants monitored electronically when compared with intermittent auscultation.

APGAR SCORES. Since their inception, Apgar scores have been used to predict neurological impairment in childhood. It is now clear that they are poor predictors except in certain circumstances. [Nelson and Ellenberg \(1984\)](#) studied the interaction between obstetrical complications and a low Apgar score as a predictor of poor neurological outcome. A variety of late pregnancy complications were identified in 62 percent of pregnancies, and when considered alone, they were not associated strongly with cerebral palsy. However, in infants with complicated births who also had 5-minute Apgar scores of 3 or less, the incidences of mortality and cerebral

palsy were increased appreciably. In the absence of complications, low Apgar scores alone were not associated with a high level of risk. [Dijxhoorn and colleagues \(1986\)](#) reported similar findings and concluded that most neonatal neurological abnormalities were due to factors other than perinatal hypoxia. [Luthy and associates \(1987\)](#) reported that in low-birthweight infants with 1-minute Apgar scores of 3 or less, the incidence of death was increased fivefold and the incidence of cerebral palsy was increased threefold.

Because it is predictive of increased neonatal death, recent data suggest that a low 5-minute Apgar score might be predictive of future neurological impairment. [Casey and colleagues \(2001\)](#) studied over 150,000 live-born infants delivered at Parkland Hospital from 1988 through 1998. They found that a 5-minute Apgar score of 0 to 3 predicts an increased incidence of neonatal death in preterm, but especially term, infants ([Table 39-5](#)). For infants born before 37 completed weeks whose 5-minute Apgar score was 0 to 3, the risk for neonatal death was increased 75-fold. In infants born at 38 weeks or more, the 5-minute Apgar of 0 to 3 was associated with a 1460-fold increase in death within 28 days.

The [American College of Obstetricians and Gynecologists \(1996\)](#) has summarized the use and misuse of the Apgar score to assess asphyxia and to predict future neurological deficit ([Chap. 16, p. 387](#)). It was concluded that low scores at 1 and 5 minutes are excellent indicators for identification of those infants who need resuscitation. It was further concluded, however, that low Apgar scores alone are not evidence for hypoxia sufficient to result in neurological damage. In a child found to have cerebral palsy, low 1- or 5-minute Apgar scores provide insufficient evidence that the damage was due to hypoxia.

UMBILICAL CORD BLOOD GAS. As summarized in [Chapter 16 \(p. 389\)](#), an important criterion in the definition of asphyxia is metabolic acidosis. In its absence, significant intrapartum hypoxia or asphyxia is generally excluded. Although there has been significant enthusiasm for the clinical use of umbilical cord acid-base determinations, when used alone, they have proven no more helpful than the 1- and 5-minute Apgar scores in predicting long-term neurological sequelae. [Dijxhoorn and associates \(1986\)](#), in a study of 805 term newborns delivered vaginally, reported that the largest number of neurologically abnormal infants had a normal umbilical arterial pH but low Apgar scores. These authors concluded that intrapartum hypoxia was not a major cause of neurological morbidity. Others have reported that neither pH measurements nor acidemia correlated with long-term neurological outcome in term infants ([American College of Obstetricians and Gynecologists, 1992](#); [Fee and associates, 1990](#)). Subsequently, it was reported that the pH cutoff for clinically significant acidemia most likely is less than 7.0 instead of the earlier arbitrarily chosen level of less than 7.2 ([American College of Obstetricians and Gynecologists, 1995d](#); [Gilstrap and associates, 1989](#); [Goldaber and associates, 1991](#)). [Nagel and associates \(1995\)](#) reported long-term follow-up in 30 infants whose umbilical artery pH was less than 7.0. Of the 28 survivors, only two had mild neurological sequelae. They concluded that infants with this degree of acidosis did well if they had no major neonatal problems.

In the previously cited study by [Casey and co-workers \(2001\)](#) of over 150,000 live-born infants, the umbilical artery pH was also used to assess predictability of neonatal death within 28 days. As the pH fell to 7.0 or less, the likelihood of neonatal death increased, and it was 1400-fold increased with a cord pH of less than or equal to 6.8 in term newborns. When cord pH was 7.0 or below and the 5-minute Apgar score was 0 to 3, the relative risk of neonatal death was 3204!

NUCLEATED RED BLOOD CELLS. Nucleated erythrocytes are immature cells that enter the circulation in response to hypoxia. Their measurement has been proposed as a means to quantify the degree of hypoxia and determine its duration. Some investigators have reported an association with cord blood nucleated red blood cells and fetal asphyxia ([Korst and associates, 1996](#)). Conversely, [Salafia and colleagues, \(1996\)](#), in a study of 465 preterm newborns, found no correlation with nucleated red cells and fetal hypoxia. Instead, these were found to be hematological markers associated with maternal and newborn infection, as well as placental histological evidence of infection.

[Naeye and Localio \(1995\)](#) provided data that serial lymphocyte and normoblast counts in the neonate helped to accurately identify the time before birth when hypoxic ischemic encephalopathy took place. They studied 16 newborns in whom intrapartum events allowed accurate assessment of the time of injury. Counts peaked 2 hours after injury and normalized in 24 to 36 hours. Further studies of both nucleated erythrocytes and lymphocytes are needed before these premises are accepted for clinical use.

PERIVENTRICULAR LEUKOMALACIA. This term refers to cystic areas deep in the white matter of the brain which develop after hemorrhagic infarction and ischemia. Tissue ischemia leads to regional necrosis, and because brain tissue does not regenerate, these irreversibly damaged areas appear as echolucent cysts on neuroimaging studies. They generally require at least 2 weeks to develop, and have been reported to develop up to 104 days after the initial insult ([Goetz and colleagues, 1995](#)). Accordingly, the presence of cystic areas at birth may determine the timing of the hemorrhagic event ([Hayakawa and co-workers, 1999](#)).

A variety of clinical and pathological data link severe intracranial hemorrhage and periventricular leukomalacia to cerebral palsy. [Luthy and colleagues \(1987\)](#) reported that more than 40 percent of low-birthweight infants with cerebral palsy had grade III or IV hemorrhages. They computed a 16-fold increased risk for cerebral palsy for these infants compared with those who had either no hemorrhage or grade I or II hemorrhage. [DeVries and colleagues \(1993\)](#) followed 504 infants born at 34 weeks or less and found that only 11 percent of those with transient cysts developed cerebral palsy. Conversely, 67 percent with localized cystic periventricular leukomalacia and 100 percent of those with extensive cystic areas developed cerebral palsy. [Allan and co-workers \(1997\)](#) evaluated multiple prenatal, perinatal, and postnatal variables in 505 infants with birthweights between 600 and 1250 g. They found that the highest rates of cerebral palsy were associated with periventricular leukomalacia (37 percent) and ventriculomegaly (30 percent). [Hsu and colleagues \(1996\)](#) showed that the size of the cyst(s) correlated directly with the risk of cerebral palsy. [Fujimoto and colleagues \(1994\)](#) demonstrated that symmetrical cystic lesions portended the highest risk.

Although some of the same factors that appear to cause intraventricular hemorrhage are associated with periventricular leukomalacia, the latter condition seems to be more strongly linked to infection and inflammation, as discussed subsequently. [Zupan and colleagues \(1996\)](#) studied 753 infants born between 24 and 32 weeks. About 9 percent developed periventricular leukomalacia, and those born before 28 weeks, or who had inflammatory events during the last days to weeks before delivery, or both, were at highest risk. [Perlman and co-workers \(1996\)](#) found that periventricular leukomalacia was strongly associated with neonatal hypotension, prolonged rupture of the membranes, and chorioamnionitis. [Spinillo and colleagues \(1995, 1998\)](#) found a strong association of leukomalacia with first-trimester hemorrhage, maternal urinary infection in labor, low birthweight, smoking, preterm labor, neonatal acidosis, meconium staining, and more than 72 hours of ritodrine therapy.

PRETERM FETUS AND PERIVENTRICULAR LEUKOMALACIA. Consideration of brain development explains why very preterm infants are most susceptible to intraventricular hemorrhage and periventricular leukomalacia. Before 32 weeks, the blood supply to the brain is composed of two systems: one penetrates into the cortex—the *ventriculopedal system*, and the other reaches down to the ventricles, but then curves to flow outward—the *ventriculofugal system* ([Weindling, 1995](#)). The area between these two blood supplies corresponds to an area near the lateral cerebral ventricles through which the pyramidal tracts pass. It is called the *watershed area* because there are no vascular anastomoses where these two blood supplies meet, and thus it is very vulnerable to ischemia. Any intracranial vascular injury occurring before 32 weeks and leading to ischemia would affect the watershed area first, damaging the pyramidal tracts and resulting in spastic diplegia. After 32 weeks, the blood supply shifts away from the brainstem and basal ganglia toward the cortex. Hypoxic injury after this time primarily damages the cortical region.

PERINATAL INFECTION. Fetal infection may be a key element in the pathway between preterm birth, intracranial hemorrhage, periventricular leukomalacia, and cerebral palsy ([Dammann and Leviton, 1997](#); [Yoon and colleagues, 1997a, 2000, 2001](#)). In the pathway proposed in [Figure 39-3](#), antenatal reproductive tract infection is characterized by the production of cytokines such as interleukins-1, -6, and -8, and tumor necrosis factor. These stimulate prostaglandin production, which may cause preterm birth ([Chap. 11, p. 274](#)). Because of their incomplete development, discussed earlier, intracranial blood vessels are susceptible to rupture and damage. The cytokines that stimulate preterm labor also have direct toxic effects on oligodendrocytes and myelin. Thus, vessel rupture, tissue hypoxia, and cytokine-mediated damage results in massive cell death. Glutamate that is released may cause damage to cerebral white matter. Glutamate causes membrane receptor changes that allow excess calcium to enter the neurons, and the high intracellular calcium levels are toxic ([Levene, 1992](#)). Glutamate may also be directly toxic to oligodendroglia ([Oka and associates, 1993](#)).

Both animal and clinical data support the role of infection and cytokines. [Yoon and colleagues \(1997a\)](#) have shown that inoculation of rabbit embryos with *Escherichia coli* causes histological white matter damage. In another study, [Yoon and associates \(1997b\)](#) also showed that tumor necrosis factor and interleukin-6 were more frequently found in the brains of infants who died with periventricular leukomalacia. Cytokines have been strongly linked to white matter lesions even when infectious organisms cannot be demonstrated. In a study in which amniotic fluid cultures were performed and cytokines were measured in 123 preterm infants, [Yoon and colleagues \(2000\)](#) showed that, while only 45 percent of the infants with cerebral palsy had microorganisms in amniotic fluid, 85 percent had abnormally elevated interleukin-6 and -8 levels.

The importance of infection separate from preterm birth has also been demonstrated. [Verma and colleagues \(1997\)](#) compared 285 infants born after preterm labor and 279 infants born after preterm prematurely ruptured membranes with 149 infants who were delivered preterm for other reasons. The incidence and severity of intraventricular hemorrhage and periventricular leukomalacia was highest in those infants with spontaneous labor or membrane rupture. In both cases, cerebral damage was significantly increased if chorioamnionitis was diagnosed. [Bejar and co-workers \(1988\)](#) showed that the most significant clinical correlates of white matter necrosis in preterm infants were funisitis, purulent amniotic fluid, and placental vascular anastomoses. [Grether and Nelson \(1997\)](#) performed a population-based

case-control study of cerebral palsy in which they focused only on affected children whose birthweight was more than 2500 g and who had no congenital brain malformations or genetic abnormalities. They found a significant ninefold increased risk of cerebral palsy after either maternal fever in labor or chorioamnionitis, and a 19-fold risk after neonatal infection.

PREVENTION. The benefits of corticosteroid therapy were discussed earlier in reference to intraventricular hemorrhage (p. 1040). Discovery of the link between infection, cytokines, and cerebral palsy may allow another step toward prevention. Aggressive treatment of or prophylaxis against infection in the woman delivering preterm may be neuroprotective.

Magnesium sulfate has been shown to stabilize intracranial vascular tone, minimize fluctuations in cerebral blood flow, reduce reperfusion injury, and block calcium-mediated intracellular damage ([Marret and associates, 1995](#)). It also appears to reduce synthesis of cytokines and bacterial endotoxins, and thus may minimize the inflammatory effects of infection ([Grether and Nelson, 1997](#)). Epidemiological evidence suggests that prenatal exposure to maternal magnesium sulfate therapy has a neuroprotective effect ([Schendel and co-workers, 1996](#)). This may be limited to preeclamptic women ([Grether and colleagues, 2000](#)). This is currently being evaluated in the *BEAM study* sponsored by the National Institutes of Health—*Randomized Clinical Trial of the Beneficial Effects of Antenatal Magnesium Sulfate*.

NEURORADIOLOGICAL IMAGING. Computed tomography and magnetic resonance performed later in childhood have been used to define the neuropathology and timing of cerebral palsy ([Perlman and Cunningham, 1993](#)). [Wiklund and colleagues \(1991a, 1991b\)](#) used computed tomography to study 28 preterm infants and 83 term infants with hemiplegic cerebral palsy between 5 and 16 years of age. Only 25 percent of these children had computed tomographic findings that were considered normal. Moreover, in 70 percent of preterm infants, findings confirmed an insult at early age. In term infants, computed tomographic findings suggested a prenatal injury in over half of cases—that is, periventricular atrophy in 37 percent and maldevelopment in 17 percent. Cortical and subcortical injury suggestive of a perinatal injury was found in 19 percent.

[Truwit and colleagues \(1992\)](#) used magnetic resonance imaging, and the predominant finding in 80 percent of preterm infants was evidence of periventricular white matter damage which is indicative of hypoxic ischemic brain injury. It was difficult to determine its exact chronology. In contrast, 50 percent of term infants had imaging findings consistent with antenatal brain damage. These included gyral abnormalities such as polymicrogyria, consistent with midpregnancy injury, and isolated periventricular leukomalacia. In 25 percent of these cases, magnetic resonance imaging findings, coupled with clinical events, were suggestive of hypoxic ischemic injury at birth.

Cranial ultrasound also provides useful information. The development of periventricular leukomalacia is shown in [Figure 39-4](#). Because ultrasonic evolution of cysts takes days to weeks to develop, ultrasound performed on the first day was critical in diagnosing antenatal brain injury. Intraventricular hemorrhage was found to be a secondary insult that developed in the nursery. Sometimes head ultrasound reveals findings different but complimentary to those with computed tomography. A grade III intraventricular hemorrhage diagnosed at birth by computed tomographic scan is shown in [Figure 39-5A](#). A head ultrasound done the same day, however, also disclosed periventricular leukomalacia, which documents injury well before birth ([Fig. 39-5B](#)).

Magnetic resonance imaging in the neonate is also valuable to study intracranial lesions relevant to the development of cerebral palsy ([Battin and associates, 1998](#); [Okumura and colleagues, 1997](#)). In a study of 30 children with cerebral palsy, [Fedrizzi and colleagues \(1996\)](#) found that magnetic resonance imaging between the ages of 1 and 2 years predicted the specific pattern of neuropsychological dysfunction, thus enabling early intervention. The severity of ventricular dilatation, the degree and extent of white matter loss, involvement of optic structures, and the degree of thinning of the corpus callosum correlated with the Wechsler full scale and performance IQ¹ test. [Jaw and co-workers \(1998\)](#) have used magnetic resonance imaging to determine the most likely time of the brain insult in 86 pediatric patients with cerebral palsy.

NEONATAL ENCEPHALOPATHY

Term infants can also suffer neurological insults resulting in permanent compromise. Neonatal encephalopathy is used to describe a defined syndrome of disturbed neurological function in the earliest days of life in the term infant. It consists of difficulty in initiating and maintaining respiration, depressed tone and reflexes, subnormal level of consciousness, and frequently seizures ([Nelson and Leviton, 1991](#)). It is generally believed to be the consequence of an hypoxic-ischemic insult, although the timing of the insult is not always known. Mild encephalopathy is generally defined as hyperalertness, irritability, jitteriness, and hypertonia and hypotonia. Moderate encephalopathy includes lethargy, severe hypertonia, and occasional seizures. Severe encephalopathy is defined by coma, multiple seizures, and recurrent apnea. Severe encephalopathy is an important predictor of cerebral palsy and future cognitive defects. In the report by [Robertson and Finer \(1985\)](#), none of the infants with severe encephalopathy had a normal neurological outcome. In contrast, normal outcomes were documented in 80 percent with moderate encephalopathy, and in all newborns with mild hypoxic encephalopathy. [Low and colleagues \(1985\)](#) studied 303 high-risk preterm and term neonates, 30 percent of whom had newborn encephalopathy. A total of 17 percent of infants developed cognitive and motor deficits; in a quarter of these there was mild or moderate encephalopathy, whereas half had severe encephalopathy. Respiratory complications were the most commonly identifiable risk factor, and perinatal hypoxia was associated with or contributed to 26 percent of cases of mild to moderate encephalopathy and 66 percent of these with severe encephalopathy. [Cordes and colleagues \(1994\)](#) performed serial head circumference measurements of 54 term infants with hypoxic-ischemic encephalopathy. They found that a decrease in the head circumference of more than 3.1 percent relative to that expected for age in the first 4 months of life predicted microcephaly, and thus permanent impairment, with 90 percent specificity.

MENTAL RETARDATION. Etiological factors for severe mental retardation, which has a prevalence of 3 per 1000 children, are shown in [Table 39-6](#). Some genetic causes of mental retardation are discussed in [Chapter 36](#). In the National Institutes of Health report, the panel ascertained that isolated mental retardation—that is, mental retardation without epilepsy or cerebral palsy—was associated with perinatal hypoxia in less than 5 percent of cases.

SEIZURE DISORDERS. Although seizure disorders may accompany cerebral palsy, isolated seizure disorders or epilepsy are not usually caused by perinatal hypoxia. [Nelson and Ellenberg \(1986b\)](#) determined that the major predictors of seizure disorders were fetal malformations (cerebral and noncerebral), family history of seizure disorders, and neonatal seizures.

ANEMIA

After 35 weeks, the mean cord hemoglobin concentration is about 17 g/dL and values below 14 g/dL are abnormal. During the first several hours of life, the hemoglobin value may rise by as much as 20 percent due to delayed cord clamping, resulting in an appreciable volume of blood being expressed from the placenta through the cord into the infant. Alternatively, if the placenta is cut or torn, a fetal vessel is perforated or lacerated, or the infant is held well above the level of the placenta for some time before cord clamping, the hemoglobin concentration may fall after delivery.

FETAL-TO-MATERNAL HEMORRHAGE. The presence of fetal red cells in the maternal circulation may be identified by use of the acid elution principle first described by Kleihauer, Brown, and Betke, or any of several modifications. This test is based on the fact that fetal erythrocytes contain hemoglobin F, which is more resistant to acid elution than hemoglobin A. After exposure to acid, only fetal hemoglobin remains. Fetal red cells can then be identified by uptake of a special stain and quantified on a peripheral smear ([Fig. 39-6](#)).

Very small volumes of blood cells commonly escape from the fetal intravascular compartment across the placental barrier into the maternal intervillous space. This routine fetal-maternal bleeding may someday serve as the basis of a screening test for fetal aneuploidy using maternal peripheral blood samples ([Chap. 37, p. 985](#)). [Choavaratana and colleagues \(1997\)](#) performed serial Kleihauer-Betke tests in 2000 pregnant women and found that, although the incidence of fetal-maternal hemorrhage in each trimester was high, the volume transfused from fetus to mother was very small ([Table 39-7](#)). Large hemorrhages are uncommon, and [Bowman \(1985\)](#) reported that only 21 of 9000 women had fetal hemorrhage at delivery exceeding 30 mL. A number of events may cause sufficient fetal-maternal hemorrhage to incite isoimmunization ([Table 39-8](#)).

The presence of D-positive fetal red blood cells in maternal blood can also be determined by the rosette test. In this test, maternal red cells are mixed with anti-D antibodies, which coat any fetal D-positive cells in the sample. Indicator red cells bearing the D antigen are then added, and "rosettes" form around the fetal cells as the indicator cells are attached to them by the antibodies. The presence of rosettes indicates that fetal D-positive cells are present. Using the erythrocyte rosette test, [Stedman and colleagues \(1986\)](#) reported fetal hemorrhage exceeding 30 mL in only 6 of 1000 women. Because the Kleihauer-Betke test is based on the detection of fetal hemoglobin, the rosette test is probably more accurate in certain cases, such as when fetal cells carry excess fetal hemoglobin as the result of a hemoglobinopathy ([Goldman and associates, 1991](#)).

The fetus who is severely anemic is more likely to demonstrate an ominous heart rate pattern. The sinusoidal pattern shown in [Figure 39-7](#) is commonly caused by severe anemia, but is not pathognomonic. It should, however, prompt immediate evaluation. In general, anemia occurring gradually or chronically as in

isoimmunization is better tolerated by the fetus than if it develops acutely. Chronic anemia may not produce fetal heart rate abnormalities until the fetus is moribund. Significant hemorrhage, either chronic or acute, often causes profound neurological fetal impairment. Acute hemorrhage causes fetal hypotension, diminished perfusion, ischemia, and cerebral infarction. Unfortunately, after an acute hemorrhage, subsequent obstetrical management usually will not change the outcome. For example, [deAlemida and Bowman \(1994\)](#) described 27 cases of fetal-maternal hemorrhage exceeding 80 mL. Despite appropriate management, almost half of these infants suffered death or spastic diplegia. In some cases, and as discussed on page 1056, fetal-to-maternal hemorrhage may be so severe as to kill the fetus ([Fig. 39-6](#)). [Samadi and colleagues \(1996\)](#) found that such hemorrhage was responsible for fetal death in about 5 percent of 319 cases (see also p. 1075).

The cause of a large fetal-to-maternal hemorrhage is often undetermined. In some cases, a placental lesion—for example, a chorioangioma—may be the cause. Placental abruption does not commonly cause appreciable fetal-to-maternal hemorrhage, although if due to trauma, the likelihood is increased ([Chap. 43, p. 1173](#)).

In addition to recognizing fetal-maternal hemorrhage, it is important to try to quantify the volume of fetal blood lost. The volume may influence obstetrical management, and is essential to determining the appropriate dose of D-immune globulin when the woman is D negative.

Using basic physiological principles, the amount of fetal hemorrhage may be calculated from the results of a Kleihauer-Betke (KB) stain using the formula:

where MBV = maternal blood volume (about 5000 mL in normal-sized normotensive women at term) and Hct = hematocrit. Thus for 1.7 percent positive [KB²](#)-stained cells in a woman of average size with a hematocrit of 35 percent giving birth to an infant weighing 3000 g:

The fetal-placental blood volume at term is 125 mL/kg and the hematocrit is 50 percent. Thus, this fetus has lost 60 mL of red cells over time into the maternal circulation. This is equivalent to 120 mL of whole blood or about a third of its blood volume of 375 mL.

ISOIMMUNIZATION

In 1892, Ballantyne established clinicopathological criteria for the diagnosis of hydrops fetalis. In 1932, Diamond, Blackfan, and Baty reported that fetal anemia characterized by numerous circulating erythroblasts was associated with this syndrome. Certainly ranking as a major contribution to medicine is the subsequent delineation of the pathogenesis of most cases of hemolytic disease in the fetus and newborn, including the related discovery of the Rhesus factor by [Landsteiner and Weiner in 1940](#). In 1941, [Levine and associates](#) confirmed that erythroblastosis was due to maternal isoimmunization with paternally inherited fetal factors, and the subsequent development of effective maternal prophylaxis was attributed to [Finn and associates \(1961\)](#) in England, and [Freda and co-workers \(1963\)](#) in the United States.

Over 400 red cell antigens have been identified. Although some of them are immunologically and genetically important, fortunately many are so rare as to be of little clinical significance. Individuals who lack a specific red cell antigen may potentially produce an antibody when exposed to that antigen. The antibody could prove harmful to the individual in the case of a blood transfusion or to a fetus during pregnancy. The vast majority of humans have at least one antigen inherited from their father but lacking in their mother. Although the mother could be sensitized if enough erythrocytes from the fetus were to reach her circulation to elicit an immune response, isoimmunization occurs infrequently. Factors explaining its rarity include:

1. Varying rates of occurrence of red cell antigens.
2. Their variable antigenicity.
3. Insufficient transplacental passage of antigen or antibody.
4. Variability of the maternal immune response to the antigen.
5. Protection from isoimmunization by ABO incompatibility of fetus and mother.

The latter confers some protection against D-isoimmunization because fetal red cells entering the mother usually are rapidly destroyed before they can elicit an antigenic response, viz., there is only a 2 percent chance of D-isoimmunization in all women by 6 months postpartum. Another factor benefitting the fetus is that isoimmunization does not always lead to erythroblastosis fetalis.

The incidence of sensitization to red cell antigens at each stage of pregnancy has been studied most extensively in D-negative women. A D-negative woman delivered of a D-positive, ABO-compatible infant has a likelihood of isoimmunization of 16 percent ([Bowman, 1985](#)). About 2 percent of such women will be immunized by the time of delivery, another 7 percent will have anti-D antibody by 6 months postpartum, and the remaining 7 percent will be "sensitized"; that is, they do not ordinarily produce anti-D antibodies but will demonstrate D-isoimmunization when challenged in a subsequent pregnancy by another D-positive fetus.

ABO BLOOD GROUP SYSTEM. Incompatibility for the major blood group antigens A and B is the most common cause of hemolytic disease in the newborn. About 20 percent of all infants have an ABO maternal blood group incompatibility, and 5 percent are clinically affected. Fortunately, ABO incompatibility invariably causes only mild disease, evident as neonatal jaundice or anemia but not erythroblastosis fetalis, and treatment is most often limited to phototherapy.

ABO incompatibility is different from CDE incompatibility for several reasons:

1. ABO disease is frequently seen in firstborn infants. This is because most group O women have anti-A and anti-B isoagglutinins antedating pregnancy, believed to result from exposure to bacterial antigens that are very similar to the A and B antigens. Anti-A or -B antibody production accelerates during the first pregnancy and is likely to recur in subsequent pregnancies.

2. Although the disease is common, it is invariably milder than D-isoimmunization and rarely results in significant anemia. Most species of A and B isoantibodies are immunoglobulin M, which cannot cross the placenta or gain access to fetal erythrocytes. Also, fetal red cells have fewer A and B antigenic sites than adult cells and are thus less immunogenic. Thus, while ABO isoimmunization can cause hemolytic disease of the newborn, it does not cause hydrops fetalis and is a disease of pediatric rather than obstetrical concern.

3. ABO incompatibility can affect future pregnancies but, unlike CDE disease, rarely gets progressively more severe. [Katz and co-workers \(1982\)](#) identified a recurrence rate of 87 percent of whom 62 percent required treatment, most often limited to phototherapy.

4. In contrast to D-isoimmunization, which preferentially affects Caucasians, African-American infants are more likely to develop ABO disease ([Kirkman, 1977](#)).

There is no need for antenatal detection as ABO incompatibility does not cause severe fetal anemia. Careful observation is essential in the neonatal period, however, because hyperbilirubinemia may require treatment. The usual criteria for diagnosis of neonatal hemolysis due to ABO incompatibility include the following:

1. The mother is blood group O, with anti-A and anti-B antibodies in her serum, while the fetus is group A, B, or AB.
2. There is onset of jaundice within the first 24 hours.
3. There are varying degrees of anemia, reticulocytosis, and erythroblastosis.
4. There has been careful exclusion of other causes of hemolysis.

Unlike CDE hemolytic disease, the Coombs test in ABO incompatibility may be negative although it is usually positive.

The principles of management of the newborn with ABO hemolytic disease are similar to those for the infant born with D-isoimmunization. For simple transfusion or exchange transfusion, group O blood is used. Because the incidence of stillbirths among ABO-incompatible pregnancies is not increased, there is no justification for early labor induction or for performing amniocentesis.

CDE (RHESUS) BLOOD GROUP SYSTEM. These red cell antigens are of considerable clinical importance because the majority of individuals who lack its major antigenic determinant, the D or Rhesus antigen, become immunized after a single exposure. The CDE genes are inherited independent of other blood group genes and are located on the short arm of chromosome 1. Like most gene products, there is no difference in the distribution of the CDE antigens with regard to sex, but there are important racial differences. Native Americans, Inuits, and Chinese and other Asiatic peoples are almost all D-positive (99 percent). Approximately 92 to 93 percent of African Americans are D-positive, but only 87 percent of Caucasians carry the D antigen. Of all racial and ethnic groups studied thus far, the Basques show the highest incidence of D-negativity (34 percent).

The Rhesus blood group system includes five red cell proteins or antigens: c, C, D, e, and E. No "d" antigen has been identified, and D-negativity is defined as the absence of "D." The C, c, E, and e antigens have lower immunogenicity than the D antigen, but they can cause erythroblastosis fetalis. All pregnant women should be tested routinely for the presence or absence of D antigen on their erythrocytes and for other irregular antibodies in their serum. [Barss and colleagues \(1988\)](#) have argued convincingly that this need be done only once during pregnancy in D-positive women.

OTHER BLOOD GROUP INCOMPATIBILITIES. Proportionately more cases of significant antenatal hemolytic disease are now caused by rarer red cell antigens because of prevention of anti-D isoimmunization. Such sensitization may be suspected from the results of the indirect Coombs test done to screen for abnormal antibodies in maternal serum ([Table 39-9](#)).

An idea of the frequency of some of these antibodies comes from the report of [Bowell and colleagues \(1986a\)](#), who screened 70,000 pregnant women over a 2-year period. They identified 677 pregnancies with atypical red cell antibodies, for an incidence of nearly 1 percent. One fourth of these were from the Lewis system, which do not cause fetal hemolysis because Lewis antigens do not develop on erythrocytes until a few weeks after birth. Of the remaining 544 antibodies, 72 percent were of the CDE group, and anti-D was most common (158), followed by anti-E (130), anti-c (49), and anti-C (19). Antibodies to the Kell system antigens also were common (76). More recently, [Howard and colleagues \(1998\)](#) evaluated all clinically important cases of isoimmunization occurring in Liverpool during a 12-month period. They also found that 1 percent of 22,264 pregnancies were sensitized, and anti-D immunization accounted for 40 percent while non-D antibodies accounted for the majority.

KELL ANTIGEN. This antigen is uncommon, and 91 percent of Caucasians are Kell negative. While 90 percent of cases of sensitization result from transfusion with Kell-positive blood, it can also occur as the result of maternal-fetal incompatibility ([Mayne and associates, 1990](#)). Maternal sensitization to Kell is different from D sensitization in that it results in a more rapid and more severe fetal anemia. Furthermore, severe anemia may not be predicted by either maternal serum antibody titer or amniotic fluid bilirubin studies. Sensitized pregnancies often have only mild or moderately increased amniotic fluid bilirubin levels as discussed below. [Caine and colleagues \(1986\)](#) described 13 Kell-sensitized pregnancies with a Kell-positive fetus in which five resulted in hydrops or perinatal death, despite favorable amniotic fluid studies one week prior to delivery. [Bowman and colleagues \(1992a\)](#) reviewed 20 Kell-sensitized pregnancies, and in four, exchange transfusions were required and four fetuses died.

According to [Weiner and Widness \(1996\)](#), anti-Kell antibodies attack fetal erythrocyte precursor cells directly in the bone marrow, which prevents the hematopoietic response to anemia. Because fewer erythrocytes are produced, there is less hemolysis, and less bilirubin despite severe anemia. Because of this disparate severity of Kell sensitization, some authorities recommend evaluation when the maternal anti-Kell titer is 1:8 or greater as discussed subsequently. [Weiner and Widness \(1996\)](#) further recommend that the initial evaluation be accomplished by cordocentesis instead of amniocentesis because of their observations indicating that Kell sensitization produces fetal anemia out of proportion to the amniotic fluid evidence of hemolysis.

OTHER ANTIGENS. Kidd (Jk^a), Duffy (Fy^a), c, E, and to a lesser extent C can all cause erythroblastosis as severe as that associated with sensitization to D ([Table 39-9](#)). Two Duffy antigens have been identified, Fy^a and Fy^b , and among blacks there is a type that lacks both. Fy^a is the most immunogenic. The Kidd system also has two antigens, Jk^a and Jk^b , with a distribution in the population as follows: Jk (a+b-), 26 percent; Jk (a-b+), 24 percent; and jK (a+b+), 50 percent ([Alper, 1977](#)). Most cases of isoimmunization to these antigens occur after blood transfusions.

The clinical importance of anti-C isoimmunization has been emphasized by [Wenk \(1986\)](#) and [Bowell \(1986b\)](#) and their colleagues. This antibody was the next most common cause of clinically significant isoimmunization following anti-D. Although anti-C isoimmunization most commonly resulted from previous pregnancies, those fetuses whose mothers had been transfused were more likely to have moderate to severe hemolysis. In a review by [Bowman and colleagues \(1992b\)](#) of 98 ongoing pregnancies with either anti-C or anti-Ce alloimmunization, there were 33 affected fetuses, of which eight required treatment after birth and none had severe diseases.

If an IgG red cell antibody is detected and there is any doubt as to its significance, the clinician should err on the side of caution and the pregnancy should be evaluated. As shown in [Table 39-9](#), many rare or *private antigens* have been associated with severe isoimmunization ([Rouse and Weiner, 1990](#)).

IMMUNE HYDROPS. The pathological changes in the organs of the fetus and newborn infants vary with the severity of the process. Excessive and prolonged hemolysis serves to stimulate marked erythroid hyperplasia of the bone marrow as well as large areas of extramedullary hematopoiesis, particularly in the spleen and liver, which may in turn cause hepatic dysfunction ([Nicolini and associates, 1991](#)). Histological examination of the liver may also disclose fatty degenerative parenchymal changes as well as deposition of hemosiderin and engorgement of hepatic canaliculi with bile. There may be cardiac enlargement and pulmonary hemorrhages. When the severely affected fetus or infant shows considerable subcutaneous edema as well as effusion into the serous cavities, this is called *hydrops fetalis*. It is defined as the presence of abnormal fluid in two or more sites such as thorax, abdomen, or skin. The diagnosis is usually made easily using sonography ([Fig. 39-8](#)). The placenta is also markedly edematous, appreciably enlarged and boggy, with large, prominent cotyledons and edematous villi. Fetal ascites, hepatomegaly, and splenomegaly may be so massive as to lead to severe dystocia. Hydrothorax may be so severe as to affect lung development and compromise respirations after birth.

The precise pathophysiology of hydrops remains obscure. Theories of its causation include heart failure from profound anemia, capillary leakage caused by hypoxia from severe anemia, portal and umbilical venous hypertension from hepatic parenchymal disruption by extramedullary hematopoiesis, and decreased colloid oncotic pressure from hypoproteinemia caused by liver dysfunction. [Nicolaidis and colleagues \(1985\)](#) performed percutaneous umbilical artery blood sampling in 17 severely D-isoimmunized fetuses at 18 to 25 weeks. All fetuses with hydrops had hemoglobin values of less than 3.8 g/dL as well as plasma protein concentrations less than 2 standard deviations from the mean for normal fetuses of the same age. The hydropic fetuses also had substantive protein concentrations in ascitic fluid. Conversely,

all nonhydropic fetuses had hemoglobin values exceeding 4 g/dL; however, 6 of 10 had hypoproteinemia of the same magnitude as the hydropic fetuses. These investigators concluded that the degree and duration of anemia and resulting hypoxia most strongly influenced the severity of ascites, which is made worse by hypoproteinemia. They also hypothesized that the severe chronic anemia associated with tissue hypoxia actually causes capillary endothelial leakage with protein loss. [Weiner and co-workers \(1989\)](#) came to similar conclusions after their evaluation of umbilical venous pressure during 20 antenatal transfusions in isoimmunized pregnancies. They found that the fetuses with immune hydrops had significantly elevated pressures that normalized within 24 hours of the transfusion. This suggests that elevated pressure was due to hypoxic myocardial dysfunction and not to portal hypertension.

Fetuses with hydrops may die in utero from profound anemia and circulatory failure ([Fig. 39-9](#)). A sign of severe anemia and impending death is the sinusoidal fetal heart rate pattern shown in [Figure 39-7](#). The live-born hydropic infant appears pale, edematous, and limp at birth, often requiring resuscitation. The spleen and liver are enlarged, and there may be widespread ecchymosis or scattered petechiae. Dyspnea and circulatory collapse are common.

HYPERBILIRUBINEMIA. Less severely affected infants may appear well at birth, only to become jaundiced within a few hours. Marked hyperbilirubinemia, if untreated, may lead to *kernicterus*, a form of central nervous system damage that especially affects the basal ganglia. Anemia, in part resulting from impaired erythropoiesis, may persist for many weeks to months in the infant who had demonstrated hemolytic disease at birth. In the absence of hypoxia, erythrocyte production normally falls after birth, especially in the preterm infant.

MORTALITY. Perinatal deaths from hemolytic disease caused by D-isoimmunization have decreased dramatically because of administration of D-immune globulin to D-negative women during or immediately after pregnancy. Another reason is that the fetus who is most likely to be seriously affected can be treated by antenatal transfusions or be delivered preterm. In the province of Manitoba, the number of perinatal deaths from hemolytic disease decreased from 29 in 1964 to only 1 in 1975 ([Bowman and colleagues, 1977](#)). Similarly, [Fretts and colleagues \(1992\)](#) reviewed the changing patterns of fetal death in their tertiary care center from 1961 to 1988 and found that death from D-isoimmunization has also virtually disappeared.

IDENTIFICATION OF THE ISOIMMUNIZED PREGNANCY. With the exception of ABO incompatibility, which requires only neonatal treatment, the management of isoimmunization is the same regardless of the inciting antigen. The first step is identifying the woman at risk by performing a type and antibody screen at the first prenatal appointment during all pregnancies. Maternal serum antibodies are detected by the *indirect Coombs test*, because the anti-D antibodies are unbound and are absorbed to red cells only in the fetal circulation.

The fetus is evaluated by the *direct Coombs test*, as the anti-red cell antibodies produced by the mother are largely absorbed to the D-positive fetal erythrocytes. The absorbed antibodies act as hemolysins, leading to an accelerated rate of red cell destruction. The neonate also is evaluated with the direct Coombs test. Maternal antibodies detectable at birth gradually disappear from over a period of 1 to 4 months. If the fetal blood type has not been determined antenatally by invasive methods discussed subsequently, then the blood type is determined at birth but may yield inaccurate results. This is because neonatal red cells may be so thoroughly coated with anti-D antibody that D antigens are not detectable and the neonate is reported incorrectly to be D-negative.

If maternal red cell antibodies are present, they are identified and determined to be either IgG or IgM. Only IgG antibodies are of concern because IgM antibodies do not usually cross the placenta in amounts that cause fetal hemolysis. The antibody titer is quantified. If the antibodies are IgG and are known to cause fetal hemolytic anemia ([Table 39-9](#)), and if the titer is above a critical level, further evaluation is indicated. For anti-D antibodies, the titer below which the fetus will not die from hemolytic disease is usually 1:16, although this varies between laboratories. A titer equal to or higher than this *critical titer* indicates the possibility of severe hemolytic disease. This critical titer of 1:16 is often extrapolated to other antibodies, but there are insufficient data to support this. An example is anti-Kell antibody discussed earlier. Conversely, for less immunogenic antigens like c or E, the critical titer may be 1:32 or higher.

The presence of maternal anti-D antibodies does not necessarily mean that the fetus will be affected or is even D-positive. For example, the titer in a previously sensitized woman may rise to high levels during a subsequent pregnancy even though her fetus is D-negative—the *amnestic response*. Because half of D-positive white males are heterozygous for the D antigen, a fourth of all fetuses of women at risk will be D-negative ([Race, 1975](#)). Similarly, many women sensitized to atypical red cell antigens become immunized after a blood transfusion and not by exposure to their antigen-negative husband.

ESTIMATING FETAL GENOTYPE. Along with paternal blood type, the most likely arrangement of his CDE genes can be estimated—the *presumed genotype*. This provides a basis for predicting whether or not the father is a heterozygote and thus whether the fetus could be D-negative. The CDE blood group gene locus is located on chromosome 1p34-p36. One gene encodes the C/c and E/e proteins and a second gene encodes D—there is no "d" gene or gene product. The laboratory first identifies all CDE antigens made by the father, and then estimates his presumed genotype based on the most common arrangement of genes for those particular antigens in men of his race. Predicting the most likely gene arrangement is improved somewhat in that cross-overs rarely occur within this gene group. For example, if the father has antigens C, c, D, and e, he could either be homozygous for D (D,D) or heterozygous (D, "d"). If he is white, there is a 94 percent chance that the arrangement of these alleles is Cde/cde; that is, he has a 94 percent chance of being heterozygous for D and thus a 47 percent ($94 \div 2$) chance of having a D-negative fetus.

If the woman is sensitized to an atypical antigen, the paternal antigen type will determine whether the fetus is at risk. Before such testing is pursued, any possibility of nonpaternity must be disclosed, as testing the wrong father could be disastrous for the fetus.

MANAGEMENT OF ISOIMMUNIZATION. After identification of isoimmunization and the fetus potentially at risk, for optimal outcome, subsequent management is individualized. It is aided by the obstetrical history, with emphasis on fetal outcome(s). Fetal anemia from hemolytic disease tends to occur earlier and be more severe with every pregnancy. Accurate dating of pregnancy is essential. If below the critical titer, maternal antibody measurements are repeated at timely intervals. If these exceed the critical titer, then further evaluation is done by spectrophotometric analysis of amniotic fluid or analysis of fetal blood.

If the results of evaluation of all these factors is that the fetus is likely to be anemic, it must be tested and therapy provided as appropriate. Early studies showed that if no treatment is given for the sensitized D-negative women with a D-positive fetus, the perinatal mortality rate is about 30 percent ([Freda, 1973](#)). With aggressive management, including diagnostic amniocentesis or studies performed on fetal blood obtained by cordocentesis, repeated ultrasound examinations, and intrauterine transfusions in selected cases, the perinatal mortality rate is lowered remarkably ([Harman and co-workers, 1983](#); [Queenan and colleagues, 1993](#)).

AMNIONIC FLUID EVALUATION. When fetal blood cells undergo hemolysis, breakdown pigments, mostly bilirubin, are present in the supernatant of amniotic fluid. The amount of amniotic fluid bilirubin correlates roughly with the degree of hemolysis and thus indirectly predicts the severity of the fetal anemia. Because these bilirubin concentrations are so low (compared with serum), its concentration is measured by a continuously recording spectrophotometer and is demonstrable as a change in absorbance at 450 nm, referred to as ?OD_{450} ([Fig. 39-10](#)). The likelihood that the fetus is anemic is determined by plotting the ?OD_{450} on a graph originated by [Liley \(1961\)](#), who compared ?OD_{450} measurements with fetal outcome in 101 isoimmunized pregnancies ([Fig. 39-11](#)).

Subsequent studies have correlated the zones of the Liley graph with fetal hemoglobin concentration. Optical density values in zone 1 generally indicate a D-negative fetus or one who will only have mild disease. In zone 2, the fetus is at moderate to severe risk; in lower zone 2, the expected fetal hemoglobin concentration is between 11.0 and 13.9 g/dL, whereas in upper zone 2, the anticipated hemoglobin level ranges from 8.0 to 10.9 g/dL. Values in zone 3 indicate a severely affected fetus with a hemoglobin level less than 8.0 g/dL, and without therapy, death within 7 to 10 days may be expected.

Values in zone 3 demand immediate fetal red blood cell transfusion or delivery. Values in zones 1 or 2 should be followed by a repeat sampling in 1 to 2 weeks, and the trend of the two values used to estimate the severity of the hemolytic process. For pregnancies in which the trend of samples forms a line parallel to the lines on the graph or decreasing within the zone, thus indicating an unaffected fetus or a stable process, amniocentesis is repeated at 2- to 3-week intervals until either transfusion or delivery are required ([American College of Obstetricians and Gynecologists, 1990](#)). Pregnancies in which the process is unstable, that is, those in which the trend of ?OD_{450} values is rising within zone 2 or has risen into zone 3, require immediate evaluation followed by transfusion or delivery as indicated. Vaginal delivery as close to term as possible, without subjecting the fetus to excess high-risk procedures, is always the goal.

EXPANDED LILEY GRAPH. Because of the age of viability contemporaneous to those times, the Liley graph only included pregnancies from 27 to 41 weeks. As the age of viability decreased, and because isoimmunized fetuses are at risk of being severely anemic well before 27 weeks, management was originally planned by extrapolation of the Liley curve back to 18 to 20 weeks. This subsequently was found to be inaccurate, because prior to 25 weeks, bilirubin concentration is normally higher and amniotic fluid ?OD_{450} results do not accurately predict the fetal hemoglobin level ([Nicolaidis and colleagues, 1986](#)).

These findings led to development of modified Liley curves for pregnancies before 27 weeks. [Queenan and colleagues \(1993\)](#) examined 845 amniotic fluid samples from 75 D-immunized and 520 unaffected pregnancies and constructed a Liley-type curve that begins at 14 weeks. This is shown in [Figure 39-12](#), and there is a large "indeterminate" zone in which values do not accurately predict fetal hemoglobin concentration. For these reasons, many clinicians forego amniocentesis in favor of

fetal blood sampling when evaluation indicates there is likely to be severe fetal anemia or hydrops before 25 weeks.

FETAL BLOOD SAMPLING. Cordocentesis is used for obtaining fetal blood. The technique for this invasive procedure is discussed in [Chapter 37 \(p. 991\)](#). Its risks exceed those of amniocentesis. For a while, some clinicians used cordocentesis primarily to evaluate all isoimmunized pregnancies, regardless of gestational age. This was because fetal blood sampling had the added advantages of determination of blood type. Advances in molecular genetic techniques now allow the fetal D-antigen type to be determined from amniocytes in amniotic fluid ([Bennett and associates, 1993](#)). This is invaluable, especially for pregnancies in which the father is a presumed heterozygote, and thus the fetus could be D-negative. In these cases, a single amniocentesis for fetal D typing and ?OD_{450} measurement may be the only invasive test needed. [Van Den Veyver and colleagues \(1996\)](#) reported 100 percent accuracy using this procedure in 112 of 114 amniotic fluid samples. [Yankowitz and co-workers \(1997\)](#) evaluated 765 adult blood samples and reported that this procedure had 99.7 percent sensitivity and 94 percent specificity. Several reference laboratories are now able to analyze amniocytes for the E, c, Kell, and Cellano antigens as well.

When the ?OD_{450} measurement indicates the possibility of fetal anemia, ultrasonography reveals fetal hepatomegaly or hydrops, or fetal testing indicates physiological stress, either fetal transfusion or delivery must be performed. As discussed earlier, cordocentesis is also a consideration for fetuses likely to be affected before 27 weeks. Cordocentesis allows determination of the fetal hemoglobin and hematocrit, as well as the reticulocyte count and indirect Coombs titer ([Weiner and associates, 1991a](#)).

[Nicolaidis and co-workers \(1988\)](#) recommend that transfusions be commenced when the hemoglobin is at least 2 g/dL below the mean for normal fetuses of corresponding gestational age ([Fig. 39-13](#)). Others perform transfusions when the fetal hematocrit is below 30 percent, which is 2 SD below the mean at all gestational ages ([Weiner and co-workers, 1991b](#)). Intraperitoneal and intraumbilical blood transfusions are discussed in [Chapter 37 \(p. 993\)](#).

SUBSEQUENT CHILD DEVELOPMENT. According to [Bowman \(1978\)](#), the great majority of fetal transfusion survivors developed normally. When 89 of these children were tested at 18 months of age or older, 74 were completely normal, four were abnormal, and development in the other 11 appeared somewhat delayed, perhaps because of preterm birth.

OTHER METHODS TO MINIMIZE FETAL HEMOLYSIS. In an attempt to prevent D-antibody formation, to remove antibody already formed, or to block antibody action on the red cell, a number of techniques have been tried without consistent success. Plasmapheresis does not appear to provide benefits that outweigh the risks and the costs. Promethazine in large doses has been cited by some as being beneficial; however, this remains unproven ([Charles and Blumenthal, 1982](#)). D-positive erythrocyte membrane in enteric-coated capsules has been administered orally to sensitized women throughout pregnancy. It was hoped that such treatment might induce T-suppressor cell formation that would in turn reduce antibody response to challenges by the antigen. Unfortunately, this approach also does not appear to provide any benefit ([Gold and co-workers, 1983](#)). Attempts at immunosuppression with corticosteroids have also proven to be of no benefit.

DELIVERY. Vaginal delivery at or near term is the goal of management. Whether serial amniotic fluid ?OD_{450} measurement or intrauterine transfusions are being performed, the pregnancy is usually closely monitored with tests of fetal well being described in [Chapter 40](#). Their initiation is determined by history as well as severity in the current pregnancy. Gestational age is usually the most important consideration in choosing which treatment option to pursue. The very immature fetus may benefit from intrauterine resuscitation by transfusions, while the fetus near term should be delivered. Fortunately, with careful monitoring and transfusions when appropriate, very early preterm delivery can usually be avoided.

In carefully monitored cases, labor can be induced as soon as pulmonary maturity is documented. The severely compromised fetus, however, may benefit from cesarean delivery. The time of birth is set and the most experienced personnel can be assembled to provide for optimal treatment. Scheduling of labor induction could have similar advantages.

EXCHANGE TRANSFUSION IN THE NEWBORN. Cord blood analysis should be carried out immediately for any pregnancy in which the D-negative mother is known to be sensitized. Cord blood hemoglobin concentration and direct Coombs test are of considerable importance when the infant is D-positive. If the infant is overtly anemic, it is often best to carry out the initial exchange promptly to correct anemia. Type O, D-negative red cells, recently collected, are used. For infants who are not overtly anemic, the need for exchange transfusion is determined by the rate of increase in bilirubin concentration, the maturity of the infant, and the presence of other complications. Because close neonatal monitoring is required, delivery should be at a center familiar with management of this disease.

PREVENTION. Anti-D immunoglobulin is a 7S immune globulin G extracted by cold alcohol fractionation from plasma containing high-titer D-antibody. Each dose provides not less than 300 ug of D-antibody as determined by radioimmunoassay. It is given to the D-negative nonsensitized mother to prevent the hazards of sensitization described above.

[Freda and co-workers \(1975\)](#) summarized their 10 years of clinical experience with D-immune globulin, confirming their original observations that such globulin given to the previously unsensitized D-negative woman within 72 hours of delivery is highly protective. Any pregnancy-related events that could result in fetal-maternal hemorrhage require D-immune globulin prophylaxis ([Table 39-8](#)). Anti-D immune globulin should be provided to D-negative women after miscarriage, abortion, or evacuation of a molar or ectopic pregnancy. Up to 2 percent of women with a spontaneous abortion and 5 percent of those undergoing elective termination become isoimmunized without D-immune globulin. [Blajchman and co-workers \(1974\)](#) reported detectable fetal-maternal hemorrhage after 6 percent of amniocenteses. [Boucher and associates \(1996\)](#) documented hemorrhage following external cephalic version.

ROUTINE ANTEPARTUM ADMINISTRATION. In addition to the previously described situations, anti-D immune globulin is also given prophylactically to all D-negative women at about 28 weeks ([American College of Obstetricians and Gynecologists, 1999b](#)). It is again given after delivery if the infant is D-positive. [Bowman and Pollock \(1978\)](#) showed that without such prophylaxis, 1.8 percent of D-negative women will become isoimmunized during pregnancy as the consequence of spontaneous silent fetal-maternal hemorrhages remote from delivery. They administered 300 ug of antibody intramuscularly at 28 weeks, at 34 weeks, and if the infant was D-positive, again after delivery. This program was followed by a reduction in the incidence of D-isoimmunization during pregnancy from 1.8 percent to 0.07 percent. Subsequently, they showed that a single dose at about 28 weeks was almost as effective as were the two doses antepartum. Indeed, only 2 of 1799 D-negative women developed D-isoimmunization despite antenatal prophylaxis.

The half life of immune globulin is 24 days, and titers decrease with time. The initial dose of 300 ug will produce a weakly positive (1:1 to 1:4) indirect Coombs titer. If an amniocentesis is performed or uterine bleeding occurs more than 3 weeks after the 28-week prophylactic dose, but before delivery, a second dose of 300 ug will protect the mother against a hemorrhage of up to 15 mL of D-positive red cells, or 30 mL of fetal blood. The small amount of antibody that crosses the placenta results at times in a weakly positive direct Coombs test in cord and infant blood. If the positive Coombs test is due to D-immune globulin, there is no evidence of anemia or exaggerated hyperbilirubinemia.

Some patients express concern that the human immunodeficiency virus or other viruses may be transmitted by plasma-derived products such as anti-D immunoglobulin. The risk of this is very low because individuals who are antibody or antigen positive for various hepatitis viruses are excluded from blood donation, and the human immunodeficiency virus is inactivated by the manufacturing process ([Centers for Disease Control, 1987](#); [Misbah and Chapel, 1993](#)).

D-negative women who receive blood or blood fractions are also at risk of becoming sensitized. Red cell and platelet transfusions and plasmapheresis can provide sufficient D-antigen to cause sensitization, which can be prevented by an injection of D-antiglobulin. [Freda \(1973\)](#), as well as [Bowman \(1985\)](#), emphasize that **when there is doubt about whether to give anti-D immune globulin, then it should be given.**

LARGE FETAL-TO-MATERNAL HEMORRHAGE. In the case of a large fetal-maternal hemorrhage, one dose of D-immune globulin may not be sufficient to neutralize the transfused fetal cells. [Bowman \(1985\)](#) estimated the incidence of excessive fetal-maternal bleeding sufficient so as not to be neutralized by one dose of immune globulin to be 1 in 1250 deliveries. [Ness and colleagues \(1987\)](#), however, provided different data regarding this incidence. Using the enzyme-linked antiglobulin test, they studied almost 800 D-negative mothers giving birth to D-positive infants, and found evidence in 1 percent of the mothers for fetal-maternal bleeding in excess of 30 mL. Another 5.6 percent of these pregnancies had fetal-maternal hemorrhage of between 11 and 30 mL. Thus, at least 1 percent, and perhaps more, of susceptible mothers would have been given insufficient immune globulin if not tested. Importantly, they determined that if extra D-immune globulin is only considered for women with risk factors such as abdominal trauma, placental abruption, placenta previa, intrauterine manipulation, multiple gestation, or manual removal of the placenta, that half of women requiring more than the 300 ug dose would be missed. They thus recommended that all women be tested at delivery with the Kleihauer-Betke or rosette test. [Stedman and co-workers \(1986\)](#), utilizing the erythrocyte rosette test, reported similar results. The dosage of anti-D immunoglobulin is calculated as described on page 1066. The fetal red cell volume is divided by 15, which is the volume that one 300-mg ampule will neutralize.

D^u ANTIGEN. The identification of the D^u antigen in a maternal blood type often causes confusion. Most laboratories designate this blood type as "weak D-positive." The D^u antigen is a variant of the D antigen. The woman confirmed to be D^u-positive does not need immune globulin ([American College of Obstetricians and](#)

[Gynecologists, 1999b](#)). Maternally detected D^u antigen (rarely) indicates the transfer of D^u-positive fetal cells into a D-negative mother. [Bowman \(1985\)](#) cites only five instances in 750,000 pregnancies in which a D^u-positive mother produced anti-D antibody. Fortunately, in none of these was the fetus severely affected. If the maternal blood type is known to be D^u-positive before conception, most authorities would treat her as D-positive, and if a D-negative woman delivers a D^u-positive infant, she should be given D-immune globulin. As before, if there is any doubt about D-antigen status, then globulin should be given.

MATERNAL-TO-FETAL HEMORRHAGE. Rarely, the D-negative fetus is exposed in utero to D antigen from the mother and becomes sensitized as a result. When such a female fetus becomes an adult, she will produce anti-D antibodies indicating sensitization even before or early in her first pregnancy. This mechanism of isoimmunization is called the "grandmother theory" because the fetus in the current pregnancy is jeopardized by antibodies initially provoked by its grandmother's blood. This accounts for very few cases of D sensitization. Major blood group (ABO) incompatibility offers appreciable protection against D-sensitization. Furthermore, maternal-fetal hemorrhage is uncommon. [Jennings and Clauss \(1978\)](#) and [Bowman \(1985\)](#), on the basis of their extensive studies, do not recommend D-immune globulin prophylaxis for D-negative babies born to D-positive mothers.

HYPERBILIRUBINEMIA

DISPOSAL OF BILIRUBIN. Unconjugated or free bilirubin is readily transferred across the placenta from fetal to maternal circulation—and vice versa, if the maternal plasma level of unconjugated bilirubin is high. Bilirubin glucuronide is water soluble and normally excreted into the bile by the liver and into the urine by the kidney when the plasma level is elevated. Conversely, unconjugated bilirubin is not excreted in the urine or to any extent in the bile.

KERNICTERUS. The great concern over unconjugated hyperbilirubinemia in the newborn, especially the preterm neonate, is its association with kernicterus. Yellow staining of the basal ganglia and hippocampus by bilirubin is indicative of profound degeneration in these regions. Surviving infants show spasticity, muscular incoordination, and varying degrees of mental retardation. There is a positive correlation between kernicterus and unconjugated bilirubin levels above 18 to 20 mg/dL, although kernicterus may develop at much lower concentrations, especially in very preterm infants.

Factors other than the serum bilirubin concentration contribute to the development of kernicterus. Hypoxia and acidosis enhance bilirubin toxicity. Both hypothermia and hypoglycemia predispose the infant to kernicterus by raising the level of nonesterified fatty acids, which compete with bilirubin for binding sites on albumin and inhibit bilirubin conjugation. Sepsis contributes to kernicterus, although the mechanism is not clear. Although it is extremely unlikely that they lead to kernicterus, sulfonamides and salicylates may increase the level of bilirubin because they compete with unconjugated bilirubin for protein-binding sites. Sodium benzoate, in injectable diazepam, furosemide, and gentamicin, displaces bilirubin from albumin. Excessive doses of vitamin K analogs may be associated with hyperbilirubinemia. The importance of the serum albumin concentration and the binding sites so provided is obvious.

BREAST MILK JAUNDICE. Jaundice in breast-fed infants has been attributed to the excretion of pregnane-3 α ,20 β -diol into breast milk. This steroid was reported by [Arias and colleagues \(1964\)](#) to block bilirubin conjugation by inhibiting glucuronyl transferase activity. Breast milk samples from mothers of infants with hyperbilirubinemia have been described to have an unusually high lipolytic activity and to liberate large quantities of fatty acids that inhibit bilirubin conjugation ([Foliot and co-workers, 1976](#)). Another explanation is that bilirubin is broken down in the intestine to form free bilirubin, which can be reabsorbed. Usually, bovine and human milk appear to block the reabsorption of free bilirubin, whereas the milk of mothers with jaundiced offspring does not, and may even enhance its reabsorption. With breast milk jaundice, the serum bilirubin level rises from about the fourth day after birth to a maximum by 15 days. If breast feeding is continued, the high levels persist for another 10 to 14 days and slowly decline over the next several weeks. No cases of overt bilirubin encephalopathy have been reported as a result of this phenomenon ([Maisels, 1979](#)).

PHYSIOLOGICAL JAUNDICE. By far the most common form of unconjugated nonhemolytic jaundice is so-called physiological jaundice. In the mature infant, the serum bilirubin increases for 3 to 4 days to achieve serum levels up to 10 mg/dL or so and then falls rapidly. In preterm infants, the rise is more prolonged and may be more intense.

TREATMENT. Phototherapy is now widely used to treat hyperbilirubinemia. By some unknown mechanism, light seems to promote hepatic excretion of unconjugated bilirubin. In most instances, its use leads to oxidation of bilirubin resulting in a lower bilirubin level. Light that penetrates the skin also increases peripheral blood flow, which further enhances photo-oxidation. As much surface area as possible should be exposed, and the infant should be turned every 2 hours with close temperature monitoring to prevent dehydration. The fluorescent bulbs must be appropriate wavelength and the eyelids should be closed and completely shielded from light. Serum bilirubin should be monitored for at least 24 hours after discontinuance of phototherapy. Rarely, exchange transfusion is required.

NONIMMUNE HYDROPS FETALIS

Hydrops is defined by the presence of excess fluid in two or more body areas, such as thorax, abdomen, or skin, and is usually associated with hydramnios and placental thickening. Because ultrasound examination has become routine, hydrops is identified frequently and the etiology is often discovered. [Santolaya and colleagues \(1992\)](#) reviewed ultrasound studies performed in 12,572 pregnant women and identified hydrops in 0.6 percent. The etiology was determined in 77 percent of cases ([Fig. 39-14](#)). Similarly, [Heinonen and colleagues \(2000\)](#) reported a hydrops incidence of 1 in 1700, of which the etiology was discovered in 95 percent.

ETIOLOGY. A variety of pathogenic mechanisms can lead to hydrops. **Cardiac abnormalities**, either structural, rhythm related, or both are associated with 20 to 45 percent of cases of nonimmune hydrops ([Allan, 1986](#); [Castillo, 1986](#); [Gough, 1986](#); [Santolaya, 1992](#), and their co-workers). **Fetal heart failure** can also result from infection leading to myocarditis or hepatitis. Approximately 35 percent of cases of hydrops are due to **chromosomal anomalies** or other **malformations**. [Shulman and colleagues \(2000\)](#) have reported that chromosomal abnormalities are commonly associated with *space suit hydrops*—dramatic and extensive subcutaneous hydrops recognized in the first trimester. Of 30 such fetuses less than 14 weeks, 87 percent had an aneuploidy, of which over half involved sex chromosomes. About 10 percent of hydrops cases are associated with **twin-to-twin transfusion syndrome** ([Chap. 30, p. 785](#)). Usually the recipient twin develops heart failure from volume overload, or the donor twin develops hydrops after the death of the recipient. Hydrops can also be caused by **severe anemia** such as might occur with parvovirus infection, acute fetal-maternal hemorrhage, or α -thalassemia ([American College of Obstetricians and Gynecologists, 1999a](#)). **Inborn errors of metabolism** such as Gaucher disease, GM 1 gangliosidosis, or sialidosis can cause recurrent hydrops ([Lefebvre and colleagues, 1999](#)). Rarely, an **anomalous lymph system** can result in lymph accumulating to cause chylothorax or chylous ascites.

The great variety of causes of hydrops were tabulated by [Holzgreve and associates \(1984\)](#) and are presented in [Table 39-10](#). The precise incidence of these various causes of hydrops is unclear, and varies according to the sophistication of the evaluation and the population studied. For example, the San Francisco group, with a large Asian population, reported a 10 percent incidence of hydrops caused by α -thalassemia ([Holzgreve and colleagues, 1984](#)).

PROGNOSIS. The outcome for hydrops caused by any of these mechanisms is poor. [McCoy and colleagues \(1995\)](#) reviewed 82 cases of nonimmune hydrops attributed to cardiovascular abnormalities (23 percent), aneuploidy (16 percent), thoracic anomalies (13 percent), genetic syndromes (11 percent), anemia and infection (9 percent), twin-to-twin transfusion (6 percent), and idiopathic causes (22 percent). The mortality rate for hydrops before 24 weeks was 95 percent. Fetuses with hydrops who survived to at least 24 weeks, and who had no congenital heart defect and were euploid, had a survival rate of 20 percent.

DIAGNOSIS. Ultrasound evaluation may provide a diagnosis. Depending on circumstances, maternal blood analysis might include hemoglobin electrophoresis, Kleihauer-Betke smear, indirect Coombs, and serological tests for syphilis, toxoplasmosis, cytomegalovirus, rubella, and parvovirus B-19. Cordocentesis is considered for karyotyping, hemoglobin concentration and electrophoresis, liver transaminases, and serological testing for IgM-specific antibodies to infectious agents. In view of the data from [McCoy and associates \(1995\)](#) described previously, a fetal echocardiogram and karyotype analysis may be the most important elements of the evaluation in predicting prognosis for fetuses still alive after 24 weeks.

MANAGEMENT. In a few cases, depending on the cause of hydrops, treatment is available. Some cardiac arrhythmias can be treated pharmacologically, severe anemia due to fetal-maternal hemorrhage or parvovirus infection can be treated with blood transfusions, and hydrops of one fetus in twin-to-twin transfusion syndrome may resolve with therapeutic amniocentesis ([Chap. 30, p. 788](#)). Because most lesions associated with these syndromes ultimately prove fatal for the fetus or newborn, however, treatment is often not possible. In general, when hydrops persists, cardiac abnormalities and aneuploidy have been ruled out, and if the fetus is mature enough that survival is likely, then delivery should be accomplished. Very preterm fetuses usually are managed expectantly. Although hydrops usually persists or worsens with time, it occasionally resolves spontaneously ([Mueller-Heubach and Mazer, 1983](#)).

MATERNAL COMPLICATIONS. A unique complication of hydrops is the so-called maternal **mirror syndrome** ([Midgley and Hardrug, 2000](#)). Believed to be caused by vascular changes in the swollen hydropic placenta, it is called the mirror syndrome because the mother develops preeclampsia with severe edema similar to the fetus. This type of preeclampsia may develop early and (rarely) may be resolved with fetal treatment. [Duthie and Walkinshaw \(1995\)](#) described a woman with parvovirus-associated fetal hydrops and severe preeclampsia whose hypertension receded at 25 weeks when fetal transfusion reversed the fetal hydrops. In most

cases, however, treatment is not possible and thus delivery is necessary. Preterm labor is common because of hydramnios. Postpartum hemorrhage sometimes occurs as the result of sudden decompression of an overdistended uterus, and retained placenta is common.

FETAL CARDIAC ARRHYTHMIAS

Recognition of fetal cardiac rhythm disturbances has become more common because of extensive use of real-time ultrasound technology. Whereas most of these arrhythmias are transient and benign, some tachyarrhythmias, if sustained, can result in congestive heart failure, nonimmune hydrops, and fetal death. Sustained bradycardia, although less often associated with hydrops, may signify underlying cardiac pathology that includes structural lesions or autoimmune myocarditis.

[Kleinman and associates \(1985\)](#) summarized their experience with fetal arrhythmias ([Table 39-11](#)). Premature atrial contractions accounted for 63 percent of cases. Fortunately, this arrhythmia is benign, related to immaturity, and usually resolves with further fetal development. Rarely this rhythm converts to a sustained supraventricular tachycardia. If the rate is more than 200 beats/min, it may cause cardiac failure, and thus requires treatment as discussed in [Chapter 37 \(p. 994\)](#).

The prognosis for the fetus with bradycardia is less promising. Bradycardia typically results from a major structural abnormality such as complete atrial-ventricular canal, or from heart block. [Taylor and colleagues \(1986\)](#) demonstrated that half of the mothers of children with congenital heart block have antibodies to fetal myocardial tissue. Anti-SS-A (anti-Ro) antibody is one of the most common, and appears to bind to the conduction tissue. Unfortunately, tissue inflammation provoked by these antibodies leads to permanent damage, and survivors frequently require a pacemaker at birth.

Fetal cardiac antigens to which anti-SS-A affixes are not confined to the conduction system, and if there is extensive myocarditis, the prognosis is poor. Many of these women have, or subsequently develop, lupus erythematosus or another connective-tissue disease. Anti-SS-A actually causes fetal heart block in the minority, and only 1 in 20 fetuses born to women positive for this antibody have cardiac disease ([Chap. 52, p. 1389](#)). Of seven affected infants described by [Ramsey-Goldman and colleagues \(1986\)](#), three died within 9 months, two required permanent pacemakers, and two underwent cardiac surgery. Only one infant had no problems. Fetal therapy in the form of maternal corticosteroid ingestion has been reported ([Chua and colleagues, 1991](#); [Finkelstein and associates, 1997](#)).

[Cameron and associates \(1988\)](#) and [Shenker and colleagues \(1987\)](#) reported that fetal cardiac anomalies are common with heart block in the absence of connective-tissue disease. They recommend fetal echocardiography and consideration for karyotyping.

HEMORRHAGIC DISEASE OF THE NEWBORN

This is a disorder of the newborn characterized by spontaneous internal or external bleeding accompanied by hypoprothrombinemia and very low levels of other vitamin K-dependent coagulation factors (V, VII, IX, and X). Bleeding may begin any time after birth but is typically delayed for a day or two. The infant may be mature and healthy in appearance, although there is a greater incidence of the disease in preterm infants.

The prothrombin and partial thromboplastin times are greatly prolonged. Causes other than vitamin K deficiency include hemophilia, congenital syphilis, sepsis, thrombocytopenia purpura, erythroblastosis, and intracranial hemorrhage.

Hypoprothrombinemia appears to be the consequence of poor placental transport of vitamin K₁ to the fetus. Plasma vitamin K₁ levels are somewhat lower in pregnant women than in nonpregnant adults, and it is not clear to what extent vitamin K crosses the placenta. [Shearer and associates \(1982\)](#) gave 1 mg of vitamin K₁ intravenously to mothers shortly before delivery and showed that maternal plasma levels were remarkably raised, but cord plasma levels still were very low. However, [Pomerance and colleagues \(1987\)](#) reported that prothrombin activity was improved in preterm neonates whose mothers were given intramuscular vitamin K₁ during labor.

The main cause of hemorrhagic disease of the newborn from vitamin K deficiency appears to be a dietary deficiency of vitamin K as the consequence of ingesting solely breast milk, which contains only very small amounts of the vitamin. [Keenan and colleagues \(1971\)](#) showed that the prothrombin time 24 hours after the start of feedings with cow milk is comparable to that found 24 hours after vitamin K administration, whereas in infants fed with human milk it remains prolonged.

Vitamin K-dependent clotting factors may also be reduced in infants of mothers taking anticonvulsant drugs ([Mountain and associates, 1970](#)). These drugs apparently have a mechanism similar to warfarin and act by depressing hepatic synthesis of several coagulation factors (VII, IX, and X). Like warfarin, anticonvulsant-induced vitamin K deficiency may produce a phenotype similar to that of *chondrodysplasia punctata* ([Chap. 38, p. 1014](#)). This is also called *Conradi-Hunermann syndrome* and is an inherited bony dystrophy resulting in typical facial abnormalities ([Howe and colleagues, 1995](#)).

PROPHYLAXIS. Hemorrhagic disease of the newborn can be avoided by the intramuscular injection of 1 mg of vitamin K₁ (phytonadione) at delivery. For treatment of active bleeding, it is injected intravenously.

THROMBOCYTOPENIA

The differential diagnosis of neonatal thrombocytopenia is provided in [Table 39-12](#). Thrombocytopenia tends to be more severe in preterm fetuses, especially those with respiratory distress and hypoxia or sepsis.

IMMUNE THROMBOCYTOPENIA. Rarely, antiplatelet IgG is transferred from the mother to cause thrombocytopenia in the fetus-neonate. The most severe cases are usually due to alloimmune thrombocytopenia, discussed next, but this disorder can also be found in association with maternal autoimmune disease, especially immune thrombocytopenia. Maternal thrombocytopenia therapy consists of corticosteroids, which increase maternal platelet levels; however, such treatment generally does not affect fetal thrombocytopenia. A detailed discussion of management and perinatal outcomes is presented in [Chapter 49 \(p. 1324\)](#).

ALLOIMMUNE (ISOIMMUNE) THROMBOCYTOPENIA (ATP). This type of thrombocytopenia differs from immunological thrombocytopenia in several important ways. Because it is caused by maternal isoimmunization to fetal platelet antigens in a manner similar to D-antigen isoimmunization (see p. 1057), the maternal platelet count is always normal. Thus, alloimmunization is not suspected until after the birth of an affected child. Another important difference is that the fetal thrombocytopenia associated with ATP is frequently severe. It thus can cause fetal intracranial hemorrhage. The incidence of ATP is reported to be from 1 in 5000 to 1 in 10,000 live births ([Nicolaides and Snijders, 1992](#); [Silver and colleagues, 2000](#)).

Fetal thrombocytopenia follows maternal isoimmunization usually against fetal platelet antigens HPA-1a, which is found in 98 percent of the population. Thus, the mother lacks the common platelet antigen and becomes immunized when exposed to the antigen by fetal platelets that enter the maternal circulation. Based on the incidence of HPA-1a negativity, 1 in 50 pregnancies is at risk. The rarity of the condition results from the fact that fetal-maternal hemorrhage significant enough to provoke an immune response must occur. The disease primarily affects offspring of women with HLA type DR-3 or B-8 ([Reznikoff-Etievant and colleagues, 1983](#)).

The diagnosis often can be made correctly on clinical grounds if the mother has a normal platelet count with no evidence of any immunological disorder, and her infant has thrombocytopenia without evidence of other disease. Fetal thrombocytopenia recurs in 70 to 90 percent of subsequent pregnancies ([Silver and associates, 2000](#)). It is often severe and occurs earlier with each successive pregnancy. Most clinicians document recurrent fetal thrombocytopenia by cordocentesis followed by maternally administered intravenous immunoglobulin in massive doses ([Chap. 37, p. 991](#)).

PREECLAMPSIA AND ECLAMPSIA. Neonatal thrombocytopenia has been suggested by some to result from preeclampsia-eclampsia. In a large number of infants born to women with pregnancy-induced hypertension at Parkland Hospital, however, [Pritchard and colleagues \(1987\)](#) identified no cases in which neonatal thrombocytopenia correlated with maternal thrombocytopenia ([Chap. 24, p. 577](#)).

POLYCYTHEMIA AND HYPERVISCOSITY

Several conditions predispose to neonatal polycythemia and blood hyperviscosity. These include chronic hypoxia in utero and placental transfusion from a twin or, much more rarely, from the mother. As the hematocrit rises above 65, blood viscosity markedly increases. Signs and symptoms include plethora, cyanosis, and neurological aberrations. Laboratory findings include hyperbilirubinemia, thrombocytopenia, fragmented erythrocytes, and hypoglycemia. Treatment consists of lowering the hematocrit by partial exchange transfusion with plasma.

NECROTIZING ENTEROCOLITIS

This bowel disorder commonly presents with clinical findings of abdominal distention, ileus, and bloody stools. There is usually radiological evidence of *pneumatosis intestinalis* caused by intestinal wall gas as the consequence of invasion by gas-forming bacteria and bowel perforation. Abdominal distention or blood in the stools may signal developing enterocolitis. At times it is so severe that bowel resection is necessary.

The disease is primarily seen in low-birthweight infants, but occasionally is encountered in mature neonates. Various causes have been suggested, including perinatal hypotension, hypoxia, or sepsis, as well as umbilical catheters, exchange transfusions, and the feeding of cow milk and hypertonic solutions ([Kliegman and Fanaroff, 1984](#)). The disease tends to occur in clusters, and coronaviruses have been suspected of having an etiological role. [Kanto and colleagues \(1987\)](#) reported that 5.7 percent of 2123 preterm infants developed necrotizing enterocolitis. The incidence of the disease was related to birthweight, but not to other perinatal factors. They concluded that gastrointestinal immaturity and not ischemia is the major causative factor for necrotizing enterocolitis. Orally administered immunoglobulin was shown to prevent enterocolitis when given to preterm infants ([Eibl and associates, 1988](#)).

FETAL DEATH

From the foregoing sections, it is apparent that a number of maternal and fetal conditions may result in fetal demise. With advances in obstetrics, clinical genetics, maternal-fetal and neonatal medicine, and perinatal pathology, a number of stillbirths which had previously been categorized as "unexplained" can now be attributed to specific causes. Because of this information, management of subsequent pregnancy is made easier. An advantage of the common use of ultrasound technology is the ease with which the suspicion of fetal death is confirmed. Conversely, because the diagnosis can be verified immediately, labor induction in a woman with an unfavorable cervix has become a problem ([Chap. 20, p. 470](#)).

DEFINITION OF FETAL MORTALITY

The National Center for Health Statistics and the [American College of Obstetricians and Gynecologists \(1995b\)](#) recommend that statistics of perinatal outcomes include only those dead fetuses and neonates born weighing 500 g or more. As shown in [Figure 39-15](#), stillbirths are much more common with decreasing gestational age. According to [Copper and colleagues \(1994\)](#), almost 80 percent of all stillbirths occur before term, and more than half are before 28 weeks.

Along with the decline in stillbirth rate over the past five decades, the pattern of causes of stillbirths has changed appreciably. [Fretts and colleagues \(1992\)](#) reviewed causes of 709 stillbirths among almost 89,000 deliveries at the Royal Victoria Hospital in Montreal. The fetal death rate per 1000 births decreased from 11.5 in the 1960s to 5.1 in the 1980s. The fetal death rate due to lethal anomalies declined by almost half between the 1970s and 1980s, from 10.8 to 5.4 per 10,000 births. This was because deaths of infants with anomalies were replaced by early pregnancy terminations. The more common recognized causes of fetal death through the 1980s included infection, malformations, fetal growth restriction, and abruptio placentae. More than a fourth of all fetal deaths during the 1980s were still unexplained, although in the previously cited Montreal study, this category diminished from 38.1 to 13.6 per 10,000 births.

CAUSES OF FETAL DEATH

There are many explanations for fetal death which generally can be categorized as fetal, placental, or maternal causes. In the past, a definable cause could not always be assigned and there was only mild enthusiasm for necropsy. Currently, however, it is recognized that a fetal autopsy performed by a pathologist with expertise in fetal and placental disorders, assisted by a team including maternal-fetal medicine, genetics, and pediatric specialists, often determines the cause of death ([Craven and colleagues, 1990](#)). [Faye-Peterson and associates \(1999\)](#) reviewed 139 fetal autopsies performed by such a team, and found that autopsy determined the cause of death in 94 percent. Some causes of fetal death or stillbirth determined by autopsy are shown in [Table 39-13](#).

FETAL CAUSES. Up to 25 to 40 percent of stillbirths have fetal causes. In a carefully defined population of stillborn infants referred to the Wisconsin Stillbirth Service Program, [Pauli and Reiser \(1994\)](#) found that 25 percent of 789 deaths could be ascribed to fetal problems, while [Fretts and Usher \(1997\)](#) attributed 35 to 40 percent of 278 fetal deaths to fetal causes. These included anomalies, infections, malnutrition, nonimmune hydrops, and anti-D isoimmunization.

The reported incidence of **major congenital malformations** in stillborns is highly variable, and depends on whether a necropsy was performed and, if so, the experience and training of the person performing it ([Cartledge and co-workers, 1995](#)). [Pauli and Reiser \(1994\)](#) reported that the vast majority of 193 stillborns attributed to fetal causes had a major malformation to explain fetal death. Conversely, in a study of 403 stillbirths reported by [Copper and colleagues \(1994\)](#), without information from fetal autopsies, malformations were identified (prenatally) in only 5.6 percent. [Faye-Peterson and colleagues \(1999\)](#) found that a third of fetal deaths were caused by structural anomalies, of which neural-tube defects, hydrops, isolated hydrocephalus, and complex congenital heart disease were the most common. Major structural anomalies, hydrops, and aneuploidy are particularly amenable to antenatal diagnosis.

The incidence of stillbirths caused by **fetal infection** appears to be remarkably consistent. From five studies totaling 2676 stillbirths, 5.6 percent were attributed to infection ([Cartledge, 1995](#); [Copper, 1994](#); [Fretts, 1992](#); [Lammer, 1989](#), and all of their colleagues; [Pauli and Reiser, 1994](#)). Most were diagnosed as "chorioamnionitis," and some as "fetal or intrauterine sepsis." In indigent and inner-city women, congenital syphilis is another common cause of fetal death. For example, 6.3 percent of the stillbirths at Parkland Hospital from 1988 to 1995 were attributable to syphilis. Other potentially lethal infections include cytomegalovirus, parvovirus B-19, rubella, varicella, and listeriosis.

PLACENTAL CAUSES. The causes of fetal death due to placental abnormalities shown in [Table 39-13](#) are somewhat arbitrary. For example, placental abruption is associated with pregnancy-induced hypertension in about half of cases; thus, such cases could be classified as "maternal causes." This is also true for placental insufficiency due to chronic hypertensive diseases and antiphospholipid antibodies. With these caveats in mind, approximately 15 to 25 percent of fetal deaths are attributed to problems of the placenta, membranes, or cord ([Alessandri and colleagues, 1992](#); [Fretts and Usher, 1997](#)).

Placental abruption is the most common single identifiable cause of fetal death (also see [Chap. 25, p. 621](#)). [Fretts and Usher \(1997\)](#) determined this to be the cause of death in 14 percent of 278 stillborns. Our experiences are similar, and 12 percent of third-trimester stillbirths in over 40,000 deliveries at Parkland Hospital from 1992 through 1994 were the consequence of placental abruption.

Clinically significant **placental and membrane infection** rarely occurs in the absence of significant fetal infection. Some exceptions perhaps are tuberculosis and malaria. In some cases, microscopic examination of the placenta and membranes may help to identify an infectious cause. Chorioamnionitis is characterized by mononuclear and polymorphonuclear leukocytes infiltrating the chorion. While many consider these findings to be nonspecific and not always associated with fetal or maternal infection, [Benirschke and Kaufmann \(2000\)](#) believe that microscopic chorioamnionitis is always due to infection ([Chap. 31, p. 814](#)).

Placental infarcts show fibrinoid trophoblastic degeneration, calcification, and ischemic infarction from spiral artery occlusion ([Chap. 32, p. 829](#)). Other common lesions are marginal and subchorionic infarcts. [Fox \(1978\)](#) found that a fourth of placentas from uncomplicated term deliveries have infarcts. When there is severe hypertension, two thirds of placentas are so involved.

Fetal-maternal hemorrhage can be of such severity as to induce fetal death. [Samadi and associates \(1996\)](#) analyzed 319 fetal deaths at Los Angeles County Women's Hospital in which Kleihauer-Betke stains of maternal blood had been performed. Massive fetal-maternal hemorrhage was found in 4.7 percent. With severe maternal trauma, life-threatening fetal-maternal hemorrhage may be encountered ([Chap. 43, p. 1173](#)). Finally, twin-to-twin transfusion is a common cause of fetal death in monochorionic multifetal pregnancy ([Chap. 30, p. 785](#)).

MATERNAL CAUSES. Perhaps surprisingly, maternal disorders make only a small contribution to fetal deaths. This is true partially because placental abruption has been designated a "placental cause." Hypertensive disorders and diabetes are the two most commonly cited maternal diseases associated with 5 to 8 percent of stillborn infants ([Alessandri and colleagues, 1992](#); [Fretts and Usher, 1997](#)).

Lupus anticoagulant and anticardiolipin antibodies are associated with decidual vasculopathy, placental infarction, fetal growth restriction, recurrent abortion, and fetal death ([Chap. 52, p. 1412](#)). While women with these autoantibodies clearly are at increased risk for adverse pregnancy outcomes, the contribution to otherwise unexplained stillbirths is minimal ([Haddow and co-workers, 1991](#); [Infante-Rivard and associates, 1991](#)).

Recently, hereditary thrombophilias have been associated with placental abruption, fetal growth restriction, and stillbirths. These disorders are discussed in detail in [Chapter 49 \(p. 1330\)](#).

UNEXPLAINED STILLBIRTHS. With careful assessment of the clinical course, meticulous examination of the fresh stillborn, and appropriate laboratory investigations including necropsy, only about 10 percent of fetal deaths will remain unclassified. The difficulty of assessing the cause of fetal death appears to be greatest in preterm

infants ([Yudkin and colleagues, 1987](#)).

EVALUATION OF THE STILLBORN INFANT

It is important to try to determine the cause of fetal death. First, the psychological adaptation to a significant loss may be eased by knowledge of a specific etiology. Second, it may help to assuage the guilt that is part of grieving. Most importantly, appropriate diagnosis makes counseling regarding recurrence more accurate and may allow therapy or some intervention to prevent a similar outcome in the next pregnancy. Identification of inherited syndromes also provides useful information for other family members.

CLINICAL EXAMINATION. A thorough examination of the infant, placenta, and membranes should be performed at delivery. This information may aid in subsequent determination of the etiology. The checklist used at Parkland Hospital to format the stillbirth note is outlined in [Table 39-14](#).

GENETIC EVALUATION. If autopsy and chromosomal studies are performed when indicated, up to 35 percent of stillborn infants are discovered to have congenital structural anomalies ([Faye-Peterson and associates, 1999](#); [Mueller and colleagues, 1983](#)). As many as 8 percent of stillbirths have chromosomal abnormalities, and about 20 percent have dysmorphic features or skeletal abnormalities ([Pauli and Reiser, 1994](#); [Saller and colleagues, 1995](#)). It is probably not cost effective to perform cytogenetic analyses in all stillbirths. Instead, the [American College of Obstetricians and Gynecologists \(1996\)](#) recommends consideration of cytogenetic studies for infants with dysmorphic features, inconsistent growth measurements, anomalies, hydrops, or growth restriction. Such studies might also be considered in cases in which absolutely no other explanation for the loss is found. Another indication is a parent who is a carrier for a balanced translocation, a mosaic chromosomal pattern, or a history of recurrent losses or stillbirths in first-degree relatives.

Appropriate consent must be obtained to take skin and other tissue samples, including fluid obtained by needle postmortem. A total of 3 mL of fetal blood, obtained from the umbilical cord (preferably) or by cardiac puncture, is placed into a sterile, heparinized (green top) tube for cytogenetic studies. Skin samples with attached dermal tissue should measure 1 cm² and be washed with sterile saline prior to placement in saline or sterile cytogenetic medium. Placement in formalin or alcohol prohibits cytogenetic analysis because the cells must remain alive for study. If the skin is macerated, 1-cm² samples of fascia should be obtained from the thigh, inguinal region, or Achilles tendon. Because a traditional cytogenetic study requires that fetal cells be stimulated to divide, it may not be possible in cases with prolonged intrauterine retention. However, fluorescent in situ hybridization (FISH) might be used to rule out trisomies or to look for certain common deletions such as DiGeorge syndrome.

AUTOPSY. As autopsy rates for adults have decreased, so have those for stillborns. Patients should be counseled that, even if they do not allow a full autopsy to be performed, valuable information can still be obtained from limited studies. [Mueller and colleagues \(1983\)](#) demonstrated the importance of gross autopsy for stillbirths. This, along with photography, radiography, bacterial cultures, and selective use of more expensive procedures such as chromosomal and histopathological studies can often determine the cause of death.

[Cartlidge and Stewart \(1995\)](#) performed a cohort analysis of 400 consecutive fetal deaths in Wales and found that the clinicopathological classification was altered by necropsy in 13 percent. New information was obtained in another 26 percent. Thus, autopsy provided important information in almost 40 percent of stillborns. [Faye-Peterson and colleagues \(1999\)](#) reported that autopsy results changed the recurrence risk estimates and parental counseling in 26 percent of cases. Similar findings were reported by [Saller and associates \(1995\)](#).

If the family refuses autopsy because of personal or religious objections, valuable information can still be obtained noninvasively. With appropriate permission, x-rays are performed to evaluate the bony skeleton, and high-resolution magnetic resonance imaging can be considered to evaluate soft tissue, depending on the degree of maceration. The fetus should be photographed to facilitate evaluation by a dysmorphologist, and if indicated, bacterial cultures should be taken from the ear canal ([Brookes and colleagues, 1996](#)).

STILLBORN PROTOCOL. The protocol shown in [Table 39-14](#) includes a systematic review of all stillbirths. A detailed note should be written regarding prenatal events, and the infant, placenta, and membranes should be carefully examined and pertinent positive and negative findings recorded. Autopsy, either complete (preferably) or limited, is encouraged. Samples are sent for cytogenetic analysis in case of fetal malformation, multiple pregnancy losses, or growth restriction, to name a few. Other laboratory evaluations include fetography and maternal blood for Kleihauer-Betke staining, testing for antiphospholipid antibodies and lupus anticoagulant if indicated, and serum glucose to exclude overt diabetes.

In many centers, maternal records and autopsy findings are reviewed on a monthly basis by a Stillbirth Committee composed of maternal-fetal medicine and neonatology fellows and faculty, clinical geneticists, and perinatal pathologists. If possible, the cause of death is assigned based on available evidence. Most importantly, parents should then be contacted and offered counseling regarding the cause of death, the recurrence risk, if any, and strategies to avoid recurrence in future pregnancies.

PSYCHOLOGICAL ASPECTS

Fetal death is a psychologically traumatic event for the woman and her family. [Radestad and colleagues \(1996\)](#) found that an interval of more than 24 hours from the diagnosis of fetal death to the induction of labor was related to excessive anxiety. Other factors included when the woman did not see her infant for as long as she wished and when she had no tokens of remembrance. The woman experiencing a stillbirth is at increased risk for postpartum depression and should be closely monitored ([Chap. 53, p. 1421](#)).

Even early miscarriage may provoke depression in as many as a third of women ([Neugebauer, 1992](#)). [Janssen and colleagues \(1996\)](#) prospectively followed 227 women who had a pregnancy loss and 213 control women who had a live birth for 18 months. Up to 6 months after pregnancy loss, women with stillborns showed greater depression, anxiety, and somatization than control women. Fortunately, the mental health of these women improved over time and at one year was comparable with that of women who had live births. During the study period, only 3 percent of the women were given psychotherapy. Importantly, [Hughes and associates \(1999\)](#) showed vulnerability to depression and anxiety during the next pregnancy. This risk diminished with time, and they recommended an interval of 12 months before conception.

MANAGEMENT OF WOMEN WITH A PREVIOUS STILLBIRTH

A woman with a prior stillbirth has long been accepted to be at increased risk for adverse outcomes in subsequent pregnancies. Fortunately, however, there are very few conditions associated with recurrent stillbirth. Other than hereditary disorders, only maternal conditions such as diabetes, chronic hypertension, or hereditary thrombophilia increase risk of recurrence.

RISKS. Several studies have cited rates of recurrent stillbirth to range from 0 to 8 percent, depending on the specific population studied ([Freeman, 1985](#); [Samueloff, 1993](#); [Weeks, 1995](#), and their colleagues). Earlier pregnancy losses, although not technically all stillborns, are associated with subsequent adverse outcomes. [Goldenberg and colleagues \(1993\)](#) identified 95 women who had a pregnancy loss at 13 to 24 weeks. Almost 40 percent of these had a preterm delivery in their next pregnancy, 5 percent had a stillbirth, and 6 percent had a neonatal death. Knowledge of the cause of fetal death allows a more precise individual recurrence risk to be calculated. For example, aneuploidy generally has a 1 percent recurrence risk, familial DiGeorge syndrome has a 50 percent recurrence, while a cord accident would not be expected to recur.

PRENATAL EVALUATION. If the cause of the previous stillbirth can be ascertained, then risk for the current pregnancy may be quantified. In general, with proper treatment infectious causes would be unlikely to recur. If there was a previous stillbirth with an abnormal karyotype or polygenic cause, then chorionic villous sampling or amniocentesis could facilitate early detection and allow termination to be considered. Maternal medical disorders associated with prior stillborns will likely be easily identified. Although early studies demonstrated a reduction in fetal death in women with treated chronic hypertension, a randomized trial by [Sibai and colleagues \(1990\)](#) showed no reduction. Importantly, placental abruption is often associated with chronic hypertension, and [Pritchard and colleagues \(1991\)](#) demonstrated an abruption recurrence rate of 10 percent.

With diabetes, a significant portion of perinatal mortality is attributable to congenital anomalies. Intensive glycemic control in the periconceptional period has been shown to reduce the incidence of malformations and generally improve outcome ([Chap. 51, p. 1369](#)). Such control requires that the pregnancy be planned, and lack of planning may account for the fact that unexplained losses still account for half of stillborns of diabetic mothers ([Hanson and Persson, 1993](#)).

There is some evidence that recurrent fetal loss due to antiphospholipid antibodies can be decreased with treatment ([Chap. 52, p. 1390](#)). In women who have an

unexplained fetal loss in the second trimester, we usually test for antiphospholipid antibodies. Conversely, such testing is not recommended for the woman with a normally grown, unexplained third-trimester stillborn.

MANAGEMENT. There are few studies that address management of the woman who has suffered a prior fetal death. In a report from the University of California at Irvine, [Freeman \(1985\)](#) and colleagues evaluated the significance of a prior stillbirth in women followed with fetal heart rate testing. In 5 percent of women referred for evaluation, prior stillbirth was the indication for testing. None of these women had a recurrent stillbirth. Those with a prior stillbirth, however, were more likely to have a positive contraction stress test than the other women. This difference was primarily accounted for by women with hypertension (12 percent) or those suspected of having fetal growth restriction (17 percent). Importantly, offspring of women with prior stillbirths had an increased incidence of respiratory distress syndrome compared with those of women tested for other reasons. This suggests that early delivery was performed empirically in women with a prior stillbirth.

The Irvine group later conducted a nonconcurrent cohort study of women with a prior stillbirth as the only indication for antepartum testing ([Weeks and colleagues, 1995](#)). There was only one recurrent stillbirth among 300 study patients. Interestingly, there was no relationship between the gestational age of the previous stillborn and the incidence or timing of abnormal tests or fetal distress in the subsequent pregnancy. Only three women had an abnormal antepartum test at less than 32 weeks, and they were subsequently delivered without incident at term. These investigators concluded that antepartum surveillance should begin at 32 weeks or later in the otherwise healthy woman with a history of stillbirth. This agrees with recommendations of the [American College of Obstetricians and Gynecologists \(1999a\)](#).

INJURIES OF THE FETUS AND NEWBORN

Considered here are several varieties of birth injuries. Others are described elsewhere in connection with specific obstetrical complications that led to or contributed to the injury.

INTRACRANIAL HEMORRHAGE

Hemorrhage within the head of the fetus-infant may be located at any of several sites: subdural, subarachnoid, cortical, white matter, cerebellar, intraventricular, and periventricular. A classification is shown in [Table 39-15](#). Intraventricular hemorrhage into the germinal matrix is the most common type of intracranial hemorrhage encountered, and as discussed on page 1045, it usually is a result of immaturity or an antepartum cerebrovascular accident. Isolated intraventricular hemorrhage in the absence of subarachnoid or subdural bleeding is not a traumatic injury. [Hayden and colleagues \(1985\)](#) reported that nearly 4 percent of otherwise normal newborns at term have sonographic evidence for subependymal germinal matrix hemorrhages unrelated to obstetrical factors.

Birth trauma is no longer a common cause of intracranial hemorrhage. The head of the fetus has considerable plasticity and may undergo appreciable molding during passage through the birth canal. The skull bones, the dura mater, and the brain itself permit considerable alteration in the shape of the fetal head without untoward results. The dimensions of the head are changed, with lengthening especially of the occipitofrontal diameter of the skull ([Fig. 39-16](#)). With severe molding and marked overlap of the parietal bones, bridging veins from the cerebral cortex to the sagittal sinus may tear. Less common is rupture of the internal cerebral veins, the vein of Galen at its junctions with the straight sinus, or the tentorium itself. Compression of the skull can stretch the tentorium cerebelli and may tear the vein of Galen or its tributaries.

[Illingworth \(1979\)](#) observed that because of superficial thinking, obstetricians have been blamed unjustifiably for causing brain damage and other injuries, the genesis of which was not limited just to difficulties during labor and delivery, but actually involved prenatal factors, including those that were genetic and environmental in nature. Nonetheless, the elimination of difficult forceps operations and appropriate management of breech delivery have contributed significantly to a reduction in the incidence of all birth injuries, including intracranial hemorrhage. It must be emphasized that intracranial hemorrhage often occurs following an apparently uneventful vaginal delivery.

As discussed in detail in [Chapter 21 \(p. 501\)](#), it has been well documented that low or outlet forceps or vacuum delivery do not lead to an increased incidence of intracranial hemorrhage or other neonatal injury ([American College of Obstetricians and Gynecologists, 2000](#); [Hagadorn-Freathy and associates, 1991](#); [Yancy and colleagues, 1991](#)). In a series of predominantly low pelvic operative deliveries, [Williams and associates \(1991\)](#) found no cases of intraventricular hemorrhage with forceps and vacuum delivery. The spectrum of subgaleal and bone injury encountered in 23 infants undergoing vacuum delivery had been described by [Govaert and co-workers \(1992\)](#). The use of pliable as opposed to rigid vacuum cups has been associated with less neonatal scalp trauma ([Kuit and associates, 1993](#)).

CLINICAL FINDINGS. According to [Volpe \(1995\)](#), there are few clinical neurological data available concerning infants suffering intracranial hemorrhage from mechanical injury. With subdural hemorrhage from tentorial tears and massive infratentorial hemorrhage, there is neurological disturbance from the time of birth. Severely affected infants—usually those weighing more than 4000 g—have stupor or coma, nuchal rigidity, and opisthotonus. Over minutes to hours, these problems worsen. Some infants are born depressed, but appear to improve until about 12 hours of age. Then drowsiness, apathy, feeble cry, pallor, failure to nurse, dyspnea, cyanosis, vomiting, and convulsions may become evident.

Subarachnoid hemorrhage most commonly is minor with no symptoms, but seizures with a normal interictal period may manifest. In some there is catastrophic deterioration. Head scanning using sonography, computed tomography, or magnetic resonance imaging not only had proven diagnostic value but has also contributed appreciably to an understanding of the etiology and frequency of some forms of intracranial hemorrhage ([Perlman and Cunningham, 1993](#)). For example, periventricular and intraventricular hemorrhages occur often in infants born quite preterm and these hemorrhages usually develop without birth trauma.

CEPHALOHEMATOMA

A cephalohematoma usually is caused by injury to the periosteum of the skull during labor and delivery, although it may also develop in the absence of birth trauma. The incidence is 2.5 percent, according to the 10-year review by [Thacker and colleagues \(1987\)](#). Hemorrhages may develop over one or both parietal bones. The periosteal limitations with definite palpable edges differentiate the cephalohematoma from caput succedaneum ([Fig. 39-17](#)). The caput, also shown in [Figure 39-16](#), consists of a focal swelling of the scalp from edema that overlies the periosteum. Furthermore, a cephalohematoma may not appear for hours after delivery, often growing larger and disappearing only after weeks or even months. In contrast, caput succedaneum is maximal at birth, grows smaller, and usually disappears within a few hours if small, and within a few days if very large.

Increasing size of the hematoma and other evidence of extensive hemorrhage are indications for additional investigation, including radiographic studies and assessment of coagulation factors.

NERVE INJURIES

SPINAL INJURY. Overstretching the spinal cord and associated hemorrhage may follow excessive traction during a breech delivery, and there may be actual fracture or dislocation of the vertebrae. [Menticoglou and associates \(1995\)](#) described 15 neonates with a high cervical spinal cord injury and found that all were associated with forceps rotations.

BRACHIAL PLEXUS INJURY. These injuries are relatively common and are encountered in between 1 in 500 to 1 in 1000 term births ([Boo and colleagues, 1991](#); [Salonen and Uusitalo, 1990](#)). In a review of over 21,500 live births, [Oppenheim and colleagues \(1990\)](#) reported 58 clavicular fractures (2.7 per 1000), three of which were associated with Erb palsy. Increasing birthweight and breech deliveries are significant risk factors and are discussed in detail in [Chapter 29 \(p. 760\)](#).

Duchenne, or *Erb paralysis* is incorrectly thought to occur only with large infants with shoulder dystocia. In reality, only 30 percent of brachial plexus injuries occur in macrosomic infants ([Walle and Hartikainen-Sorri, 1993](#)). These neurological lesions involve paralysis of the deltoid and infraspinatus muscles, as well as the flexor muscles of the forearm, causing the entire arm to fall limply close to the side of the body with the forearm extended and internally rotated. The function of the fingers usually is retained. The lesion likely results from stretching or tearing of the upper roots of the brachial plexus. Because lateral head traction is frequently employed to effect delivery of the shoulders in normal vertex presentations, Erb paralysis can result without the delivery appearing to be difficult. As emphasized by [Sandmire and DeMott \(2000\)](#), however, the propulsive efforts of delivery may actually cause nerve stretching with damage. [Ubachs and colleagues \(1995\)](#) described 130 infants who underwent surgical treatment for brachial plexus injuries. Most cases that involved C₅₋₆ nerve roots were associated with breech delivery, whereas more extensive forms—involving C₅₋₇ or C_{5-T₁} roots—followed difficult cephalic deliveries.

Less frequently, trauma is limited to the lower nerves of the brachial plexus, which leads to paralysis of the hand, or *Klumpke paralysis*.

As discussed in [Chapter 29](#), risk factors for shoulder dystocia are common and nonspecific. [Nocon and associates \(1993\)](#), after an analysis of over 12,000 vaginal

deliveries, concluded:

Most of the traditional risk factors for shoulder dystocia have no predictive value; shoulder dystocia itself is an unpredictable event and infants at risk for permanent injury are virtually impossible to predict. In addition, no delivery method in shoulder dystocia was superior to another with respect to injury.

FACIAL PARALYSIS. The incidence likely is influenced by the vigor with which it is sought. For example, [Levine and colleagues \(1984\)](#) reported facial nerve injury in 7.5 per 1000 term births. [White and associates \(1996\)](#) reported 27 cases of facial nerve palsy in 18,500 deliveries for an incidence of 1.4 per 1000. [Salonen and Uusitalo \(1990\)](#) observed only one case of facial nerve palsy in over 14,000 live births.

Facial paralysis may be apparent at delivery or it may develop shortly after birth ([Fig. 39-18](#)). It is seen with delivery of an infant in which the head has been seized obliquely with forceps. The injury is caused by pressure exerted by the posterior blade of the forceps on the stylomastoid foramen, through which the facial nerve emerges. Facial marks from the forceps may be obvious ([Fig. 39-19](#)). The condition is also encountered after spontaneous delivery. [White and associates \(1996\)](#) observed that only 18 percent of facial nerve palsies were associated with forceps delivery and that the majority followed spontaneous vaginal or cesarean delivery. [Levine and co-workers \(1984\)](#) reported that a third of cases followed spontaneous delivery. Spontaneous recovery within a few days is the rule ([Fig. 39-17](#)). [Galbraith \(1994\)](#) described an increase in injuries to the sixth cranial nerve with resultant lateral rectus paralysis following operative vaginal delivery.

SKELETAL AND MUSCLE INJURIES

FRACTURES. *Clavicular fractures* are surprisingly common if a careful search is made. They have been identified in up to 18 per 1000 live births ([Oppenheim and colleagues, 1990](#); [Salonen and Uusitalo, 1990](#); [Turpenny and Nimmo, 1993](#)). [Chez and colleagues \(1994\)](#) reported an incidence of 9 per 1000 vaginally delivered newborns and were unable to identify any specific factor that could be changed to avoid such fractures. [Roberts and associates \(1995\)](#) identified 215 clavicular fractures in infants born to nearly 65,000 women at Parkland Hospital for an incidence of 3.3 per 1000 deliveries. Both of these latter investigators concluded that clavicular fracture was an unpredictable and unavoidable complication of normal birth.

Humeral fractures are less common. Difficulty encountered in the delivery of the shoulders in cephalic deliveries and extended arms in breech deliveries often produce such fractures. Up to 70 percent of cases, however, follow uneventful delivery ([Turpenny and Nimmo, 1993](#)). Upper extremity fractures associated with delivery are often of the greenstick type, although complete fracture with overriding of the bones may occur. Palpation of the clavicles and long bones should be performed on all newborns when a fracture is suspected, and any crepitation or unusual irregularity should prompt radiographic examination.

Femoral fractures are relatively uncommon and usually associated with breech delivery.

Skull fracture may follow forcible attempts at delivery, especially with forceps, spontaneous delivery, or even cesarean section ([Saunders and colleagues, 1979](#); [Skajaa and associates, 1987](#)). In the radiograph shown in [Figure 39-20](#), a focal, but marked, depressed skull fracture is apparent. Labor was characterized by vigorous contractions, full dilatation of the cervix, and arrest of descent of the head, which was tightly wedged in the pelvis. The fracture was the consequence of compression of the skull against the sacral promontory of the mother, or perhaps from pressure from an assistant's hand in the vagina or as the head was pushed upward out of the birth canal at cesarean delivery. Surgical decompression was successful.

MUSCULAR INJURIES. Injury to the sternocleidomastoid muscle may occur, particularly during a breech delivery. There may be a tear of the muscle or possibly of the fascial sheath, leading to a hematoma and gradual cicatricial contraction. As the neck lengthens in the process of normal growth, the head is gradually turned toward the side of the injury, because the damaged muscle is less elastic and does not elongate at the same rate as its normal contralateral counterpart, thus producing *torticollis*. [Roemer \(1954\)](#) reported that 27 of 44 infants showing this deformity had been delivered by breech or internal podalic version. He postulated that lateral hyperextension sufficient to rupture the sternocleidomastoid may occur as the aftercoming head passes over the sacral promontory.

CONGENITAL INJURIES

AMNIONIC BAND SYNDROME. Focal ring constrictions of the extremities and actual loss of a digit or a limb are rare complications. Their genesis is debated. [Streeter \(1930\)](#), and others since, maintain that localized failure of germ plasm usually is responsible for the abnormalities. [Torpin \(1968\)](#) and others contend that the lesions are the consequence of early rupture of the amnion, which then forms adherent tough bands that constrict and at times actually amputate an extremity of the fetus. Occasionally, the amputated part may be found within the uterus.

CONGENITAL POSTURAL DEFORMITIES. Mechanical factors arising from chronically low volumes of amniotic fluid and restrictions imposed by the small size and inappropriate shape of the uterine cavity may mold the growing fetus into distinct patterns of deformity, including talipes or clubfoot ([Fig. 37-9](#), p. 989), scoliosis, and hip dislocation ([Miller and co-workers, 1981](#)). Hypoplastic lungs also can result from oligohydramnios ([Chap. 31, p. 822](#)).

TABLE 39-1. Effects of Surfactant Treatment in Infants with Respiratory Distress Syndrome or at High Risk for the Disease

Surfactant and Strategy	Percent Change in Incidence ^a (incidence in untreated infants)		
	<i>Pneumothorax</i>	<i>Bronchopulmonary Dysplasia</i>	<i>Death by Day 28</i>
Synthetic surfactant			
Delivery-room prophylaxis	-34 (15)	+ 7 (18)	-30 (24)
Treatment of disease	-33 (22)	-30 (8)	-34 (14)
Natural surfactant			
Delivery-room prophylaxis	-64 (23)	-6 (44)	-39 (18)
Treatment of disease	-58 (31)	-0 (38)	-31 (29)

^a Percentages were calculated from the total numbers of patients studied in the trials that served as the basis for each meta-analysis.

From Soll (1991a, 1991b, 1991c, 1991d). Data compiled by Jobe (1993) and includes 35 randomized controlled trials. Used with permission.

TABLE 39-3. Outcomes in 6-Month Survivors Born at 23 to 25 Weeks

Outcome	Gestational Age at Birth		
	23 Weeks (n = 6)	24 Weeks (n = 19)	25 Weeks (n = 31)
	Mean ± SD		
Mechanical ventilation (days)	60 ± 29	51 ± 42	24 ± 19
Oxygen administration (days)	89 ± 40	81 ± 48	52 ± 33
Age oxygen discontinued (week)	36 ± 6	36 ± 7	32 ± 5
Length of stay (days)	120 ± 23	107 ± 37	76 ± 23
	Percent		
Retinopathy of prematurity	83	53	32
Intraventricular hemorrhage			
Any	83	74	32
Grade III	7	11	10
Grade IV	33	32	0
Periventricular leukomalacia	33	21	3
Severe abnormality on cranial ultrasonography	83	64	13

TABLE 39-4. Prenatal and Perinatal Risk Factors in Children with Cerebral Palsy

Risk Factors	Risk Ratio	95% CI
Long menstrual cycle (> 36 days) ^a	9.0	2.2-37.1
Hydramnios ^a	6.9	1.0-49.3
Premature placental separation ^a	7.6	2.7-21.1
Intervals between pregnancies < 3 months or > 3 years	3.7	1.0-4.4
Birthweight < 2000 g ^a	4.2	1.8-10.2
Breech, face, or transverse lie ^a	3.8	1.6-9.1
Severe birth defect ^a	5.6	8.1-30.0
Nonsevere birth defect	6.1	3.1-11.8
Time-to-cry more than 5 min ^a	9.0	4.3-18.8
Low placental weight ^a	3.6	1.5-8.4

^a Also associated with cerebral palsy in the Collaborative Perinatal Project (Nelson and Ellenberg, 1985, 1986a, 1986b).

TABLE 39-15. Major Types of Intracranial Hemorrhage in the Newborn

Type	Gestational Age	Incidence and Severity	Cause(s) and Pathogenesis
Subdural	Term > Preterm	Uncommon Serious	Venous tears Trauma common
Primary subarachnoid	Preterm > term	Common Benign	Trauma—term "Hypoxia"—preterm
Intracerebellar	Preterm > term	Uncommon Serious	Multifactorial
Intraventricular	Preterm	Common	Thin-walled vessels of germinal matrix Multifactorial causes
Miscellaneous	Term > preterm	Uncommon	Trauma, hemorrhagic infarction, coagulopathy, vascular defect, ECMO

ECMO = extracorporeal membrane oxygenation.

Data from Volpe (1995).

FIGURE 39-4.

Preterm infant delivered at 27 weeks because of placental abruption. **A.** Head ultrasound performed on the first postnatal day shows small bilateral cysts in the periventricular white matter and bilateral germinal-matrix hemorrhages. These findings indicate a much older lesion than one caused by perinatal asphyxia. **B.** Repeat ultrasound of same infant on day 3 of life showed bilateral intraventricular hemorrhage and a large intraparenchymal echodensity on the right. (Courtesy of Dr. Jeffrey Perlman.)

SECTION XI - TECHNIQUES USED TO ASSESS FETAL HEALTH

40. Antepartum Assessment

The rate of foetal heart is subject to considerable variations which afford us a fairly reliable means of judging as to the well-being of the child. As a general rule, its life should be considered in danger when the heart-beats fall below 100 or exceed 160.

J. Whitridge Williams

The preceding statement is the only comment on judging fetal well-being in the 1903 first edition of *Williams Obstetrics*. At that time, the mother was the patient for whom care was given, and the fetus was simply a transient maternal organ. During the past two decades, remarkably intimate knowledge of the fetus along with technological developments have prompted a new phenomenon in medicine: forecasts of fetal health. The fetus is now a second patient, who faces greater risks of serious morbidity and mortality than the mother. The technological boundary for fetal assessment has even been extended to the embryonic period—for example, [Oasin and colleagues \(1997\)](#) found that embryonic heart rates may be predictive of pregnancy outcome!

In this chapter, the evolution of several techniques employed to forecast fetal well-being is considered. Focus is on contemporary testing procedures that depend upon fetal physical activities, including movement, breathing, amniotic fluid production, and heart rate. According to the [American College of Obstetricians and Gynecologists \(1999\)](#), the goal of antepartum fetal surveillance is to prevent fetal death. In most cases, a normal test result is highly reassuring since fetal deaths within 1 week of a normal test result are rare. Indeed, the negative predictive values (true negative test) for most of the tests described in this chapter are 99.8 percent or higher. In contrast, estimates of the positive predictive values (true positive test) for abnormal test results are quite low and range between 10 percent and 40 percent ([American College of Obstetricians and Gynecologists, 1999](#)). Importantly, the widespread use of antepartum fetal surveillance is primarily based on circumstantial evidence because there have been no definitive randomized clinical trials.

FETAL MOVEMENTS

Passive unstimulated fetal activity commences as early as 7 weeks and becomes more sophisticated and coordinated by the end of pregnancy ([Vindla and James, 1995](#)). Indeed, beyond 8 menstrual weeks, fetal body movements are never absent for time periods exceeding 13 minutes ([DeVries and co-workers, 1985](#)). Between 20 and 30 weeks, general body movements become organized and the fetus starts to show rest-activity cycles ([Sorokin and co-workers, 1982](#)). In the third trimester, fetal movement maturation continues until about 36 weeks, when behavioral states are established in 80 percent of normal fetuses. [Nijhuis and colleagues \(1982\)](#) studied fetal heart rate patterns, general body movements, and eye movements and described four fetal behavioral states:

- **State 1F** is a quiescent state (quiet sleep), with narrow oscillatory bandwidth of the fetal heart rate.
- **State 2F** includes frequent gross body movements, continuous eye movements, and wider oscillation of the fetal heart rate. This state is analogous to rapid eye movement (REM) or active sleep in the neonate.
- **State 3F** includes continuous eye movements in the absence of body movements and no accelerations of the heart rate. The existence of this state is disputed ([Pillai and James, 1990a](#)).
- **State 4F** is one of vigorous body movement with continuous eye movements and fetal heart rate accelerations. This state corresponds to the awake state in infants.

Fetuses spend most of their time in states 1F and 2F. For example, at 38 weeks, 75 percent of their time is spent in states 1F and 2F ([Nijhuis and colleagues, 1982](#)).

These behavioral states, particularly 1F and 2F, corresponding to quiet sleep and active sleep, have been used to develop an increasingly sophisticated understanding of fetal behavior. [Oosterhof and co-workers \(1993\)](#) studied fetal urine production in normal pregnancies in states 1F or 2F. As shown in [Figure 40-1](#), bladder volumes increased during quiet sleep (state 1F). During state 2F, the fetal heart rate baseline bandwidth increased appreciably, and bladder volume was significantly diminished. The latter occurred due to fetal voiding as well as decreased urine production. These phenomena were interpreted to represent reduced renal blood flow during active sleep.

An important determinant of fetal activity appears to be sleep-awake cycles, which are independent of the maternal sleep-awake state. "Sleep cyclicity" has been described to vary from about 20 minutes to as much as 75 minutes. [Timor-Tritsch and associates \(1978\)](#) reported that the mean length of the quiet or inactive state for term fetuses was about 23 minutes. [Patrick and associates \(1982\)](#) measured gross fetal body movements with real-time ultrasound for 24-hour periods in 31 normal pregnancies and found the longest period of inactivity to be 75 minutes. Amniotic fluid volume is another important determinant of fetal activity. [Sherer and colleagues \(1996\)](#) assessed the number of fetal movements in 465 pregnancies during biophysical profile testing (see p. 1104) in relation to amniotic fluid volume estimated using ultrasound. They observed decreased fetal activity with diminished amniotic volumes, and suggested that a restricted intrauterine space might physically limit fetal movements.

[Sadovsky and colleagues \(1979b\)](#) studied fetal movements in 120 normal pregnancies and classified the movements into three categories according to both maternal perceptions and independent recordings using piezoelectric sensors. Weak, strong, and rolling movements were described, and their relative contributions to total weekly movements throughout the last half of pregnancy were quantified. As pregnancy advances, weak movements decrease and are superseded by more vigorous movements, which increase for several weeks then subside at term. Presumably, declining amniotic fluid and intrauterine space account for diminishing activity at term. [Figure 40-2](#) shows fetal movements during the last half of gestation in 127 pregnancies with normal outcomes. The mean number of weekly movements calculated from 12-hour daily recording periods increased from about 200 at 20 weeks to a maximum of 575 movements at 32 weeks. Fetal movements then declined to an average of 282 at 40 weeks. Normal weekly counts of fetal movements ranged between 50 and 950, with large daily variations that included counts as low as 4 to 10 per 12-hour day in normal pregnancies.

CLINICAL APPLICATION OF FETAL MOVEMENT ASSESSMENT

Since [Sadovsky and Yaffe \(1973\)](#) described seven case reports of pregnancies with decreased fetal activity that preceded fetal death, there have been various methods described to quantify fetal movement to prognosticate well-being. Methods include use of a tocodynamometer, visualization with real-time ultrasound, and maternal subjective perceptions. Most investigators have reported excellent correlation between maternally perceived fetal motion and movements documented by instrumentation. For example, [Rayburn \(1980\)](#) found that 80 percent of all movements seen during ultrasonic monitoring were perceived by the mother. In contrast, [Johnson and colleagues \(1992\)](#) reported that beyond 36 weeks, mothers perceived only 16 percent of fetal body movements recorded by a Doppler device. Fetal motions lasting more than 20 seconds were identified more accurately by the mother than shorter episodes.

Although several fetal movement counting protocols have been used, neither the optimal number of movements nor the ideal duration for counting them has been defined. For example, in one method, perception of 10 fetal movements in up to 2 hours is considered normal ([Moore and Piaquadio, 1989](#)). In another, women are instructed to count fetal movements for 1 hour a day and the count is accepted as reassuring if it equals or exceeds a previously established baseline count ([Neldam, 1983](#)).

A particularly bothersome clinical situation occurs when women present in the third trimester with a chief complaint of subjectively reduced fetal movement. This is not uncommon, and [Harrington and colleagues \(1998\)](#) reported that 7 percent of 6793 women delivered at a London hospital presented with a complaint of decreased fetal movement. Fetal heart rate monitoring tests were employed if ultrasound scans for fetal growth or Doppler velocimetry were abnormal. The pregnancy outcomes for women who complained of decreased fetal movement were not significantly different than those of women without this complaint. Nonetheless, the authors recommended evaluation to reassure the mother.

[Grant and co-workers \(1989\)](#) performed an unparalleled investigation of maternally perceived fetal movements and pregnancy outcome. More than 68,000 pregnancies, regardless of risk category, were randomized between 28 and 32 weeks. Women in the fetal movement arm of the study were instructed by specially employed midwives to record the time needed to feel 10 movements each day. This required an average of 2.7 hours of counting time each day. Women in the control group were informally asked about movements during prenatal visits. Reports of decreased fetal motion were evaluated with tests of fetal well-being. Antepartum death rates for normally formed singletons were similar in the two study groups regardless of prior risk status. Despite the counting policy, most of the fetuses who

died were dead by the time the mothers received medical attention. Importantly, these investigators did not conclude that maternal perceptions of fetal activity were meaningless. Conversely, they concluded that informal maternal perceptions were as good as formally counted and recorded fetal movement.

FETAL BREATHING

After decades of uncertainty as to whether the fetus normally breathes, [Dawes and co-workers \(1972\)](#) showed small inward and outward flows of tracheal fluid indicating fetal thoracic movement in sheep. These chest wall movements differed from those following birth in that they were discontinuous. Another interesting feature of fetal respiration was *paradoxical chest wall movement*. As shown in [Figure 40-3](#), during inspiration the chest wall paradoxically collapses and the abdomen protrudes ([Johnson and co-authors, 1988](#)). In the newborn or adult, the opposite occurs. One interpretation of the paradoxical respiratory motion might be coughing to clear amniotic fluid debris. Although the physiological basis for the breathing reflex is not completely understood, such exchange of amniotic fluid appears to be essential for normal lung development.

Two types of respiratory movements have been identified: (1) *gasps (or sighs)*, which occurred at a frequency of 1 to 4 per minute; and (2) *irregular bursts of breathing*, occurring at rates up to 240 cycles per minute ([Dawes, 1974](#)). The latter rapid respiratory movements were associated with REM¹. [Badalian and co-workers \(1993\)](#) studied the maturation of normal fetal breathing using color flow and spectral Doppler analysis of nasal fluid flow as an index of lung function. They suggested that fetal respiratory rate decreased in conjunction with increased respiratory volume at about 33 to 36 weeks, coincidental with lung maturation.

Many investigators have examined fetal breathing movements utilizing ultrasound to determine whether monitoring chest wall movements might be of benefit to evaluate fetal health. Several variables in addition to hypoxia were found to affect fetal respiratory movements. These included labor—during which it is normal for respiration to cease—hypoglycemia, sound stimuli, cigarette smoking, amniocentesis, impending preterm labor, gestational age, and the fetal heart rate itself.

Because fetal breathing movements are episodic, interpretation of fetal health when respirations are absent may be tenuous. [Patrick and associates \(1980\)](#) performed continuous 24-hour observation periods using real-time ultrasonography in an effort to characterize fetal breathing patterns during the last 10 weeks of pregnancy. A total of 1224 hours of fetal observation was completed in 51 pregnancies. [Figure 40-4](#) shows the percentage of time spent breathing near term. Clearly, there is diurnal variation, because breathing substantively diminishes during the night. In addition, breathing activity increases somewhat following maternal meals. Total absence of breathing was observed in some of these normal fetuses for up to 122 minutes, indicating that fetal evaluation to diagnose absent respiratory motion may require long periods of observation.

The potential for breathing activity to be an important marker of fetal health is unfulfilled because of the multiplicity of factors that normally affect breathing. Most clinical applications have included assessment of other fetal biophysical indices, such as heart rate. More recently, as will be discussed, fetal breathing has become a component of the *biophysical profile*.

CONTRACTION STRESS TESTING

As amniotic fluid pressure increases with uterine contractions, myometrial pressure exceeds collapsing pressure for vessels coursing through uterine muscle, ultimately isolating the intervillous space. Brief periods of impaired oxygen exchange result, and if uteroplacental pathology is present, these elicit late fetal heart rate decelerations ([Chap. 14](#)). Uterine contractions may also produce a pattern of variable decelerations due to cord compression suggesting oligohydramnios, which is often a concomitant of placental insufficiency.

[Ray and colleagues \(1972\)](#) used this concept in 66 complicated pregnancies and developed what they termed the **oxytocin challenge test**, and later called the **contraction stress test**. Contractions were induced using intravenous oxytocin, and the fetal heart rate response was recorded using standard monitoring. The criterion for a positive (abnormal) test was uniform repetitive fetal heart rate decelerations. These reflected the uterine contraction waveform and had an onset at or beyond the acme of a contraction. Such late decelerations could be due to uteroplacental insufficiency. The tests were generally repeated on a weekly basis, and the investigators concluded that negative (normal) contraction stress tests forecast fetal health. One disadvantage cited was that the average contraction stress test required 90 minutes to complete.

Fetal heart rate and uterine contractions are simultaneously recorded with an external monitor. If at least three spontaneous contractions of 40 seconds or longer are present in 10 minutes, no uterine stimulation is necessary ([American College of Obstetricians and Gynecologists, 1999](#)). Contractions are induced with either oxytocin or nipple stimulation (see discussion that follows) if there are fewer than three in 10 minutes. If oxytocin is preferred, a dilute intravenous infusion is initiated at a rate of 0.5 mU/min and doubled every 20 minutes until a satisfactory contraction pattern is established ([Freeman, 1975](#)). The results of the contraction stress test are interpreted according to the criteria shown in [Table 40-1](#).

Nipple stimulation in lieu of oxytocin-induced uterine contractions has been reported to be usually successful for contraction stress testing ([Huddleston and associates, 1984](#)). One method recommended by the [American College of Obstetricians and Gynecologists \(1999\)](#) involves the woman rubbing one nipple through her clothing for 2 minutes or until a contraction begins. She is instructed to restart after 5 minutes if the first nipple stimulation did not induce three contractions in 10 minutes. Advantages include reduced cost and shortened testing times. Although [Schellpfeffer and associates \(1985\)](#) reported unpredictable uterine hyperstimulation with fetal distress, others did not find excessive nipple-stimulated induced uterine activity to be harmful ([Fragar and Miyazaki, 1987](#)).

NONSTRESS TESTING

[Freeman \(1975\)](#) and [Lee and colleagues \(1975\)](#) introduced the **nonstress test** to describe fetal heart rate acceleration in response to fetal movement as a sign of fetal health. This test involved the use of Doppler-detected fetal heart rate acceleration coincident with fetal movements perceived by the mother. By the end of the 1970s, the nonstress test had become the primary method of testing fetal health. The nonstress test was much easier to perform, and normal results were used to further discriminate false-positive contraction stress tests. Simplistically, the nonstress test is primarily a test of *fetal condition*, and it differs from the contraction stress test, which is a test of *uteroplacental function*. Currently, nonstress testing is the most widely used primary testing method for assessment of fetal well-being and has also been incorporated into the biophysical profile testing system (see later discussion).

PHYSIOLOGY OF FETAL HEART RATE ACCELERATION. Fetal heart rate is normally increased or decreased on a beat-to-beat basis by autonomic influences mediated by sympathetic or parasympathetic impulses from brainstem centers. Thus, fetal heart rate acceleration is believed to be an indication of fetal autonomic function. Beat-to-beat variability is also under the control of the autonomic nervous system ([Matsuura and colleagues, 1996](#)). Consequently, pathological loss of acceleration may be seen in conjunction with significantly decreased beat-to-beat variability of the fetal heart rate (see p. 346). Loss of such reactivity, however, is most commonly associated with sleep cycles (discussed earlier), and may be due to central depression from medications.

The nonstress test is based on the hypothesis that the heart rate of a fetus who is not acidotic as a result of hypoxia or neurological depression, will temporarily accelerate in response to fetal movement. An example that supports this hypothesis is shown in [Figure 40-5](#). Similarly, [Smith and colleagues \(1988\)](#) observed a decrease in the number of accelerations in preterm fetuses subsequently found to have lower umbilical artery blood PO₂ values compared with those who had normal heart rate characteristics. Thus, nonstress testing is considered to reflect fetal condition.

Gestational age influences acceleration or reactivity of fetal heart rate. [Pillai and James \(1990b\)](#) studied the development of fetal heart rate acceleration patterns during normal pregnancy. The percentage of body movements accompanied by acceleration and the amplitude of these accelerations increased with gestational age ([Fig. 40-6](#)). [Guinn and colleagues \(1998\)](#) studied nonstress test results between 25 and 28 weeks in 188 pregnancies that ultimately had normal outcomes. Only 70 percent of these normal fetuses demonstrated the required 15 bpm or more of heart rate acceleration (see next paragraph). Lesser degrees of acceleration, i.e., 10 bpm, occurred in 90 percent of the tested pregnancies.

The [National Institute of Child Health and Human Development fetal monitoring workshop \(1997\)](#) has defined acceleration based on gestational age. The acme of acceleration is 15 bpm or more above the baseline rate and the acceleration lasts 15 seconds or longer for less than 2 minutes in fetuses at or beyond 32 weeks. Before 32 weeks, accelerations are defined as having an acme 10 bpm or more for 10 seconds or longer.

DEFINITION OF NORMAL NONSTRESS TESTS. There have been many different definitions of normal nonstress test results. They vary as to the number, amplitude, and duration of accelerations, as well as the test duration. The definition currently recommended by the [American College of Obstetricians and Gynecologists \(1999\)](#) is two or more accelerations that peak at 15 bpm or more, each lasting 15 seconds or more, and all occurring within 20 minutes of beginning the test ([Fig. 40-7](#)). It was also recommended that accelerations with or without fetal movements be accepted, and that a 40-minute or longer tracing—to account for fetal sleep cycles—should be performed before concluding that there was insufficient fetal *reactivity*. [Miller and colleagues \(1996\)](#) reviewed fetal outcomes after nonstress tests

considered as nonreactive because there was only one acceleration. They concluded that one acceleration was just as reliable in predicting healthy fetal status as were two.

Although a normal number and amplitude of accelerations seems to reflect fetal well-being, "insufficient acceleration" does not invariably predict fetal compromise. Indeed, some investigators have reported false-positive nonstress test rates in excess of 90 percent when acceleration was considered insufficient ([Devoe and colleagues, 1986](#)). Because healthy fetuses may not move for periods of up to 75 minutes, [Brown and Patrick \(1981\)](#) considered that a longer duration of nonstress testing might increase the positive predictive value of an abnormal, or nonreactive test. They concluded that either the test became reactive during a period of time up to 80 minutes, or that the test remained nonreactive for 120 minutes, indicating that the fetus was very ill.

Not only are there many different definitions of normal nonstress test results, but the reproducibility of interpretations is problematic. For example, [Hage \(1985\)](#) mailed five nonstress tests, blinded to specific patient clinical data, to a national sample of obstetricians for their interpretations. He concluded that although nonstress testing is very popular, the reliability of test interpretation needs improvement. Such problems with subjective interpretation have prompted efforts to computerize analysis of nonstress tests. [Bracero and co-authors \(1999\)](#) randomized 404 women to either human or computer interpretation of nonstress tests. They concluded that computerized analysis was a more cost-effective, reliable, and objective method of fetal surveillance.

ABNORMAL NONSTRESS TESTS

There are abnormal nonstress test patterns that reliably forecast severe fetal jeopardy. [Hammacher and co-workers \(1968\)](#) described not only acceleration in response to movement, but also antepartum fetal heart rate tracings with what they termed a *silent oscillatory pattern*. This pattern consisted of a fetal heart rate baseline that oscillated less than 5 bpm and presumably indicated absent acceleration as well as beat-to-beat variability. Hammacher considered this pattern ominous.

[Visser and associates \(1980\)](#) described a "terminal cardiotocogram," which included:

1. Baseline oscillation of less than 5 bpm.
2. Absent accelerations.
3. Late decelerations with spontaneous uterine contractions.

These results were very similar to experiences from Parkland Hospital in which absence of accelerations during an 80-minute recording period in 27 pregnancies was associated consistently with evidence of uteroplacental pathology ([Leveno and associates, 1983](#)). The latter included fetal growth restriction (75 percent), oligohydramnios (80 percent), fetal acidosis (40 percent), meconium (30 percent), and placental infarction (93 percent). We concluded that inability of the fetus to accelerate its heart rate, when not due to maternal sedation, was an ominous finding ([Fig. 40-8](#)). Similarly, [Devoe and co-workers \(1985\)](#) concluded that nonstress tests that were nonreactive for 90 minutes were almost invariably (93 percent) associated with significant perinatal pathology.

INTERVAL BETWEEN TESTING

The interval between tests, originally rather arbitrarily set at 7 days, appears to have been shortened as experience evolved with nonstress testing. According to the [American College of Obstetricians and Gynecologists \(1999\)](#), more frequent testing is advocated by some investigators for women with postterm pregnancy, type 1 diabetes, fetal growth restriction, or pregnancy-induced hypertension. In these circumstances, some investigators perform twice-weekly tests with additional testing performed for maternal or fetal deterioration regardless of time elapsed since the last test. Some clinicians perform nonstress tests daily or even more frequently. For example, [Chari and co-workers \(1995\)](#) recommend daily fetal testing in women with severe preeclampsia remote from term.

DECCELERATIONS DURING NONSTRESS TESTING. Fetal movements may produce heart rate decelerations. [Timor-Tritsch and co-authors \(1978\)](#) reported that decelerations may be observed during nonstress testing in half to two thirds of tracings, depending on the vigor of the fetal motion. Such a high incidence of decelerations inevitably makes interpretation of their significance problematic. Indeed, [Meis and co-workers \(1986\)](#) reported that variable fetal heart rate decelerations during nonstress tests were not a sign of fetal compromise. The [American College of Obstetricians and Gynecologists \(1999\)](#) has concluded that variable decelerations, if nonrepetitive and brief (less than 30 seconds), do not indicate fetal compromise nor the need for obstetrical intervention. In contrast, repetitive variable decelerations—at least three in 20 minutes—even if mild, have been associated with an increased risk of cesarean delivery for fetal distress. Decelerations lasting 1 minute or longer have been reported to have an even worse prognosis ([Bougeois and colleagues, 1984](#); [Druzin and colleagues, 1981](#); [Pazos and colleagues, 1982](#)).

[Hoskins and associates \(1991\)](#) attempted to refine interpretation of testing that shows variable decelerations by adding ultrasonic estimation of amniotic fluid volume. The incidence of cesarean delivery for intrapartum fetal distress progressively increased coincidentally with the severity of variable decelerations and diminished amniotic fluid volume. For example, severe variable decelerations during a nonstress test plus an amniotic fluid index of 5 cm or less resulted in a 75 percent cesarean rate. Fetal distress in labor, however, also frequently developed in those pregnancies with variable decelerations but with normal amounts of amniotic fluid. Similar results were reported by [Grubb and Paul \(1992\)](#).

FALSE-NORMAL NONSTRESS TESTS. [Smith and associates \(1987\)](#) performed a detailed analysis of the causes of fetal death within 7 days of normal nonstress tests. The most common indication for testing was postterm pregnancy. The mean interval between testing and death was 4 days, with a range of 1 to 7 days. The single most common autopsy finding was meconium aspiration, often associated with some type of umbilical cord abnormality. They concluded that an acute asphyxial insult had provoked fetal gasping. They also concluded that nonstress testing was inadequate to preclude such an acute asphyxial event and that other biophysical characteristics might be beneficial adjuncts. For example, assessment of amniotic fluid volume was considered likely of value. Other ascribed frequent causes of fetal death included intrauterine infection, abnormal cord position, malformations, and placental abruption.

ACOUSTIC STIMULATION TESTS

In 1935 [Sontag and Wallace](#) reported that the fetus responds to sound. [Benzaquen \(1990\)](#) and [Richards \(1992\)](#) and their colleagues used miniaturized hydrophones to study the intrauterine sound environment during labor. External low frequency sounds of less than 125 Hz are enhanced, but sounds of greater frequency are attenuated with maximum attenuation at 4000 Hz. Sound levels of the maternal voice were enhanced at an average of 5 dB whereas external male or female voices were attenuated by 2 to 3 dB. Maternal cardiovascular sounds as well as bowel sounds are also audible inside the uterus. Uterine contractions did not affect the fetal sound environment. The background noise level was about 60 dB and consisted primarily of low-frequency sounds; that is, less than 100 Hz. This investigation indicates that the intrauterine environment is relatively quiet. [Hykin and colleagues \(1999\)](#), using functional magnetic resonance imaging, detected fetal brain activity in response to music played over the woman's abdomen.

Loud external sounds have been used to startle the fetus, provoking acceleration of the heart rate. Acoustic devices used to stimulate the fetus during antepartum surveillance tests generate sound pressures considerably above those just described. [Eller and associates \(1995\)](#) used a commercially available acoustic stimulator (Corometrics model 146) to measure intrauterine sound levels. Satisfactory sound intensity between 100 and 105 dB (100 dB is generated by a jet plane at takeoff) was maintained until the stimulator was moved more than 20 cm from the maternal abdomen. To perform acoustic stimulation, an artificial larynx is positioned on the maternal abdomen and a stimulus of 1 to 2 seconds is applied. This may be repeated up to three times for up to 3 seconds ([American College of Obstetricians and Gynecologists, 1999](#)).

[Read and Miller \(1977\)](#) were the first to suggest that acoustic stimulation could be used to examine fetal health. [Romero and co-authors \(1988\)](#), in their review of acoustic stimulation for determination of fetal well-being, recommended vigorous clinical evaluation before such testing becomes a part of standard obstetrical care.

BIOPHYSICAL PROFILE

[Manning and colleagues \(1980\)](#) proposed the combined use of five fetal biophysical variables as a more accurate means of assessing fetal health than any one used alone. They hypothesized that consideration of five variables could significantly reduce both false-positive and false-negative tests. Required equipment includes a real-time ultrasound device and Doppler ultrasound to record fetal heart rate. Typically, these tests require 30 to 60 minutes of examiner time. Shown in [Table 40-2](#) are the five biophysical components assessed, which include:

1. Fetal heart rate acceleration.
2. Fetal breathing.
3. Fetal movements.
4. Fetal tone.
5. Amniotic fluid volume.

Normal variables were assigned a score of two each and abnormal variables a score of zero. Thus, the highest score possible for a normal fetus is 10.

[Manning and colleagues \(1987\)](#) tested over 19,000 pregnancies using the biophysical profile interpretation and management shown in [Table 40-3](#). They reported a false-normal test rate, defined as an antepartum death of a structurally normal fetus, of approximately 1 per 1000. Importantly, more than 97 percent of the pregnancies tested had normal test results. The most common identifiable causes of fetal death after normal biophysical profiles include fetal-maternal hemorrhage, umbilical cord accidents, and placental abruption ([Dayal and colleagues, 1999](#)). Identifiable causes could be found in almost two thirds of fetal deaths. [Manning and coauthors \(1993\)](#) published a remarkable description of 493 fetuses in which biophysical scores were performed immediately before measurement of umbilical venous blood pH values obtained via cordocentesis. Approximately 20 percent of tested fetuses had growth restriction and the remainder had alloimmune hemolytic anemia. As shown in [Figure 40-9](#), a biophysical score of zero was invariably associated with significant fetal acidemia, whereas normal scores of 8 or 10 were associated with normal pH. An equivocal test result—a score of 6—was a poor predictor of abnormal outcome. A decrease from an abnormal result—a score of 2 or 4—to a very abnormal score (zero) was a progressively more accurate predictor of abnormal outcome. Similarly, [Salvesen and colleagues \(1993\)](#) correlated the biophysical profile with umbilical venous blood pH obtained at cordocentesis in 41 pregnancies complicated by diabetes. They also found that abnormal pH was significantly associated with abnormal biophysical profile scores. They concluded, however, that the biophysical profile was of limited value in the prediction of fetal pH, because nine mildly acidemic fetuses had normal antepartum tests. [Weiner and colleagues \(1996\)](#) assessed the meaning of antepartum fetal tests in 135 overtly growth-restricted fetuses and came to a similar conclusion. They found that morbidity and mortality in severe fetal growth restriction was primarily determined by gestational age and birthweight and not by abnormal fetal tests.

MODIFIED BIOPHYSICAL PROFILE

Because the biophysical profile is labor-intensive and requires a person trained in ultrasonic visualization of the fetus, [Clark and co-workers \(1989\)](#) used an abbreviated biophysical profile as their first-line antepartum screening test. Specifically, a vibroacoustic nonstress test and amniotic fluid index were performed twice weekly in 2628 singleton pregnancies. Amniotic fluid indices less than 5 cm were considered abnormal. The typical test required only 10 minutes to perform. These investigators concluded that this abbreviated biophysical profile was a superb method of antepartum surveillance because there were no unexpected fetal deaths.

[Nageotte and colleagues \(1994\)](#) also combined biweekly nonstress tests with ultrasonic assessment of amniotic fluid. An index of 5 cm or less was also considered abnormal in their study. They performed 17,429 modified biophysical profiles in 2774 women and concluded that such testing was an excellent method of fetal surveillance. They randomized women with abnormal test results to backup testing with either a complete biophysical profile or a contraction stress test. Contraction stress testing increased intervention for a false-abnormal test. [Miller and associates \(1996\)](#) reported results of over 54,000 modified biophysical profiles in 15,400 high-risk pregnancies at the University of Southern California. They described a false-negative rate of 0.8 per 1000 and a false-positive rate of 1.5 percent. The [American College of Obstetricians and Gynecologists \(1999\)](#) has concluded that the modified biophysical profile test is an acceptable means of antepartum fetal surveillance.

AMNIONIC FLUID VOLUME

Assessment of amniotic fluid has become an integral component in the antepartum assessment of pregnancies at risk for fetal death. This is based on the rationale that decreased uteroplacental perfusion may lead to diminished fetal renal blood flow, decreased micturition, and ultimately, oligohydramnios. The amniotic fluid index ([Rutherford and colleagues, 1987](#)), the largest vertical pocket ([Chamberlain and co-authors, 1984](#)), and the 2 × 2 cm pocket of the biophysical profile ([Manning and colleagues, 1984](#)) are some ultrasonic techniques used to estimate amniotic fluid volume. [Chauhan and colleagues \(1999\)](#) reviewed 42 reports on the amniotic fluid index published between 1987 and 1997 and concluded that an index of 5.0 cm or less significantly increased the risk of either cesarean delivery for fetal distress or a low 5-minute Apgar score. Similarly, [Casey and colleagues \(2000\)](#), in a retrospective analysis of 6423 pregnancies managed at Parkland Hospital, found that an amniotic fluid index of 5 cm or less was associated with significantly increased perinatal morbidity and mortality. In contrast, [Magann and colleagues \(1999\)](#) evaluated the utility of amniotic fluid indices of 5 cm or less in 1001 pregnancies receiving antepartum fetal testing. About 20 percent of pregnancies studied had amniotic fluid index values of less than 5 cm. They concluded that the index was a poor diagnostic test. A similar conclusion was reached by [Schucker and colleagues \(1996\)](#) in their analysis of 136 pregnancies complicated by severe preeclampsia. In the only randomized trial reported to date, [Conway and colleagues \(2000\)](#) concluded that nonintervention to permit spontaneous onset of labor was as effective as induction in term pregnancies with amniotic fluid index values of 5 cm or less.

UMBILICAL ARTERY DOPPLER VELOCIMETRY

Doppler ultrasonography is a noninvasive technique to assess blood flow by characterizing downstream impedance. The umbilical artery systolic/diastolic ratio (S/D), the most commonly used index, is considered abnormal if it is elevated above the 95th percentile for gestational age or if diastolic flow is either absent or reversed. Absent or reversed end-diastolic flow signifies increased impedance ([Fig. 40-10](#)), and it is uniquely associated with fetal growth restriction ([American College of Obstetricians and Gynecologists, 2000](#)). Such increased impedance to umbilical artery blood flow is reported to result from poorly vascularized placental villi ([Todros and co-authors, 1999](#)). Absent, or reversal of end-diastolic flow is seen in the most extreme cases of fetal growth restriction and may suggest fetal compromise. For example, [Zelop and colleagues \(1996\)](#) reported that perinatal mortality for reversed end-diastolic flow was approximately 33 percent and that for absent end-diastolic flow was about 10 percent.

Doppler ultrasonography has been subjected to more rigorous and extensive assessment with randomized controlled trials than has any previous test of fetal health ([Alfirevic and Neilson, 1995](#)). [Williams and colleagues \(2000\)](#) randomized 1240 high-risk women to either nonstress tests or Doppler velocimetry and found these two fetal surveillance tests to be equivalent in their ability to predict pregnancy outcome. The utility of umbilical artery Doppler velocimetry has been reviewed by the [American College of Obstetricians and Gynecologists \(1999, 2000\)](#). It was concluded that no benefit has been demonstrated for umbilical artery velocimetry for conditions other than suspected fetal growth restriction ([American College of Obstetricians and Gynecologists, 1999](#)). The use of Doppler velocimetry in the management of fetal growth restriction, however, has been recommended as a possible adjunct to other fetal evaluation techniques such as nonstress testing or biophysical profile ([American College of Obstetricians and Gynecologists, 2000](#)). No benefit has been demonstrated for umbilical artery velocimetry for other conditions such as postterm pregnancy, diabetes, systemic lupus erythematosus, or antiphospholipid antibody syndrome. Similarly, velocimetry has not proved of value as a screening test for detecting fetal compromise in the general obstetrical population.

It is possible to evaluate blood flow in other fetal vessels in addition to the umbilical artery. The middle cerebral artery has received particular attention because of observations that the hypoxic fetus compensates by "brain sparing" via reduced impedance—increased blood flow—in cerebral vessels. Based upon this premise, it has been suggested that the ratio of the middle cerebral artery S/D² value to umbilical artery S/D value might reflect fetal compromise ([Mari and Deter, 1992](#)). Studies to date of this premise have been inconclusive. For example, [Ott and colleagues \(1998\)](#) randomized 665 women undergoing modified biophysical profiles to either this test alone or combined with middle cerebral artery to umbilical artery velocity flow ratios. There were no significant differences in pregnancy outcomes between these two study groups. This technique currently is considered investigational by the [American College of Obstetricians and Gynecologists \(1999\)](#).

CURRENT ANTENATAL TESTING RECOMMENDATIONS

According to the [American College of Obstetricians and Gynecologists \(1999\)](#), there is no overall agreement regarding the best test to evaluate fetal well-being. All three testing systems—contraction stress test, nonstress test, and biophysical profile—have different end points that are considered depending on the clinical situation.

The most important consideration in deciding when to begin antepartum testing is the prognosis for neonatal survival. The severity of maternal disease is another important consideration. In general, with the majority of high-risk pregnancies, most authorities recommend that testing begin by 32 to 34 weeks. Pregnancies with severe complications might require testing as early as 26 to 28 weeks. The frequency for repeating tests has been arbitrarily set at 7 days, but more frequent testing is

often done.

At Parkland Hospital, antepartum fetal heart rate recordings have been limited to about 700 women admitted to the High-Risk Pregnancy Unit each year. Such recordings are often obtained several times throughout the week—for example, Monday, Wednesday, and Friday—in these pregnancies. The primary focus of fetal heart rate assessments is detection of decelerations, and delivery is not withheld simply because accelerations are witnessed. Clinical and ultrasonic estimations of amniotic fluid volume may also be used to assess fetal health. Outpatients do not undergo fetal heart rate testing. If there is concern about fetal movement or amniotic fluid volume, then the woman may be observed in the labor suite with fetal heart rate monitoring. Depending on results, she is either discharged, transferred to the High-Risk Unit, or labor is induced. Despite this limited use of antepartum testing, the fetal death rate in structurally normal infants is quite low in high-risk women. Indeed, most antepartum fetal deaths that we encounter are in low-risk pregnancies and are attributable to unpreventable placental abruptions and umbilical cord accidents.

SIGNIFICANCE OF FETAL TESTING

Does antenatal fetal forecasting really make a difference? [Platt and co-workers \(1987\)](#) reviewed the impact of fetal testing between 1971 and 1985 at Los Angeles County Hospital. During this 15-year period, more than 200,000 pregnancies were managed at their hospital and nearly 17,000 of these underwent antepartum testing of various types. Fetal surveillance increased from less than 1 percent of pregnancies in the early 1970s to 15 percent in the mid-1980s. They concluded that such testing was clearly beneficial because the fetal death rate was significantly less in the tested high-risk pregnancies compared with the rate in those not tested.

A contrasting opinion on the benefits of antenatal fetal testing was offered by [Thacker and Berkelman \(1986\)](#). It was their view that efficacy is best evaluated in randomized controlled trials. After reviewing 600 reports, they found only four such trials, all performed with the nonstress test and none with the contraction stress test. The numbers in these four trials were considered too small to detect important benefits. They projected that the costs of such testing exceeded \$200 million per year in 1986 and that published studies did not support the use of either test.

[Mohide and Keirse \(1991\)](#), using the Oxford Database of Perinatal Trials, exhaustively reviewed evidence from controlled clinical trials concerning antepartum fetal surveillance. They found virtually no investigations where the antepartum test was compared with management without some other test of fetal well-being. The few suitable studies revealed no benefits. They concluded that use of these tests has not been demonstrated to confer benefits in the care of an individual woman. Indeed, antepartum tests were subsequently described as "forms of care likely to be ineffective or harmful" (Erkin and co-authors, 1995).

Another important and unanswered question is whether antepartum fetal surveillance identifies fetal asphyxia early enough to prevent brain damage. [Todd and co-workers \(1992\)](#) attempted to correlate cognitive development in infants up to 2 years following either abnormal Doppler velocimetry or nonstress tests. Abnormal nonstress tests were associated with marginally poorer cognitive outcomes, but not those associated with abnormal Doppler velocimetry. Importantly, these investigators concluded that by the time fetal compromise is diagnosed with antenatal testing, fetal damage has already been sustained.

[Manning and co-authors \(1998\)](#) studied the incidence of cerebral palsy in 26,290 high-risk pregnancies managed with serial biophysical profile testing compared with 58,657 low-risk pregnancies that did not receive antepartum testing. The rate of cerebral palsy was 1.3 per 1000 in tested pregnancies compared with 4.7 per 1000 in untested women. In a prior report, however, [Manning and colleagues \(1996\)](#) also found that cerebral palsy was significantly associated with low biophysical profile scores suggesting that identification of the truly compromised fetus may be too late.

Antenatal forecasts of fetal health have clearly been the focus of intense interest for more than two decades. When such testing is reviewed, several themes emerge. First, the methods of fetal forecasting have evolved continually, a phenomenon that itself suggests dissatisfaction with the efficacy of any given method. Second, the biophysical performance of the human fetus is characterized by wide ranges of normal variation, resulting in difficulty determining when such performance should be considered abnormal. *How many movements, respirations, or accelerations? In what time period?* Unable to easily quantify normal fetal biophysical performance, most investigators have resorted to somewhat arbitrary answers for such questions. Third, despite the invention of increasingly complex testing methods, abnormal results are seldom reliable, prompting many clinicians to use antenatal testing to forecast fetal *wellness* rather than *illness*.

TABLE 40-1. Criteria for Interpretation of the Contraction Stress Test

Negative: no late or significant variable decelerations.

Positive: late decelerations following 50% or more of contractions (even if the contraction frequency is fewer than three in 10 min).

Equivocal-suspicious: intermittent late decelerations or significant variable decelerations.

Equivocal-hyperstimulatory: fetal heart rate decelerations that occur in the presence of contractions more frequent than every 2 min or lasting longer than 90 sec.

Unsatisfactory: fewer than three contractions in 10 min or an uninterpretable tracing.

41. Ultrasound and Doppler

The impact of ultrasonography on the practice of obstetrics has been profound. Ultrasonic methods for evaluating the fetus are now employed widely for the many reasons summarized in this chapter and cited frequently throughout the book. A carefully performed ultrasound examination reveals vital information about fetal anatomy, as well as fetal environment, growth, and well-being with no confirmed biological hazards. Ultrasound technology has evolved from producing images of the pregnancy to methods for measurement of both maternal and fetal circulatory function. The phenomenon of Doppler shift forms the technical basis for acquisition of information about the maternal-fetal hemodynamic circulations.

ULTRASONOGRAPHY

Since the first obstetrical application of ultrasound imaging by [Donald and co-workers \(1958\)](#), ultrasonic evaluation of the pregnant uterus has become indispensable. By 1989, 45 percent of pregnancies in the United States were evaluated sonographically ([National Center for Health Statistics, 1992](#)). The percentage continued to increase, which led the National Institutes of Health to commission the Routine Antenatal Diagnostic Imaging with Ultrasound (RADIUS) trial in an effort to determine whether all pregnant women should undergo ultrasound examinations. Their findings have sparked a lively debate within obstetrics and radiology as to the necessity for routine prenatal sonographic screening.

TECHNOLOGY

The picture displayed on the ultrasound screen is produced by sound waves reflecting back from the fetus or imaged structure. When alternating current is applied to a transducer made of a piezoelectric material, intermittent high-frequency sound waves exceeding 20,000 cps are generated. Applying a coupling agent, such as a water-soluble gel, diminishes the loss of ultrasound waves at the transducer-skin interface. The transducer emits a pulse of sound waves that passes through the layers of soft tissue. When an interface between structures of different tissue densities is encountered, some of the energy is reflected back to the transducer. The amount of energy reflected is proportional to the difference in densities at the interface. The reflected energy generates a small electrical voltage that is amplified and displayed on a screen, and appears as a shade of color or brightness somewhere on the continuum between white and black. Bone, for example, is dense (echogenic) and generates a voltage that appears white on the screen, while fluid (anechoic) appears black. Soft tissues appear as varying shades of gray.

Transabdominal scanning is most commonly performed with a 3.5- to 7-mHz curvilinear transducer which uses sequential firing of multiple crystals and generates an image so fast (more than 40 frames/sec) that the picture on the screen appears to be moving in "real-time." Higher frequency transducers yield better image resolutions; however, lower frequencies afford better tissue penetration.

SAFETY. No confirmed biological effects in mammalian tissue have been demonstrated in the frequency range of medical ultrasound ([American Institute of Ultrasound in Medicine 1991](#)). In the low-intensity range of gray-scale imaging, no fetal risks have been demonstrated in over 30 years of use ([Chap 42, p. 1153](#)).

CLINICAL APPLICATIONS

Sonography has proved valuable for monitoring pregnancy in a variety of ways as shown in [Table 41-1](#). The already widespread use of sonography in obstetrics and its potential for identification of fetal abnormalities and for providing reassurance of fetal well-being have stimulated several questions that are difficult to answer:

1. Should sonography be used in all pregnancies and, if so, when should it be initiated, how often should it be repeated, and how vigorous an examination for possible fetal abnormalities should be carried out?
2. Who should perform the examination, and who should interpret the results?
3. What should be the responsibilities of the obstetrician?
4. In what circumstances should sonography be performed by a certified obstetrical or radiological specialist highly trained in sonography?

Some of these questions have been addressed and partially answered. The [American College of Obstetricians and Gynecologists \(1993\)](#) recommends that basic ultrasound examinations be performed by or reviewed by an appropriately trained operator. Shown in [Table 41-2](#) are the guidelines recommended for a basic obstetrical ultrasound examination in both the first and second trimesters. Vaginal sonography may be necessary during the first trimester if abdominal scanning is insufficient to identify these specified components. A fetal anatomical survey is included in a basic second trimester examination. When a complete second- or third-trimester fetal anatomical survey cannot be completed—for example, when visualization is impaired due to oligohydramnios, fetal position, engaged fetal head, or maternal obesity—it should be noted in the report.

Targeted examinations, including a detailed evaluation of all fetal anatomy, are performed when an abnormality is suspected. These should be performed by an operator with especial expertise in such scanning.

A third type of ultrasound procedure is the "limited examination," in which many components of a basic examination are not done. Examples include estimation of amniotic fluid volume, placental localization, determination of fetal presentation, confirmation of fetal life or death, as an adjunct to amniocentesis or external cephalic version, or as part of fetal biophysical profile testing. Each examination should be labeled as limited, basic, or comprehensive, and any missing data should be addressed in the report.

The [American Institute of Ultrasound in Medicine \(1994\)](#) has provided similar guidelines for the performance of antepartum ultrasound examinations. The Institute specifically recommends evaluation of the cerebral ventricles and cerebellum, thorax and four-chamber view of the heart, spine, stomach, kidneys and bladder, umbilical cord insertion on the abdominal wall, and extremities.

SELECTED VERSUS ROUTINE ULTRASONIC SCANNING

Whether all pregnant women should undergo ultrasound screening remains unclear, but is the subject of lively debate by those for and against. Advantages of routine screening have included more accurate pregnancy dating, less frequent labor induction for postterm pregnancy, detection of multiple gestation and fetal growth restriction, and identification of fetal malformations.

Several researchers have demonstrated that ultrasonic estimated gestational age is more accurate than using the last menstrual period, and thus reduces the number of postterm pregnancy inductions. [Waldenstrom and colleagues \(1988\)](#), performed a single scan at approximately 15 weeks in nearly 2500 Swedish women. They found that the incidence of labor inductions for postterm pregnancy was 5.9 percent in screened compared with 9.1 percent in control women. Likewise, [Tunon and colleagues \(1996\)](#) compared the estimated delivery date by both an 18-week ultrasound and by the last period in 15,241 unselected Norwegian women. They reported the postterm delivery rate to be 10 percent according to the menstrual data but only 4 percent with ultrasound dating. [Olsen and Clausen \(1997\)](#), however, have made a statistical argument that overestimation of postterm pregnancy could be prevented by simply adding 283 days to the last period instead of 280 days.

Another argument for routine ultrasound evaluation is that identifying fetal anomalies allows either pregnancy termination or optimization of delivery. Several studies are in conflict concerning this, and at least two support universal screening. [Saari-Kemppainen and colleagues \(1990\)](#) randomized over 9300 Finnish women to routine ultrasound between 16 and 20 weeks or to routine care with sonography if indicated. Perinatal mortality was significantly lower in the sonography group, largely because of pregnancy terminations for malformed fetuses and early detection and appropriate care of twin pregnancies. Routine ultrasound also resulted in improved pregnancy dating and a reduced rate of postterm pregnancy. Similarly, [Luck \(1992\)](#) performed routine ultrasound scanning at 19 weeks in over 8800 British women and concluded that this approach reduced perinatal morbidity and mortality because of pregnancy termination in 25 fetuses with crippling or lethal malformations.

By way of contrast, [Bucher and Schmidt \(1993\)](#) performed a meta-analysis of four trials in which nearly 16,000 women were randomized to routine versus selected scanning. They concluded that routine scanning may be effective and useful for malformation screening, but that it did not significantly improve pregnancy outcome as measured by live births or reduced perinatal mortality. Conflicting data such as these stimulated the larger [RADIUS¹](#) trial described next.

THE RADIUS TRIAL. This investigation was named the Routine Antenatal Diagnostic Imaging with Ultrasound trial. It was sponsored by the National Institute of Child Health and Human Development and results reported by [Ewigman and colleagues \(1993\)](#). It involved over 15,000 women at low risk for perinatal problems. Women assigned to universal screening underwent ultrasonic evaluation at 15 to 22 weeks and again at 31 to 35 weeks, while control-group women had indicated sonography only. A mean number of 0.6 procedures was performed in the control group, compared with 2.2 in the universally screened group. The rate of adverse perinatal outcomes was about 5 percent in each group. There were no significant differences in the incidence or outcomes of preterm delivery, postterm pregnancy, multifetal gestation, or growth-restricted infants. Moreover, ultrasonic detection of congenital anomalies had no effect on perinatal outcome. The [RADIUS¹](#) trialists concluded that routine ultrasound screening for low-risk women did not improve perinatal outcome and thus did not justify routine ultrasound screening, which would increase the cost of perinatal care by \$1 billion.

The [RADIUS¹](#) trial and its conclusions have been widely criticized. The trial included only "low-risk" women who were so rigorously defined that by one estimate only 0.8 percent of pregnancies would qualify ([American Institute of Ultrasound in Medicine, 1994](#)). [Berkowitz \(1993\)](#), in his review of these data, rightfully emphasized that because women in this study were of the lowest risk, if universal screening is not chosen, then health-care providers will have to be extremely vigilant in searching for problems or conditions that would be indicators for scanning.

Another criticism was the below average detection of fetal anomalies. Only 17 percent of major anomalies were detected before 24 weeks in the routine screening group. In other studies, as many as half of anomalies were reported to be identified. This is thought to be why identification of anomalies had such little impact on outcome. Specifically, only a third of affected fetuses could be terminated compared with two thirds in the Finnish trial reported by [Saari-Kemppainen and co-workers \(1990\)](#).

Finally, selection of perinatal morbidity and mortality as primary outcome measures are considered inappropriate for the very low-risk population studied. Thus, cost estimates for routine ultrasound are unjustified. In a financial analysis based on the results of the Helsinki trial, [DeVore \(1996\)](#) concluded that routine ultrasound would save the United States health-care system at least \$280 million.

For all these reasons, the [RADIUS¹](#) trial has not settled the controversy over routine ultrasonic screening in pregnancy. Although it is not currently recommended for low-risk women, this is defined rigorously and the physician must be vigilant for any changes in risk status. Finally, the yield of a routine ultrasound examination appears to be directly related to the skill of the operator and possibly the quality of the equipment.

FETAL MEASUREMENTS

There are many tables and nomograms that describe the normal growth of various fetal structures. Shown in [Tables 41-3](#) and [41-4](#) are commonly used gestational age nomograms for crown-rump length, biparietal diameter, head circumference, abdominal circumference, and femur length. There also are nomograms for dimensions of other fetal structures such as cerebellum, kidney, spleen, liver, humerus, ulna, tibia, fibula, clavicle, foot, and intraocular and binocular distances. For determining gestational age in the first trimester, the crown-rump length is accurate to within 3 to 5 days. In the second trimester, the biparietal diameter and femur length are most accurate, while a combination of measurements is usually used to estimate the fetal weight.

Between 14 and 26 weeks, a combination of measurements is used to most accurately estimate gestational age. In most cases, the biparietal diameter is the easiest and most reproducible measurement to obtain accurately, and has a variation of only ± 7 to 10 days ([Mongelli and colleagues, 1996](#); [Tunon and co-workers, 1996](#)). If there is brachycephaly or dolichocephaly, the biparietal diameter frequently is inaccurate so the head circumference usually is more reliable after 14 weeks. Femur and humerus lengths correlate strongly with both the biparietal diameter and gestational age; the variation in femur length measurement is 7 to 11 days in the second trimester. The abdominal circumference has a wider variation (± 2.8 weeks) than either the biparietal diameter or the femur length, and thus it may not be useful for determining gestational age if the fetus is not growing appropriately.

After 26 weeks, all measurements are less accurate for estimating gestational age. In the third trimester, the variation in both biparietal diameter and femur measurements increases to ± 14 to 21 days. If a third-trimester ultrasound determination must be used to estimate gestational age, serial examinations may be helpful to confirm normal fetal growth.

Using sonographic measurements to determine gestational age employs a wide range of measurements that are cited by percentiles. For example, a biparietal diameter of 40 mm could represent a 16-week fetus (90th percentile), a 19-week fetus (10th percentile), or a 17-week fetus (50th percentile). From a thorough review, [Jeanty \(1991\)](#) determined that a combination of measurements is superior to a single measurement. Thus, the inherent inaccuracy in each measurement is reduced by averaging several different measurements. It is important, however, that each dimension be assessed individually before it is averaged with the others. If one measurement is significantly different from the rest, it might not be appropriate to include it in the gestational age calculation. Various fetal anomalies and certain genetic conditions can influence the growth of the biparietal diameter, abdominal circumference or femur length as well.

AMNIONIC FLUID MEASUREMENT

This has become an important method of fetal assessment ([Chap. 40](#)). There are various definitions of diminished amniotic fluid volume (oligohydramnios) and excessive fluid (hydramnios). These definitions depend on the method used to quantify fluid volume. The volume can also be assessed subjectively, and oligohydramnios is defined by obvious crowding of the fetus and absence of any significant fluid pockets, while hydramnios is an obvious excess of fluid and multiple areas containing sufficient fluid to accommodate a cross section of the fetal abdomen ([Williams, 1993](#)). Indeed, some believe that a subjective assessment by an experienced examiner is more accurate than other measurement schemes. One such method is measurement of the **maximum vertical fluid pocket** in which less than 2 cm indicates oligohydramnios, 2 to 8 cm is considered normal, and more than 8 cm signifies hydramnios ([Chamberlain and colleagues, 1984](#); [Manning and associates, 1980](#)). [Phelan and co-workers \(1987\)](#) introduced the now-popular technique termed the **amniotic fluid index**. This technique is described in detail in [Chapter 31](#), and normal values are shown in [Table 31-3](#), p. 816, and [Figure 31-2](#), p. 817.

FIRST TRIMESTER

Early pregnancy may be evaluated with abdominal or vaginal ultrasonography. All the components listed in [Table 41-2](#) should be assessed. Using abdominal scanning, the gestational sac is reliably seen by 6 weeks menstrual age and fetal echoes and heart activity by 7 weeks. With transvaginal scanning, these are seen about 1 week earlier. When the serum β -hCG is 1800 mIU/mL, the gestational sac should be visible.

Early sonography is valuable in diagnosing anembryonic gestation or missed abortion. Visualization of an intrauterine pregnancy excludes ectopic pregnancy unless there is a heterotopic pregnancy ([Chap. 34, p. 892](#)). Multifetal gestation can be identified and the number of chorions determined. Indeed, the first trimester may be the most accurate time to evaluate this. A limited assessment of fetal anatomy may also be possible.

FETAL ANATOMY

Most attempts to survey fetal anatomy using ultrasound take place during the early second trimester or later. [Green and Hobbins \(1988\)](#) generally were unable to identify fetal structures transabdominally before 9 weeks; their success rate improved remarkably, however, as gestation progressed. By 12 weeks, they were able to visualize the stomach in 95 percent, the anterior abdominal wall in 80 percent, the adrenal glands in 100 percent, the kidneys in 100 percent, and the bladder in 60 percent. Similarly, [Timor-Tritsch and associates \(1990\)](#) reported consistent success at imaging the skull, brain, spine, limbs, and anterior abdominal wall in 35 fetuses examined transvaginally between 9 and 14 weeks. By 11 weeks, they were able to visualize the fingers and feet.

Although there are increasing numbers of case reports that describe detection of a variety of fetal anomalies during the first trimester, and in spite of the obvious potential for identifying congenital fetal malformations at this point, caution is recommended for several reasons:

1. Normal first-trimester embryological development may mimic pathological changes typically seen in the second and third trimesters; for example, physiological anterior wall herniation may mimic an omphalocele.
2. Grossly abnormal embryos may appear normal, as with anencephaly.
3. Some abnormal embryos may manifest only with a crown-rump length that is less than expected for their gestational age ([Levi and associates, 1990](#)).

The [American College of Obstetricians and Gynecologists \(1993\)](#) cautions that whichever method is used, and regardless of the stage of pregnancy evaluated, it is

unrealistic and unreasonable to expect detection of all fetal anomalies even with the most expert and thorough scanning. [Goncalves and colleagues \(1994\)](#) reported that the overall sensitivity of sonography in detecting fetal defects was 53 percent. Overall specificity was 99 percent. Although the technique was about 90 percent sensitive for detecting lethal malformations, it missed serious cardiac defects, microcephaly, and many musculoskeletal deformities.

CENTRAL NERVOUS SYSTEM

Prenatal sonography has proven an excellent method to detect and characterize fetal central nervous system abnormalities. This is especially important because of the frequency of these abnormalities as well as their potential for causing severe disability or death. By adopting a systematic approach to the ultrasound evaluation of the central nervous system, it may be possible to identify virtually all fetuses with major abnormalities ([Filly and colleagues, 1989](#)). Early identification allows timely consideration of prognosis and therapeutic options.

Three transverse (axial) sonographic views are recommended to depict the fetal brain and cranium ([Nyberg, 1989](#)). The transthalamic view ([Fig. 41-1](#)), which is used to measure biparietal diameter and head circumference, includes the thalami, cavum septi pellucidum, and the frontal horns of the lateral ventricles. Moving superiorly yields the transventricular view ([Fig. 41-2](#)) of the atria of the lateral ventricles which contain the echogenic choroid plexus. It also allows visualization of cranial contour. The transcerebellar view ([Fig. 41-3](#)) is obtained by angling through the posterior fossa and demonstrates the cerebellum, cisterna magna, and nuchal fold. Normal transverse cerebellar diameters for fetuses between 13 and 40 weeks have been described ([Goldstein and associates, 1987](#)). Between 15 and 22 weeks, the cerebellar diameter in millimeters is roughly equivalent to gestational age in weeks. The combined use of these three views has led to relatively sophisticated antenatal diagnoses, including aqueductal stenosis, holoprosencephaly, hydranencephaly, cerebral atrophy, porencephalic cysts, and intracranial tumors.

[Filly and colleagues \(1989\)](#) reported their experiences with 137 fetuses between 15 and 39 weeks who had sonographically diagnosed central nervous system abnormalities. Of these, 25 had an obvious neural-tube defect and 99 had hydrocephalus. Seven of the remaining 13 fetuses had a cisterna magna either smaller than 2 mm or larger than 11 mm in anterior-posterior diameter. While 6 of 137 fetuses with abnormalities were not identified, there were other apparent abnormalities in three. Thus, using this relatively simple sequence of evaluation, 134 of 137 fetuses with central nervous system abnormalities would have been identified. This same group also studied 150 normal fetuses between 15 and 40 weeks and found that the ventricular atrium could be identified and measured in 99 percent and the cisterna magna in 90 percent.

[Monteaquedo and associates \(1991\)](#) found that transvaginal ultrasonography in the second and third trimesters may help refine the diagnosis in fetuses with central nervous system abnormalities. Using this approach, they improved their diagnosis in 5 of 13 fetuses. Recent reports such as that by [Levine and colleagues \(1999\)](#) suggest that in selected cases, fetal magnetic resonance imaging may improve prenatal diagnosis of central nervous system abnormalities ([Chap. 42, p. 1156](#)).

HYDROCEPHALUS. This is defined as the presence of excessive cerebrospinal fluid within the intracranial cavity. Its incidence is 0.3 to 0.8 per 1000 births ([Romero and associates, 1988](#)). On ultrasound, the excess fluid is reflected by ventriculomegaly, an enlargement of the ventricles. Some authors use the terms *hydrocephalus* and *ventriculomegaly* interchangeably. Others reserve hydrocephalus for cases in which the intracranial pressure is increased and the cranium enlarged.

The lateral ventricle is commonly measured at the atria, which is the confluence of the temporal and occipital horns ([Fig. 41-4](#)). In the past, hydrocephalus was diagnosed based on the lateral ventricular width—hemispheric width ratio, for which gestational-age specific nomograms have been developed ([Jeanty, 1991](#)). More recently, it has been established that the atrial measurement is relatively constant—between 6 and 9 mm—from 15 weeks until term ([Cardoza and co-workers, 1988b](#)). Mild ventriculomegaly, diagnosed when the atrial measurement is 10 to 15 mm, has been associated with developmental delay in up to 25 percent of affected infants ([Bloom and colleagues, 1997](#)). As the atrial measurement increases further (hydrocephalus), so does the likelihood of abnormal outcome. "Dangling" of the choroid plexus within the lateral ventricle is a characteristic finding in such cases ([Cardoza and associates, 1988a](#); [Mahony and colleagues, 1988](#)).

Hydrocephalus is caused by a wide variety of genetic and environmental insults. The three most common associated anomalies are aqueductal stenosis (43 percent), Dandy-Walker syndrome (12 percent), and communicating hydrocephalus (38 percent). Each of these has multiple causes and prognosis is determined by the etiology. For example, mild to moderate hydrocephalus due to a spinal neural-tube defect generally has a good prognosis because brain development is often normal. Conversely, hydrocephalus caused by aqueductal stenosis generally has a poor prognosis, probably because it reflects abnormal brain development. It also is commonly associated with systemic fetal infection and aneuploidy. In a review of 53 consecutive cases of hydrocephalus caused by aqueductal stenosis, [Levitsky and colleagues \(1995\)](#) reported a mortality of 40 percent and normal development in only 10 percent of survivors. Dandy-Walker syndrome also is associated with single-gene and chromosomal disorders. Conversely, communicating hydrocephalus frequently is idiopathic and has a better prognosis. Although prenatal identification of the cause of hydrocephalus may be difficult, in some cases it may be inferred by the presence of associated malformations. For example, the finding of additional malformations other than a neural-tube defect implies a genetic etiology and an increased risk of intrinsic brain pathology. Almost three fourths of cases have associated malformations ([Drugan and colleagues, 1989](#)).

If hydrocephalus is isolated, the rate of progression of ventriculomegaly also strongly influences outcome. Relatively mild ventricular dilatation and slow progression usually has a good prognosis because enlargement is due to delayed parenchymal and cerebrospinal fluid pathway development and not necessarily a major cerebral malformation ([Bannister and associates, 2000](#)). [Bloom and colleagues \(1997\)](#) found that 25 percent of such infants had a developmental delay. [Gupta and co-workers \(1994\)](#) reviewed the outcomes of 276 cases of isolated hydrocephalus and found that 70 percent survived. Of these survivors, the 60 percent with normal developmental quotients were those with stable, nonprogressive ventriculomegaly. Fetuses with progressive pathology generally have an unfavorable outcome, most likely because the initial infectious, hemorrhagic, chromosomal, or genetic insult was catastrophic.

Initial evaluation of hydrocephalus includes a thorough survey of fetal anatomy, karyotyping, and evaluation for congenital viral infection. With apparent isolated ventriculomegaly, serial ultrasound examinations to monitor the degree and rate of dilatation are recommended. Unfortunately, prognostic information is generally not available when decisions about pregnancy termination must be made.

NEURAL-TUBE DEFECTS. These are the second most common class of congenital anomalies after cardiac defects. Their incidence is about 1.6 per 1000 live births in the United States, and it approaches 8 per 1000 in the United Kingdom. Neural-tube defects result from failure of tube closure by the sixth gestational week (embryonic age 26 to 28 days). A more detailed account of the etiology of neural-tube anomalies is found in [Chapter 36 \(p. 958\)](#), and their diagnosis and management is discussed in [Chapter 37 \(p. 984\)](#).

Anencephaly can theoretically be diagnosed as early as 8 weeks; however, it can be missed in the first trimester ([Levi and associates, 1990](#)). In the second trimester, if an adequate ultrasound examination can be performed, anencephaly is diagnosed with virtually 100 percent accuracy (see [Fig. 37-6](#), p. 982). It is characterized by absence of the cranial vault and brain above the base of the skull and orbits. Failure to obtain an adequate view of the biparietal diameter in the second trimester should raise suspicion. Hydramnios from impaired fetal swallowing commonly accompanies anencephaly but is typically a late finding. [Goldstein and Filly \(1988\)](#) reported increased amniotic fluid in 85 percent of anencephalic fetuses after 25 weeks, but in only about 10 percent before this time. Associated fetal anomalies are common but have not been extensively described because anencephaly itself is uniformly fatal.

Encephalocele is when the meninges and brain herniate through a cranial defect. A **meningocele** is when only meninges herniate. This lesion most commonly results from an occipital midline defect. Sonographically, these lesions vary in size and may have a cystic or solid appearance. If the cerebellum herniates into the defect, it is termed a *Chiari III malformation*. Encephaloceles are commonly associated with either hydrocephaly or microcephaly and there is a high incidence of mental impairment. An encephalocele is an important feature of *Meckel-Gruber syndrome* and frequently accompanies *amniotic band syndrome*. An occipital encephalocele can usually be detected using transthalamic and transcerebellar views. If a skull defect cannot be seen, the differential diagnosis should include cystic hygroma (see later discussion).

Spina bifida consists of a hiatus in the vertebrae, through which a meningeal sac may protrude, forming a *meningocele*. If the sac contains neural elements, as it does in 90 percent of cases, the anomaly is called a *meningomyelocele* (see [Fig. 36-11](#), p. 960). Spine defects can usually be visualized sonographically if the fetal spine is examined with sagittal, transverse, and coronal views ([Fig. 41-5](#)). Transverse images provide the best opportunity to detect the presence and extent of defects in the spine and overlying soft tissues. Movement of the lower extremities and urination may be seen despite the presence of neurologically significant spina bifida, and do not predict normal function after birth.

Some spine defects cannot be visualized directly. However, 99 percent of fetuses with spina bifida have one or more of five cranial signs on targeted sonography:

1. Small biparietal diameter.
2. Ventriculomegaly.

3. Frontal bone scalloping (*lemon sign*, see [Fig. 37-7](#), p. 982).
4. Abnormal curvature of the cerebellum (*banana sign*) or cerebellum that cannot be visualized.
5. Effacement or obliteration of the cisterna magna.

These sonographic signs indicate the presence of the *Arnold-Chiari II* malformation, in which the medulla and fourth ventricle are elongated and, in combination with a portion of the cerebellum, extend through the foramen magnum into the upper cervical spinal canal. When a cranial sign is present, but a spine defect cannot be visualized, targeted ultrasound and amniocentesis for amniotic fluid alpha-fetoprotein and acetylcholinesterase measurement may be diagnostic.

CHOROID PLEXUS CYSTS. These cysts form when neuroepithelial folds in the choroid plexus of the lateral ventricle fill with cerebrospinal fluid. They vary in size from 2 to 20 mm and are usually transient, resolving by 24 weeks ([Fig. 41-6](#)). They do not interfere with normal brain development and are not associated with functional abnormalities. Because choroid plexus cysts are identified in 70 percent of fetuses with trisomy 18, in the past their presence often prompted genetic amniocentesis. It is now known, however, that these cysts are found in 1 to 3 percent of normal fetuses ([Benacerraf and co-workers, 1990a](#); [Chinn and associates, 1990](#)). As discussed in [Chapter 37 \(p. 988\)](#), identification of choroid plexus cysts should prompt a targeted examination to search for other fetal anomalies. In most cases, if other anomalies are present, the risk of aneuploidy is high enough to warrant genetic amniocentesis ([Leonardi and colleagues, 1996](#)).

In the absence of associated findings, genetic amniocentesis likely is not warranted, especially if the age-related risk of aneuploidy is low and maternal serum screening does not indicate increased risk. [Benacerraf and co-workers \(1990b\)](#) calculated that if all second-trimester fetuses with isolated choroid plexus cysts underwent genetic amniocentesis, then 478 procedures would be done to identify each case of trisomy 18. From their meta-analysis, they identified only two cases among 478 such fetuses. [Gupta and colleagues \(1997\)](#) reviewed results from over 200,000 ultrasound examinations to determine the final trisomy 18 risk with isolated cyst according to maternal age. They concluded that invasive genetic testing might be indicated when an isolated cyst is identified in women over age 32.

CYSTIC HYGROMAS

This is a congenital malformation of the lymphatic system that appears as a large, often multiseptated, fluid-filled sac extending off the back or to the sides of the fetal neck ([Fig. 41-7](#)). Cystic hygromas usually develop as part of lymphatic obstruction sequence. Lymphatic fluid from the head ordinarily drains into the jugular vein near the heart. If this connection fails to develop by 40 days of gestation, lymph collects in the jugular lymphatic sac, which causes formation of a cystic hygroma in the cervical region. Lymphatic obstruction can also cause cardiac defects. The enlarged thoracic duct impinges on the developing heart, altering blood flow and in some cases leading to the development of hypoplastic left heart, coarctation of the aorta, or other flow-related anomalies.

Cystic hygromas may be identified during routine sonography. They are also detected by abnormal multiple marker screening tests, either because of the associated fetal aneuploidy or because of hydropic changes which lead to elevated hCG and alpha-fetoprotein levels ([Saller and colleagues, 1992](#); [Wenstrom and co-workers, 1996](#)). Hygromas may be an isolated finding, part of a genetic syndrome such as Noonan syndrome, or in association with a chromosome anomaly. Approximately 60 to 70 percent are associated with fetal aneuploidy; 45, X (Turner syndrome) accounting for 75 percent, and trisomies 21, 18, 13, and mosaic aneuploidies for the remainder ([Johnson, 1993](#); [Romero, 1988](#); [Shulman, 1992](#), and their colleagues).

Small, simple hygromas identified in the first trimester sometimes resolve. Resolution, however, does not reduce the risk of aneuploidy, and a full diagnostic workup is still performed. [Johnson and colleagues \(1993\)](#) evaluated 68 first-trimester fetuses with simple nuchal cystic hygromas and found that 60 percent were aneuploid. If the karyotype is normal, the prognosis depends largely on whether there is an accompanying heart defect or another genetic syndrome. Fetuses with normal karyotypes and cardiac anatomy and in whom there is spontaneous resolution of the hygroma usually have a good prognosis ([Shulman and co-workers, 1994](#); [Trauffer and collaborators, 1994](#)). These infants may have redundant nuchal tissue (pterygium colli), which can be surgically corrected.

Large, multiseptated lesions virtually never resolve, and have a worse prognosis than those without septations. [Brumfield and colleagues \(1996\)](#) described 61 fetuses with cystic hygroma and reported that those with septated lesions were more likely to have an abnormal karyotype or to develop hydrops, and their survival was significantly diminished. In a similar study of 150 fetuses, [Bronstein and co-workers \(1993\)](#) found that 94 percent of fetuses with nonseptated hygromas were live born, compared with only 12 percent among fetuses with septated lesions.

THORAX

The fetal lungs develop between 20 and 25 weeks, and are usually visualized after this period. A variety of thoracic malformations can develop. Some of the more common include cystic adenomatoid malformation, bronchopulmonary sequestration, bronchogenic cysts, and chylothorax ([Crane and colleagues, 1994](#); [Goncalves and associates, 1994](#)). Prenatal diagnosis and therapy of these lesions is discussed in [Chapter 37 \(p. 995\)](#). [Treadwell and associates \(1996\)](#) have provided experiences that support a better prognosis than previously reported.

DIAPHRAGMATIC HERNIA. These congenital hernias result from incomplete fusion of the pleuroperitoneal membrane. They occur more frequently on the left, and have a frequency of 1 in 2000 to 5000 births ([Callen, 1994](#); [Romero and associates, 1988](#)). The diagnosis and treatment of congenital diaphragmatic hernia is discussed in [Chapter 37 \(p. 995\)](#). Classically, with a left-sided hernia, the four-chamber cardiac view shows the heart pushed to the middle or to the right of the thorax by the stomach or bowel, which appear as cystic structures behind the left atrium. With a right-sided lesion, the liver is visualized in the right thorax, displacing the heart to the far left. Associated findings include absence of an intra-abdominal stomach bubble, a small abdominal circumference, and peristalsis in the fetal chest. Hydramnios is also common and was identified in 75 percent of affected fetuses studied by [Adzick and co-workers \(1985\)](#). Because diaphragmatic hernia is associated with other major anomalies or aneuploidy in almost half of all cases, a thorough evaluation of all fetal structures should be performed and amniocentesis offered.

HEART

As a group, cardiac malformations are the most common congenital anomalies, with an incidence of about 8 in 1000 live births ([Chap. 36, p. 960](#)). Almost 90 percent of cardiac defects are multifactorial or polygenic. Another 1 to 2 percent occur as part of a monogenic syndrome such as Holt Oram, Noonan, or a gene-deletion syndrome, which may be suspected after identification of specific associated anomalies. About 1 to 2 percent result from exposure to a teratogen such as isotretinoin or hydantoin or to maternal diabetes. Postnatal data suggest that about 5 percent of infants with congenital cardiac malformations have chromosomal abnormalities; however, this is 30 to 40 percent when a cardiac defect is diagnosed prenatally ([Abuhammad, 1997](#)). Approximately 50 to 70 percent of such fetuses will have other (extracardiac) anomalies identifiable sonographically. Nonetheless, the likelihood of aneuploidy or a deletion syndrome with an isolated cardiac malformation is believed to be at least 15 percent. For these reasons, fetal karyotype is indicated in affected fetuses. The most frequently encountered aneuploidies are trisomies 21, 18, and 13, and 45, X (Turner syndrome).

A general examination of the heart—four-chamber view, rate, and rhythm—should be included in the basic ultrasound examination. A more detailed targeted examination should be performed if any of the following risk factors are present: suspected cardiac abnormality seen on the four-chamber view; arrhythmia; presence of extracardiac anomalies; parent or sibling with heart defect; maternal diabetes; teratogen exposure; and nonimmune hydrops. If the fetus is known to have Down or Turner syndrome, or any other genetic syndrome that includes a cardiac defect, the cardiac examination may influence parental decisions.

Heart motion can be visualized sonographically by 6 to 7 weeks, and the four chambers become visible in the second trimester. A detailed cardiac evaluation, however, is usually not possible until at least 18 weeks. Even at this time, adequate anatomical cardiac assessment is dependent on fetal position and activity, maternal size, amniotic fluid volume, and availability of proper equipment and expertise. The study is often time consuming and may require collaboration with a pediatric cardiologist.

The four-chamber view is central to fetal cardiac assessment ([Fig. 41-8](#)). This view is obtained by imaging a transverse plane through the fetal thorax at a level just above the diaphragm. This view allows evaluation of the size, location, and orientation of the fetal heart. The atrial and ventricular chambers can be evaluated, the septum primum, foramen ovale, and interventricular septum viewed, and the atrioventricular valves observed. The moderator band is noted in the apex of the right ventricle and the foramen ovale flap in the left atrium. In addition, in some cases, the pulmonary veins and descending aorta are seen. Normally, the two atria and the two ventricles are similar in size, and the apex of the heart forms a 45-degree angle with the left anterior chest wall. The sensitivity of the four-chamber view for the detection of cardiac malformations averages about 50 percent in low-risk women ([Abuhammad, 1997](#)). In high-risk women undergoing targeted examination, it is as high as 90 percent ([Bromley and associates, 1992](#); [Copel and colleagues, 1987](#)).

The four-chamber view allows evaluation of the cardiac axis, another good screening tool. The apex of the heart should be oriented along an imaginary line 45 degrees (± 15 degrees) to the left of the anterior-posterior dimension ([Fig. 41-9](#)). Deviation from that axis, usually to the left, indicates a high risk of cardiac and associated anomalies. [Smith and colleagues \(1995\)](#) evaluated 41,500 second- and third-trimester fetuses and found that 75 percent of those with congenital cardiac malformations had a cardiac axis greater than 75 degrees to the left. In a case-control study of 75 fetuses with congenital heart defects, [Shipp and co-workers \(1995\)](#) found that 45 percent of fetuses with abnormal hearts had left axis deviation, compared with none of the controls.

A complete cardiac evaluation should include examination of the ventricular outflow tracts and blood flow patterns through the heart. Starting with the four-chamber view, slight rotation of the transducer toward the right fetal shoulder shows the aortic outflow tract (long-axis view). In this view, the interventricular septum is visualized to be continuous with the anterior wall of the aorta, and the mitral valve continuous with the posterior aortic wall. Lack of continuity could indicate a ventricular septal defect. Once the aortic outflow tract has been identified, rotating the transducer in the opposite direction will allow visualization of the pulmonary outflow tract, as these two arteries appear to cross each other ([Fig. 41-10](#)). The aortic arch is best seen longitudinally ([Fig. 41-11](#)). Pulse Doppler and real-time Doppler color-flow mapping can then be used to evaluate blood flow through the fetal cardiovascular system ([DeVore and associates, 1987](#); [Shenker and colleagues, 1988](#)). In addition, M-mode echocardiography is essential for arrhythmia evaluation and to measure chamber size, wall thickness, and wall and valve motion.

ACCURACY. Ultrasound examination to detect fetal cardiac disease is imperfect, and its accuracy depends on the operator and the population studied. [Crawford and colleagues \(1988\)](#) reported their experiences with almost 1000 women at high risk for having children with cardiac abnormalities. They performed over 1750 fetal echocardiograms and successfully identified 74 of 91 anomalies (80 percent). In almost half of those with cardiac anomalies, chromosomal or extracardiac structural defects were also found. They emphasized that heart disease diagnosed prenatally is often severe and is associated with a poor long-term prognosis.

By way of contrast, [Benacerraf and associates \(1987\)](#) studied a group of women who underwent ultrasonic studies for multiple reasons. Although 49 fetuses were subsequently found to have 66 cardiac defects, only 33 (50 percent) of these were detected antenatally. According to both of these reports, ventricular septal defects, anomalous pulmonary venous return, and aortic or pulmonic stenosis were especially likely to be missed by fetal ultrasound evaluation. Additionally, those cardiac defects characterized by inadequate growth—for example, hypoplastic left heart or aortic stenosis—may not have fully developed at the time of the midtrimester examination.

[Ott \(1995\)](#) reported a 14 percent sensitivity for detection of congenital heart disease in a low-risk population, compared with 63 percent in the high-risk group. [Lanouette and co-workers \(1996\)](#) correctly emphasized that routine cardiac views are not consistently available for each routine ultrasound examination. They calculated the adjusted positive-predictive value to be about 55 percent. [Berghella and associates \(1996\)](#) found that collaboration with pediatric cardiologists significantly improved characterization of lesions in some cases. All women undergoing targeted ultrasound examination should be counseled about its limitations to detect fetal abnormalities, particularly certain types of cardiac malformations.

GASTROINTESTINAL TRACT

Using high-resolution diagnostic sonography, the integrity of the abdominal wall, umbilical cord insertion, and intraabdominal organs can be assessed with confidence ([Fig. 41-12](#)). The liver, spleen, gallbladder, and bowel can be identified in most fetuses. The stomach should be clearly identified during all examinations, as it is visible in 98 percent of fetuses after 14 weeks. Nonvisualization of the stomach is associated with an abnormal outcome in about half of fetuses studied after 14 weeks and 100 percent after 19 weeks ([Millener and colleagues, 1993](#); [Pretorius and co-workers, 1988](#)). Associated abnormalities include tracheoesophageal fistula, esophageal atresia, diaphragmatic hernia, abdominal wall defects, and neurological abnormalities that inhibit fetal swallowing. Repeat sonograms should be performed for all cases of stomach nonvisualization, although subsequent visualization does not guarantee a normal outcome. [Millener and co-workers \(1993\)](#) evaluated 7200 sonograms performed after 14 weeks' gestation and found that a third of cases in which the stomach was seen on a subsequent examination had an abnormal outcome.

Normally, the appearance of the fetal bowel changes with gestational age, and considerable overlap exists between the sonographic appearance of normal and pathological conditions ([Hertzberg, 1994](#)). A common finding is **hyperechogenic bowel**, which has been associated with fetal aneuploidy and other genetic syndromes such as cystic fibrosis. Hyperechogenic bowel is generally defined as having a brightness equivalent to or greater than that of bone. The appearance of hyperechogenicity is affected by the transducer frequency, as it is much more likely to be visualized using a frequency of 8 MHz than 5 MHz ([Vincoff and associates, 1999](#)). One way to confirm hyperechogenicity is to isolate a view in which both bowel and bone (iliac crest) can be clearly visualized. Then, using a frequency of 5 MHz, gradually turn down the gain. If the bowel echogenicity disappears before the bone, it is not truly hyperechogenic ([Slotnick and Abuhamad, 1996](#)). Truly hyperechogenic bowel indicates an increased risk for aneuploidy, cystic fibrosis, congenital infection, and associated malformations ([Berlin and collaborators, 1999](#); [Yaron and co-workers, 1999](#)). Some clinicians believe this should prompt a complete fetal evaluation, but others believe that as an isolated finding that only targeted ultrasonography is indicated. Hyperechogenic bowel has also been associated with bleeding into the amniotic fluid and unexplained fetal death ([Nyberg and associates, 1993](#)).

ABDOMINAL WALL DEFECTS. These defects as a group are relatively common malformations. The two most common are omphalocele and gastroschisis, and each has a frequency of approximately 1 in 5000 live births. Because of maternal serum alpha-fetoprotein screening programs and the performance of routine sonograms, these two defects are usually ascertained early in pregnancy. Although they have many similarities, it is important to recognize that they differ markedly in developmental pathology, association with other major abnormalities, and prognosis.

Gastroschisis is the result of an early vascular accident causing occlusion of either the right umbilical vein (the left vein persists in the cord) or the terminal segment of the right omphalomesenteric artery. The resulting localized ischemia produces a full-thickness defect in the abdominal wall to the right of the umbilical cord insertion, through which bowel can herniate into the amniotic cavity ([Fig. 41-13](#)). Because it occurs as the result of a vascular accident, it does not have the same associations with aneuploidy as does omphalocele. However, associated bowel defects have been reported in 10 to 30 percent of cases ([Hoyme and co-workers, 1983](#)). They usually have a good prognosis with survival of 80 to 90 percent ([Callen, 1994](#)). In rare cases the defect can be large enough to permit liver herniation, in which case the necessary reconstructive surgery is more complex and the outcome less sure. Gastroschisis is identified by the presence of extra-abdominal bowel floating free in the amniotic fluid, with the umbilical cord inserting in the usual place on the fetal abdomen.

An **omphalocele** occurs when there is failure of the lateral ectomesodermal folds to meet in the midline of the abdomen between the third and fourth weeks. As a result, the abdominal contents are covered only by a thin, two-layered sac composed of amnion and peritoneum, and the umbilical cord inserts into the apex of the sac ([Fig. 41-14](#)). It is associated with aneuploidy in 35 to 60 percent of cases—particularly trisomy 13, 18, and 20. It may occur as part of a genetic syndrome such as Beckwith-Weidemann syndrome or pentalogy of Cantrell ([Callen, 1994](#)). Omphalocele is also associated with other major anomalies in 50 to 70 percent of cases. [Romero and colleagues \(1988\)](#) described cardiac anomalies (45 percent), genitourinary anomalies (40 percent), and neural-tube defects (40 percent). The prognosis is thus determined not only by the size of the defect, but by the etiology and accompanying abnormalities. Recognition of an omphalocele mandates a complete fetal evaluation, including karyotype.

GASTROINTESTINAL ATRESIA. Most atresias are characterized by obstruction with proximal bowel dilatation. In general, the more proximal the obstruction, the more likely it is to be associated with hydramnios. **Esophageal atresia** is one of the most common gastrointestinal anomalies, and is encountered in about 1 in 3000 births ([Robertson and colleagues, 1994](#)). The diagnosis is suspected when hydramnios is found in the absence of a fluid-filled stomach. This is an uncommon presentation, however, because up to 90 percent of cases are associated with a **tracheoesophageal fistula**. The latter cannot be diagnosed reliably in utero because the fistula permits fluid to enter the stomach ([Pretorius and colleagues, 1987a](#)). About half of fetuses with esophageal atresia have associated anomalies, including aneuploidy in 20 percent and growth restriction in 40 percent. Cardiac malformations are especially common.

Duodenal atresia occurs in about 1 in 10,000 live births ([Robertson and colleagues, 1994](#)). The lesion may be diagnosed prenatally by the demonstration of the *double-bubble sign*, which represents distention of the stomach and the first part of the duodenum ([Fig. 41-15](#)). Demonstrating continuity between these two structures will differentiate duodenal atresia from other causes of cystic structures in the fetal abdomen. The diagnosis of duodenal atresia generally is difficult before 24 weeks, although it has been made as early as 19 weeks ([Romero and associates, 1988](#)). About 30 percent of cases diagnosed antenatally have trisomy 21 and more than half have other associated anomalies. Obstructions in the lower small bowel usually result in multiple dilated loops, which may have increased peristaltic activity. BR> **Large bowel obstructions** and **anal atresia** are less readily diagnosed in utero because hydramnios is not a typical feature and the bowel may not be significantly dilated. The transverse view through the pelvis may reveal a fluid-filled structure (the enlarged rectum) between the bladder and the sacrum.

GENITOURINARY TRACT

Using transabdominal sonography, the fetal kidneys are visualized as paraspinal masses frequently as early as 14 weeks, and routinely by 18 weeks ([Patten and](#)

[co-workers, 1990](#)). Using transvaginal sonography, the kidneys are visible before 14 weeks ([Bronstein and colleagues, 1990](#)). Normal kidneys appear elliptical in parasagittal planes ([Fig. 41-16](#)) and circular in transverse planes ([Fig. 41-17](#)). Initially, fetal kidneys are uniformly hypoechoic; however, as pregnancy advances, more detail is visualized. The renal cortex, which is echogenic, surrounds the hypoechoic medullary pyramids and is outlined by perinephric fat and the renal capsule. The renal pelvis is centrally located and anechoic. An adrenal gland sits atop each kidney like a cap covering the upper pole, and appears very hypoechoic. They may be overlooked under ordinary circumstances, but become more visible when there is renal agenesis.

Nomograms have been developed that describe fetal kidney dimensions throughout pregnancy ([Sagi and associates, 1987](#)). In general, the kidney length in millimeters is roughly equivalent to the menstrual age in weeks ([Callen, 1994](#)). In general, the anterior-posterior (AP) dimension of the renal pelvis should be less than half of the entire kidney AP^2 dimension.

Urine production normally begins late in the first trimester, and consequently the fetal bladder can be observed as an anechoic area in the pelvis early in the second trimester. Fetal urine production increases from 5 mL/hr at 20 weeks to about 50 mL/hr at 40 weeks ([Rabinowitz and co-workers, 1989](#)). In the normal fetus, the bladder fills and empties every 20 to 45 minutes. The placenta and membranes can produce normal amounts of amniotic fluid early in gestation. After 16 to 20 weeks, most of the fluid is produced by the kidneys, and otherwise unexplained oligohydramnios suggests a urinary abnormality. Conversely, normal amniotic fluid volume in the second half of pregnancy suggests urinary tract patency with at least one functioning kidney.

The overall incidence of fetal renal anomalies is cited as 0.2 to 1.4 percent. Several large prospective screening programs have reported that the incidence and type of anomaly identified depends on gestational age. For example, before 24 weeks, the detection of urinary tract anomalies is reported to be relatively low, and identified lesions tend to be serious or lethal. After 24 weeks, their detection increases, but identified lesions are less severe. Importantly, various forms of obstruction tend to develop over time. As shown in [Table 41-5](#), obstruction accounts for the majority of urinary tract defects identified at birth.

[Fugelseth and colleagues \(1994\)](#) performed ultrasound examination at 17 and 32 weeks on 22,310 women. They identified 47 (0.18 percent) urinary tract abnormalities, of which 62 percent were found only at the second screening. Approximately half the anomalies were hydronephrosis and 20 percent were multicystic kidney, both of which develop over time. [Gunn and co-workers \(1995\)](#) prospectively evaluated 3856 fetuses after 28 weeks for obstetrical indications. Significant renal tract anomalies were identified prenatally and confirmed at birth in 55 fetuses (1.4 percent). These lesions included renal agenesis, multicystic dysplasia, and various types of reflux.

OBSTRUCTIVE UROPATHY. Renal agenesis, multicystic dysplasia, and various urinary tract abnormalities all result from obstruction. Timing of insult determines the outcome. Obstruction at the ureteropelvic junction is most common. It affects males twice as often as females. Renal function is likely to be preserved even with prominent pelvic dilatation, because the obstruction is most often a functional one, unlike urethral obstructions, which are more often anatomical. Obstruction is bilateral in a third of cases, and when unilateral, there is an increased likelihood of anomalies involving the contralateral kidney, particularly multicystic dysplasia (see later discussion).

Obstruction can also occur at the ureterovesical junction or at the urethra. The severity and location of the obstruction can be determined by assessing amniotic fluid volume and the location of dilatation within the urinary tract. Renal pelvis dilatation usually indicates obstruction at the ureteropelvic junction or possibly at the ureterovesical junction. As a general rule, normal fetal ureters cannot be visualized, and thus their identification indicates hydroureter due to a lower block; for example, posterior urethral valves. Bladder outlet obstruction is usually accompanied by enlargement of the bladder and hydroureter.

Mild hydronephrosis (up to 4 to 5 mm) occurs in 2 to 3 percent of normal fetuses in the second trimester, but in as many as 25 percent with trisomy 21. In the absence of other risk factors, the likelihood that a fetus with isolated mild pyelectasis will have trisomy 21 is estimated to be only 1 in 340. Thus, amniocentesis is not usually performed for this finding alone ([Benacerraf and colleagues, 1990b](#)).

After 20 weeks the fetal renal pelvis may be easily visible, and by convention, they are measured in the AP^2 dimension. Based on studies that included postnatal follow-up, upper limits of the normal pelvis is 4 mm before 33 weeks and 7 mm after 33 weeks ([Corteville, 1991](#); [Mandell, 1991](#); [Wilson, 1997](#), and their colleagues). Alternatively, [Grignon and colleagues \(1986\)](#) reported that dilatation less than 10 mm is usually physiological. While the size of the pelvis increases along with maternal hydration, it returns to normal ([Robinson and co-workers, 1998](#)).

Diagnosis of renal pelvis dilatation is important because it may identify those fetuses who require neonatal intervention to preserve kidney function. [Ghidini and cohorts \(1990\)](#) reported results from 70 fetuses with ureteropelvic junction obstruction. Those with renal pelvis dilatation less than 1 cm uniformly did well, whereas three fourths of those with dilatation more than 2 cm required postnatal pyeloplasty. Surprisingly, those with dilatation of 1 to 2 cm—about half of the total—did well if the findings were bilateral. Conversely, about 10 percent with unilateral dilatation of this magnitude eventually required pyeloplasty. Similarly, [Adra and colleagues \(1995\)](#) followed 84 cases of fetal pyelectasis and found that two thirds of those with renal pelvis greater than 8 mm had renal pathology at birth, including ureteropelvic junction obstruction in 37 percent, vesicoureteral reflux in 33 percent, and problems such as malformations of the ureters or collecting system in the remainder.

RENAL AGENESIS. This has an incidence of about 1 in 4000 births. No kidneys are visualized sonographically at any point during gestation. The adrenal glands typically enlarge and occupy the renal fossae, and can be mistaken for kidneys. Without kidneys there is no urine production and the severe oligohydramnios that develops leads to pulmonary hypoplasia, limb contractures, a distinctive compressed face ([Fig. 41-18](#)), and ultimately death. When this combination of abnormalities is caused by renal agenesis, it is called *Potter syndrome*, after [E. L. Potter who described it in 1946](#). When these abnormalities result from oligohydramnios of some other etiology, it is called *oligohydramnios sequence*.

The recurrence risk for isolated bilateral renal agenesis is generally quoted as 3 percent, but a fetal autopsy is essential to rule out a mendelian syndrome, which could have a recurrence risk as high as 50 percent. The diagnosis of fetal renal agenesis should also prompt sonographic evaluation of the kidneys of parents and siblings. [Roodhooft and colleagues \(1984\)](#) showed that 13 percent of the first-degree relatives of fetuses with isolated bilateral renal agenesis had unilateral agenesis or other asymptomatic renal malformations. If a parent or sibling is discovered to be affected, the recurrence risk is much higher.

POLYCYSTIC KIDNEY DISEASE. Of the hereditary polycystic diseases, only autosomal recessive infantile polycystic kidneys may be reliably diagnosed antenatally. The autosomal dominant condition usually does not manifest until adulthood, but prenatal diagnosis has been described ([Pretorius and associates, 1987b](#)). Infantile polycystic kidney disease is characterized by abnormally large kidneys that fill the fetal abdomen and appear to have a solid, ground-glass texture. The abdominal circumference is enlarged, and there is usually severe oligohydramnios. The polycystic changes of these kidneys can only be identified microscopically.

MULTICYSTIC DYSPLASTIC KIDNEYS. These result from complete obstruction or atresia at the level of the renal pelvis or proximal ureter prior to 10 weeks ([Callen, 1994](#)). An affected kidney is partially or completely nonfunctional, and the diagnosis can usually be made antenatally. Sonographically there is abnormally dense renal parenchyma with multiple peripheral cysts of varying sizes that do not communicate with each other or the renal pelvis. This distinguishes them from obstructive pelviectasis, in which the fluid-filled areas do connect. If the insult occurred very early, the kidneys may simply be abnormally small—less than the fifth percentile in all three dimensions—and dense. Later insults can produce abnormally large dimensions.

Most often, segmental dysplasia is unilateral. Contralateral renal anomalies occur in 40 percent of cases; the most common is ureteropelvic junction obstruction ([Callen, 1994](#); [Kleiner and colleagues, 1986](#)). The prognosis is generally good if findings are unilateral and amniotic fluid volume is normal, although occasionally the normal-appearing kidney may have segmental dysplastic changes that cannot be visualized sonographically. If multicystic dysplasia is bilateral, this generally has an extremely poor prognosis. Even if amniotic fluid volume remains adequate, antenatal destruction of renal tissue may result in neonatal renal failure.

DOPPLER VELOCIMETRY

The Doppler shift is a physical principle that states that when a source of light or sound waves is moving relative to an observer, the observer detects a shift in the wave frequency. Thus, when sound waves strike a moving target, the frequency of the sound waves reflected back is shifted proportionate to the velocity and direction of the moving target. Because the magnitude and direction of the frequency shift depend on the relative motion of the moving target, their velocity and direction can be determined.

Important to obstetrics, the Doppler principle is used to determine the volume and rate of blood flow through maternal and fetal vessels. In this situation the sound source is the ultrasound transducer, the moving target is the red blood cells flowing through the circulation, and the reflected sound waves are observed by the ultrasound transducer. Two kinds of Doppler are used in medicine. The continuous wave Doppler machine has two crystals—one that transmits a high-frequency sound wave, and another that continuously receives signals. It can record high frequencies using low power output and is easy to use. Unfortunately, it is

nonselective, recognizing all signals along its path, and does not allow visualization of the blood vessel(s). In M-mode echocardiography, continuous wave Doppler is used to evaluate motion through time. It defines the blood flow through the heart, but because the cardiac structures are not visualized it requires the correlation with the sequence of waveforms produced with the sequence of structures interrogated by the sound wave.

The other type, pulse wave Doppler, has equipment that uses only one crystal, which transmits the signal and then waits until the returning signal is received before transmitting another one. It is more expensive and requires higher power, but allows precise targeting and visualization of the vessel of interest. Pulse wave Doppler can also be configured to allow color-flow mapping, in which computer software makes blood flowing away from the transducer look blue and blood flowing toward the transducer look red.

Various combinations of continuous Doppler, pulse wave Doppler, color-flow Doppler, and real-time ultrasound are commercially available, and are loosely referred to as duplex Doppler. Doppler is generally used in two ways to estimate circulatory hemodynamics:

1. Direct measurement of the volume of blood flow.
2. Indirect estimation of flow velocity using waveform analysis.

BLOOD FLOW MEASUREMENT

Doppler-shifted sound frequencies depend on a number of factors ([Fig. 41-19](#)). Pragmatic concerns include the angle of insonation (θ). The cosine of this angle remains close to 1 as long as the angle is kept low, but at higher angles of insonation, especially those more than 60 degrees, considerable error in measurement is introduced. Thus measurements are better if flow is directed "head on" to the transducer, a feat sometimes difficult to accomplish.

The equation in [Figure 41-19](#) includes a factor (v) for the velocity of blood in the vessel studied. The equation is used to estimate the velocity of red cells and derivatives from that factor. Because volume flow (mL/min) is simply velocity times cross-sectional area of the blood vessel (area equals π times the square of the radius), it is possible to calculate volume flow by measuring the blood vessel diameter using ultrasound. Unfortunately, there are several technical difficulties with measurement of vessel diameters. The vessels are dynamic with changing diameters during the cardiac cycle, and their measurement is very sensitive to the angle of insonation. The many technical difficulties inherent in Doppler blood volume flow measurements result in high error rates for this methodology. Estimates of error up to 15 percent have been reported even under the best circumstances, and errors up to 50 percent are not uncommon ([Burns, 1987](#); [Gill, 1985](#)). Because of these methodological problems, blood volume flow measurements have been largely abandoned in clinical applications.

BLOOD VELOCITY WAVEFORM ANALYSIS

Errors encountered in direct measurement of the volume of blood flow have led to development of several indirect indices of flow that compare different parts of the waveform. Because the indices are independent of the angle of insonation and do not require measurement of the diameter of the vessel, they provide useful information about flow without engendering excessive errors.

Doppler waveforms of vessels have been described in a variety of ways, but all the calculated indices are based upon the relationship between systole and diastole. The simplest of these indices to compute is the ratio of the maximal systolic flow velocity to the minimal end-diastolic flow velocity, or S/D ratio ([Fig. 41-20](#)). By evaluating blood flow during diastole, the S/D ratio provides an estimation of downstream resistance. In nonpregnant individuals, S/D ratios can be obtained only from the carotid and renal arteries, because only these arteries maintain continuous diastolic blood flow visible on waveform analysis. During pregnancy, the uterine and umbilical arteries normally maintain diastolic blood flow and the normal placental bed is characterized by low resistance and high blood flow. Thus the most useful S/D ratios are obtained from the maternal uterine or fetal umbilical arteries, and provide an indirect estimate of the adequacy of blood flow to the fetus. Blood flow velocity has also been studied in the umbilical vein and fetal cerebral circulation. Because of the low diastolic velocities seen in more central fetal vessels, such as the descending aorta, the S/D ratio is not useful elsewhere in the fetal circulation. [Figure 41-21](#) illustrates several of the vessels in which S/D ratios have been studied, as well as the corresponding S/D waveforms for blood velocity in these vessels.

The resistance to umbilical artery blood flow during diastole is initially high but decreases as gestation progresses; the S/D ratio decreases from about 4.0 at 20 weeks to about 2.0 at 40 weeks. An easy-to-remember rule is that the S/D ratio is generally less than 3.0 after 30 weeks ([Fleischer and associates, 1985](#)). Increases in S/D ratio can be found with maternal hypertension, lupus, and poorly controlled insulin-dependent diabetes. Elevated S/D ratios have been associated with fetal growth restriction and have been used as a screen for "fetal stress." Because there is a fair amount of variation in the S/D ratio, however, it is generally not used alone to direct pregnancy management. One exception to this rule concerns absent or reversed diastolic flow. This is a particularly ominous finding indicating extreme downstream resistance, placental dysfunction, and fetal compromise ([Fig. 41-22](#)). Absent diastolic flow should prompt a complete fetal evaluation, because almost half of cases may be due to fetal aneuploidy or a major congenital abnormality ([Wenstrom and associates, 1991](#)). In the absence of a fetal anomaly or a reversible maternal medical complication, absent or reversed end-diastolic flow should prompt consideration for delivery.

Another measure of resistance to blood flow is provided by the Pourcelot index, or resistance index ([Fig. 41-20](#)). This index is the difference between the systolic and diastolic values, divided by the systolic value ($(S - D)/S$, also expressed as $1 - [D/S]$). This ratio is also applicable only to the umbilical and the uterine arteries, as low diastolic values limit its usefulness in the fetal aorta or other central vessels. The most complicated index to measure is the pulsatility index (systolic-diastolic/time-averaged velocity). It requires a digitized waveform for calculating the mean of the maximal frequencies represented. Because of the mean value in the denominator, this index can be computed using flow data from the fetal descending aorta without encountering the excessive variation that can be caused by division by small numbers as with the other two indices.

TECHNIQUES FOR SPECIFIC VESSELS

UTERINE AND ARCUATE ARTERIES. Uterine blood flow increases from 50 mL/min shortly after conception, to 500 to 750 mL/min by term. Its Doppler waveform shape is unique, characterized by high diastolic velocities similar to those in systole and highly turbulent flow, with many different velocities apparent ([Fig. 41-21](#)). The diastolic velocity increases and thus the indices decrease as term approaches ([Hendricks and co-workers, 1989](#)). A failure of this pattern to appear or the presence of a notch in the waveform at end-systole has been reported with fetal growth restriction ([Schulman and associates, 1986](#)). The external iliac arteries can be distinguished from the uterine arteries because they normally do not have diastolic flow ([Fig. 41-21](#)).

UMBILICAL VEIN. The intra-abdominal portion of the umbilical vein is relatively straight and the flow tends to be constant rather than pulsating. Therefore, the umbilical vein is a reasonable vessel for measuring volume flow rather than indexed flow. Umbilical vein blood flow measurements range from 108 to 153 mL/kg per minute, with decreasing flows as gestation advances ([Gerson and co-workers, 1987](#)).

FETAL DESCENDING AORTA. The descending aorta receives the majority of right-ventricular output via the ductus arteriosus, while the majority of left-ventricular output supplies the fetal head and upper arms. Flow in the descending aorta is highly pulsatile, with little diastolic flow. The straight course of the aorta also makes it amenable to volume flow studies. Waveform flow measurement is limited to the pulsatility index because of the lack of diastolic flow. Measurements of fetal descending aorta blood flow range from 185 to 246 mL/kg per minute ([Eik-Nes and co-workers, 1982](#); [Griffin and associates, 1985](#)).

CEREBRAL BLOOD FLOW. Fetal heart rate testing evaluates the central nervous system control of cardiac function, which can be altered by cerebral hypoxemia. It has been hypothesized that Doppler evaluation of blood flow through cerebral vessels might allow detection of altered cerebral circulation before hypoxemia significant enough to change the fetal heart rate has occurred. The carotid arteries can be identified reliably, but they are too narrow to measure accurately. The middle cerebral artery is the most accessible vessel, and has been reported to demonstrate reductions in the pulsatility index at the onset of hypoxemia ([Wladimiroff and co-workers, 1987](#)). [Chandran and colleagues \(1993\)](#) compared middle cerebral artery pulsatility indices with fetal heart rate analysis in 27 growth-restricted fetuses. They found that Doppler was a more sensitive predictor of hypoxemia at birth than fetal heart rate testing (100 versus 82 percent) but had a lower specificity (50 versus 75 percent).

Middle cerebral artery (MCA) Doppler has been used to assess fetuses with anti-D isoimmunization. [Mari and colleagues \(1997\)](#) studied MCA³ blood velocity in 135 fetuses, and reported that the velocity increases at a predictable rate with advancing gestational age. Interestingly, they found that anemic fetuses have higher velocities than normal. This same group then studied 17 isoimmunized pregnancies and found that MCA Doppler correlated directly with fetal hematocrit ([d'Ancona and associates, 1997](#)). They postulated that it could be used to noninvasively identify anemic fetuses.

FETAL CARDIAC FUNCTION

The measurement of fetal cardiac function may have immediate clinical importance as well as research implications.

CARDIAC OUTPUT. Doppler techniques that measure fetal cardiac output are extremely difficult to apply because of fetal movement, cardiac movement, and the technical factors discussed earlier. Combined use of two-dimensional ultrasound and Doppler echocardiography, however, does allow an assessment of blood flow through the heart. Normal flow patterns have been studied. [Reed and colleagues \(1986a, 1986b\)](#) reported that the normal mean right-ventricular output was 307 mL/kg/min and left-ventricular output was 232 mL/kg/min (right-to-left ventricular output ratio 55:45). [DeSmedt and associates \(1987\)](#) reported a slightly higher value for combined ventricular output. Abnormal flow patterns can be detected by calculating the ratio of right and left cardiac outputs (thus minimizing the effects of measurement errors, which would likely affect both ventricles equally), and by performing serial studies over a short time interval. Abnormal flow patterns suggest the presence of a congenital defect, which can then be studied with two-dimensional images.

DUCTUS ARTERIOSUS. Doppler evaluation of the ductus can be used to monitor fetal status and response to specific medications. Indomethacin is a prostaglandin synthase inhibitor used for tocolysis which has been implicated in premature (antenatal) closure of the ductus arteriosus. Premature closure leads to retrograde blood flow through the tricuspid valve or into the pulmonary arteries. Resulting increased pulmonary flow then causes reactive hypertrophy of the pulmonary arterioles and eventually pulmonary hypertension. [Huhta and colleagues \(1987\)](#) first observed reversible ductal constriction in three fetuses whose mothers received indomethacin for treatment of preterm labor. They subsequently confirmed ductus constriction in exposed lamb and human fetuses but not in 25 normal pregnancies. [Vermillion and colleagues \(1997\)](#) studied 61 indomethacin-treated women and reported that half of exposed fetuses developed ductal constriction. Fortunately, ductal constriction is largely reversible if medication is discontinued before 32 weeks ([Moise, 1993](#)).

FETAL ARRHYTHMIAS. Using several techniques, a variety of fetal cardiac arrhythmias can be diagnosed, and many can be treated antenatally. Most commonly, diagnosis requires a two-dimensional, real-time ultrasound examination to evaluate cardiac anatomy, followed by an M-mode echocardiographic evaluation to characterize the arrhythmia. An electrocardiogram (ECG), which documents the electrical depolarizing events in the heart, cannot be obtained in a fetus. M-mode echocardiography, however, measures the mechanical response to the depolarizing events, and thus can provide similar information indirectly. It is useful for diagnosing fetal cardiac arrhythmias, and in assessing ventricular wall function and functional atrial and ventricular outputs as well as the timing of these events. Precise diagnosis of a fetal arrhythmia is important because some, for example, supraventricular tachycardia, require pharmacological treatment to prevent or treat heart failure. Others, for example, premature atrial contractions, resolve spontaneously and need not be treated. The antenatal treatment of fetal arrhythmias is discussed in [Chapter 37](#).

FETAL WELL-BEING. A recurring goal for Doppler ultrasound is that it could somehow be used to distinguish normal from abnormal pregnancies. It has been investigated as a means to predict fetal growth restriction, hypoxia, and distress. It has also been proposed that abnormal uteroplacental waveforms may identify women at risk for preeclampsia. Applications of this technology are discussed in relation to its use in the diagnosis and management of a variety of pregnancy complications, and their management is presented throughout this book. Doppler velocimetry has been proposed as a method of fetal surveillance, as discussed in [Chapter 40](#). According to the [American College of Obstetricians and Gynecologists \(1999\)](#), Doppler velocimetry is not recommended for screening to detect fetuses at risk. It may have benefits in surveillance for suspected fetal growth restriction. Finally, the College considers fetal middle cerebral artery velocimetry to be investigational.

TABLE 41-1. Some Indications for Obstetrical Ultrasonic Examinations

Estimation of gestational age with uncertain dates or verification of dates for women undergoing repeat cesarean delivery, labor induction, or elective abortion
Evaluation of fetal growth
Vaginal bleeding of undetermined etiology
Determination of fetal presentation
Suspected multiple gestation
Adjunct to amniocentesis
Significant uterine size/clinical dates discrepancy
Pelvic mass
Suspected molar pregnancy
Suspected ectopic pregnancy
Adjunct to special procedures, e.g., cerclage
Suspected fetal death
Suspected uterine abnormality
Intrauterine contraceptive device localization
Biophysical evaluation of fetal well-being
Observation of intrapartum events
Suspected polyhydramnios or oligohydramnios
Suspected abruptio placentae
Adjunct to external version from breech to vertex presentation
Estimation of fetal weight and/or presentation in preterm prematurely ruptured membranes and/or preterm labor
Abnormal serum alpha-fetoprotein value
Follow-up observation of identified fetal anomaly
Follow-up evaluation of placental location for identified placenta previa
History of previous congenital anomaly
Serial evaluation of fetal growth in multifetal gestation
Evaluation of fetal condition in late registrants for prenatal care

As adapted from the National Institutes of Health (1984) by the American College of Obstetricians and Gynecologists (1993).

SECTION XII - MEDICAL AND SURGICAL COMPLICATIONS IN PREGNANCY

42. General Considerations and Maternal Evaluation

Medical and surgical illnesses complicating pregnancy require collaboration between obstetrician, internist, surgeon, anesthesiologist, and frequently other specialists. Because pregnancy does not make a woman immune to any disease, obstetricians must have a working knowledge of medical and surgical diseases common to childbearing-age women. Likewise, nonobstetricians should be familiar with effects that these diseases have on the pregnant woman, or vice versa. Importantly, normal pregnancy-induced physiological changes must be interpreted in relation to their effects on underlying nonobstetrical disorders. Finally, changes induced by pregnancy in many laboratory tests must be considered.

The purpose of this chapter is to review generalizations concerning the rational approach to management of pregnancy when complicated by medical or surgical diseases. One axiom to consider is: **A woman should never be penalized because she is pregnant.** Put another way: If a proposed medical or surgical regimen is altered simply because the woman is pregnant, can it be justified? This approach still allows individualization of care for women with most medical and surgical disorders that complicate pregnancy. Importantly, it may be especially helpful when dealing with consultants asked to see these women.

PHYSIOLOGICAL ALTERATIONS AND CHANGES IN LABORATORY VALUES

Pregnancy induces profound physiological changes in most organ systems and these may amplify or obfuscate evaluation of coincidental medical and surgical disorders. The wide ranges of pregnancy effects on normal physiology are discussed in [Chapter 8](#) and are reviewed in the various chapters that follow.

Along with the marked physiological changes induced by pregnancy, a number of standard laboratory evaluations are also altered. Some of these would, in the nonpregnant woman, suggest marked aberrations or conversely, normalcy, at a time when the woman was either completely normal or actually quite ill. Many normal laboratory values for pregnancy are discussed both in [Chapter 8](#) as well as in the following chapters in which the effects of superimposed disease are considered.

MEDICATIONS DURING PREGNANCY

Consideration for antepartum management of medical and surgical disorders always includes administration of a variety of drugs. Fortunately, the vast majority of medications necessary for management of the most commonly encountered complications can be used with relative safety. There are, however, a few notable exceptions. These are considered in detail in [Chapter 38](#) as well as in individual chapters in this section.

SURGERY DURING PREGNANCY

EFFECT OF SURGERY AND ANESTHESIA ON PREGNANCY OUTCOME

The risk of an adverse pregnancy outcome does not appear to be increased in women undergoing most uncomplicated surgical or anesthetic procedures. This risk may be increased, however, when surgical disorders or procedures are associated with complications. For example, complications from perforative appendicitis with feculent peritonitis are associated with increased maternal and perinatal morbidity and mortality even if surgical and anesthetic techniques are flawless. Conversely, if there are complications from these procedures, pregnancy outcome may be adversely affected. By way of example, if the woman who undergoes uncomplicated surgery for nonperforative appendicitis suffers vomiting with aspiration of acidic gastric contents, then resulting respiratory failure may cause fetal death, preterm labor, or both, as well as significant maternal morbidity and even mortality.

The most extensive experiences regarding anesthetic and surgical risks to pregnancy are from the Swedish Birth Registry and reported by [Mazze and Kallen \(1989\)](#). These investigators studied the effects of 5405 nonobstetrical surgical procedures performed in 720,000 pregnant women from 1973 to 1981 ([Table 42-1](#)). Surgery was performed most commonly in the first trimester—41 percent—compared with 35 percent in the second trimester and 24 percent in the third. Abdominal surgery comprised a fourth of all operations, and another 19 percent were gynecological and urological procedures. Laparoscopic procedures were done in 16 percent of the women, and the vast majority were performed in the first trimester. Although laparoscopy was the most commonly performed first-trimester operation, appendectomy was the most commonly done procedure in the second trimester.

The types of anesthesia administered to the 5405 women in the Swedish report are shown in [Table 42-2](#). Over half of these procedures were done using general anesthesia, and in 98 percent of these, nitrous oxide supplemented by another inhalation agent or intravenous medication was used.

PERINATAL OUTCOMES. [Mazze and Kallen \(1989\)](#) concluded that excessive perinatal morbidity associated with nonobstetrical surgery during pregnancy was attributable to the disease itself, rather than to adverse effects of surgery and anesthesia. They compared pregnancy outcomes for the 5405 women undergoing surgery with those in the total database of 720,000 pregnancies. As shown in [Table 42-3](#), there was a significantly increased incidence of low-birthweight and preterm infants as well as neonatal deaths by 7 days in women who had undergone surgery.

An important observation from the Swedish study is that stillbirth and congenital malformation rates were not increased significantly. The latter observation is strengthened by the report from [Czeizel and colleagues \(1998\)](#) that anesthetic agents are not teratogenic. In another report, however, [Kallen and Mazze \(1990\)](#) scrutinized 572 operations performed on the Swedish women at 4 to 5 weeks' gestation. They found a possible causal relationship with increased neural-tube defects. [Sylvester and co-workers \(1994\)](#) analyzed first-trimester outcomes in the Metropolitan Atlanta Congenital Defects Program. In a case-control study, they found a significantly increased risk of hydrocephaly associated with other major defects—especially eye anomalies—in women exposed to general anesthesia. Thus, as [Rosen \(1999\)](#) concluded, we cannot state categorically that anesthetic agents are not teratogenic.

LAPAROSCOPIC SURGERY DURING PREGNANCY

Over the past decade, the use of laparoscopic techniques has become common for diagnosis and management of a number of surgical disorders complicating pregnancy. The obvious application is diagnosis and management of ectopic pregnancy ([Chap. 34, p. 894](#)). With established pregnancy, in most studies laparoscopy has been used for exploration and treatment of adnexal masses ([Chap. 35, p. 930](#)), or for cholecystectomy or appendectomy ([Chap. 48, pp. 1296 and 1281](#)). [Lachman and colleagues \(1999\)](#) recently reviewed 518 reported procedures that were performed during pregnancy. Cholecystectomy was the most common (45 percent), followed by adnexal surgery (34 percent), and appendectomy (15 percent).

The precise effects of laparoscopy in the human fetus are currently unknown. Studies of pregnant ewes have been reported by [Barnard and associates \(1995\)](#) and [Hunter and colleagues \(1995\)](#). Using carbon dioxide insufflation for pneumoperitoneum, they found that uteroplacental blood flow falls when pressure exceeds 15 mm Hg. This was due to decreased perfusion pressure and increased placental vessel resistance. In some, but not all of the fetuses, acidemia developed. [Reedy and colleagues \(1995\)](#) studied these effects in baboons at the human equivalent gestation of 22 to 26 weeks. While there were no substantive changes at 10 mm Hg insufflation, pressure of 20 mm Hg caused significant maternal cardiovascular and respiratory changes by 20 minutes. Some of these include increased respiratory rate, respiratory acidosis, diminished cardiac output, and increased pulmonary artery pressure with concomitantly increased wedge pressure.

To study the impact of laparoscopy on perinatal outcomes, [Reedy and colleagues \(1997b\)](#) used the updated Swedish Birth Registry described earlier. From 1973 to 1993, the database contained outcomes from slightly over 2 million deliveries. During this same time, 2181 laparoscopies and 1522 laparotomies were performed during pregnancy in these women. As shown in [Figure 42-1](#), laparoscopy was used primarily in the first trimester. These investigators compared perinatal outcomes with surgery versus those in the overall database. While they found an increased risk of low birthweight, preterm delivery, and fetal growth restriction in the operative group, there were no differences in outcome when laparoscopy and laparotomy were compared. The risk for congenital malformations also was not different in any of the comparisons.

Risks inherent to laparoscopy do not appear increased compared with those in nonpregnant women. These risks appear to be uncommon, and indeed [Nezhat and associates \(1997\)](#) found no complications in their literature review. Conversely, [Reedy and co-workers \(1997a\)](#) surveyed 192 laparoscopic surgeons by mail and reported a number of complications, including those inherent to laparoscopy as well as one case of intrauterine placement of the Veress needle.

Many clinicians recommend **gasless laparoscopy** during pregnancy. This accomplishes two goals: it avoids cardiovascular changes with pneumoperitoneum and it

decreases the risk of uterine perforation with the trocar or Veress needle. [Akira and co-workers \(1999\)](#) compared this technique with laparotomy in 35 women undergoing ovarian cystectomy at 12 to 16 weeks. They reported significant benefits with laparoscopy. For a detailed discussion of techniques, the reader is referred to [Chapter 26](#) in the second edition of *Operative Obstetrics* by [Gilstrap and colleagues \(2001\)](#).

IMAGING TECHNIQUES

A number of imaging modalities are used as an adjunct for both diagnosis and therapy during pregnancy. These include ultrasound, magnetic resonance imaging, and x-ray. Of these, x-ray is the most worrisome to both the obstetrician and the patient with regard to fetal safety. Although now less common, some radiological procedures are performed prior to recognition of early pregnancy. These procedures are usually undertaken because of emergencies such as trauma or life-threatening illness. Fortunately, most diagnostic x-ray procedures are associated with little or no known significant fetal risks. As with drugs and medications, however, radiological procedures during pregnancy may lead to litigation if there is an adverse pregnancy outcome, including therapeutic abortion because of either patient or physician anxiety.

IONIZING RADIATION

Radiation is a poorly understood term that often is applied not only to x-rays, but also to microwaves, ultrasound, diathermy, and radiowaves. The latter four energy forms have rather long wavelengths and are of low energy ([Brent, 1999](#)). Conversely, x-rays and gamma rays have short wavelengths with very high energy, and are forms of ionizing radiation. The types of radiation and their biological effects are summarized in [Table 42-4](#).

Ionizing radiation from x-rays and gamma rays, with their high energy, is of primary concern from a biological standpoint. Ionizing radiation refers to waves or particles (photons) of significant energy that can break chemical bonds, such as those in DNA, or create free radicals or ions capable of causing tissue damage ([Hall, 1991](#)). Methods of measuring x-ray effects are summarized in [Table 42-5](#). The standard terms used are the exposure (in air), the dose (to tissue), and the relative effective dose (to tissue). In the range of energies for diagnostic x-rays, the dose, expressed in rad, and the relative effective dose, expressed in rem, are the same and these units can be used interchangeably. For the sake of consistency, all doses to follow will be expressed in rad, the traditional unit, or in gray (Gy), the modern unit (1 Gy = 100 rad).

X-RAY DOSE ESTIMATION. When calculating the dose of ionizing radiation such as that from x-ray, several factors are considered:

1. Type of study.
2. Type and age of equipment.
3. Distance of the organ in question from the source of radiation.
4. Thickness of the body part penetrated.
5. Method or technique used for the study ([Wagner and colleagues, 1997](#)).

When evaluating dose estimates, consideration is given not only to the mathematical model used but also to when the data were compiled. The use of faster screen film combinations, higher-frequency x-ray generators, and other technical improvements have contributed significantly to reduce radiation exposures in recent years.

Estimates of dose to the uterus and embryo for a variety of commonly used radiological examinations (plain film) are summarized in [Table 42-6](#). Radiological studies of maternal body parts at the greatest distances from the uterus—for example, the head—result in a very small dose of scattered radiation to the developing embryo or fetus. The specific anthropometric features of the woman, x-ray techniques used, and performance parameters of the equipment should all be considered. Thus, data presented in the tables should serve only as a guideline. When the radiation dose for a specific individual is required, a medical physicist can be consulted.

POTENTIAL ADVERSE FETAL EFFECTS. The harmful effects of radiation exposure according to [Brent \(1999\)](#) are direct or indirect:

1. Cell death, which affects embryogenesis.
2. Growth restriction.
3. Congenital malformation.
4. Carcinogenesis (controversial).
5. Microcephaly and neonatal mental retardation.
6. Sterility.

The harmful fetal effects of ionizing radiation have been extensively studied in the case of cell damage with resultant dysfunction of embryogenesis, both in the animal model as well as from human studies of Japanese atomic bomb survivors.

ANIMAL STUDIES. Interestingly, adverse radiation effects in animals appear to be somewhat different than in humans. A number of animal studies have addressed these potential embryopathological effects ([Brent, 1971, 1999](#); [Wilson and colleagues, 1953](#)). Several conclusions can be drawn:

1. High-dose ionizing radiation is most likely to be lethal to the preblastocyst during the preimplantation stage—the embryo is very insensitive to teratogenic or other effects of radiation at this time.
2. During the period of organogenesis, high-dose radiation is more likely to cause teratogenic changes, growth restriction, or lethal effects.
3. During the fetal period, the fetus will more likely manifest growth restriction and central nervous system effects.

In animal studies, various organs manifest teratogenic effects, whereas in humans, growth restriction and central nervous system anomalies are the most common following high-dose ionizing radiation. Most studies involved large doses—100 to 200 rad (1 to 2 Gy)—and a threshold phenomenon has been demonstrated ([Brent, 1999](#)). Unfortunately, as with drugs and medications, it is not always possible to extrapolate animal data directly to the human.

HUMAN DATA. Possible adverse human fetal effects of high-dose ionizing radiation are principally derived from two sources. One includes earlier reports of large-dose radiation given to treat women for malignancy, menorrhagia, and uterine myomas ([Brent, 1989](#)). [Goldstein and Murphy \(1929\)](#) reported that adverse effects of estimated radiation exposure of over 100 rad were either microcephaly or hydrocephaly in 19 of 75 exposed embryos. Other adverse effects included mental retardation, abnormal genitalia, growth restriction, microphthalmia, and cataracts. [Dekaban \(1968\)](#) reported 22 infants with microcephaly, mental retardation, or both following exposure to an estimated 250 rad in the first half of pregnancy. In both of these studies, other organ malformations were not found unless there was microcephaly, eye abnormalities, or growth restriction ([Brent, 1999](#)).

The second and most often quoted human data are derived from multiple studies of atomic bomb survivors from Hiroshima and Nagasaki ([Miller and Mulvihill, 1982](#); [Otake and co-workers, 1987](#)). Adverse effects from in utero exposure to fallout from the atomic bomb in these two cities was summarized by [Yamazaki and Schull \(1990\)](#). As shown in [Figure 42-2](#), there is an increased risk of microcephaly and severe mental retardation with high exposure beginning at certain gestational ages. The risk is greatest at 8 to 15 weeks, and larger doses were necessary at 16 to 25 weeks to cause an equivalent proportion of mental retardation. Another important observation is the suggestion of a nonthreshold linear relationship of radiation dose at 8 to 15 weeks, so that even very low doses will cause a slight increase in mental retardation compared with the general population ([Hall, 1991](#)). There is no documented increased risk of mental retardation in humans at gestational ages less than 8 weeks or greater than 25 weeks, even with doses exceeding 50 rad ([Committee on Biological Effects, 1990](#)).

The effect of ionizing radiation on intelligence quotient (IQ) scores in children who were exposed in utero is also dependent on gestational age as well as radiation

dose. The highest risk again is at 8 to 15 weeks, followed by 16 to 25 weeks for doses greater than 50 rad.

The implications of these findings seem straightforward. At 8 to 15 weeks, the embryo is most susceptible to radiation-induced mental retardation. This risk is probably a nonthreshold linear function of dose, with the risk of severe mental retardation being as low as 4 percent for 10 rad and as high as 60 percent for 150 rad ([Committee on Biological Effects, 1990](#)). These doses are many hundreds of times higher than from diagnostic radiation. Cumulative doses from multiple procedures may enter that harmful range, however, especially at 8 to 15 weeks' gestation. At 16 to 25 weeks, the risk is less, and there is no proven risk at 0 to 8 weeks or after 25 weeks.

Current evidence suggests that there is no increased fetal risk of malformations, growth restriction, or abortion from a radiation dose of less than 5 rad ([Brent, 1999](#)). In fact, the risk of spontaneous abortion, malformations, and fetal growth restriction in the general population not exposed to diagnostic radiation is much greater than that which can be theorized from exposure to 1 to 5 rad. According to [Brent \(1999\)](#) gross congenital malformations will not be increased in a human pregnant population exposed to less than 20 rad (0.2 Gy).

ONCOGENIC EFFECTS OF IONIZING RADIATION. It is controversial whether there is an association between in utero diagnostic radiation exposure and an increased risk of childhood cancers. According to some investigators, these cancers, and especially leukemia are increased ([Diamond and colleagues, 1973](#); [Shu and associates, 1994](#); [Stewart and Kneale, 1970](#)). Conversely, [Brent \(1999\)](#) and others have questioned such an association, and according to the [National Radiological Protection Board \(1993\)](#) of the United Kingdom, the risk barely exceeds threshold for diagnostic studies. The relative risk of childhood leukemia from fetal exposure of 1 to 2 rad has been estimated from several studies to be 1.5 to 2.0, or from 1 in 3000 in the general population to about 1 in 2000 after exposure ([Chap. 18, p. 438](#)). [Brent \(1999\)](#) emphasizes that if elective abortion is chosen based on this, 2000 exposed normal fetuses would be aborted for each case of leukemia prevented—a risk much lower than that for a sibling of a leukemic child, which is approximately 1 in 700.

In another study, two cases of childhood cancer were detected among 1630 atomic bomb survivors, each of whom had high exposure ([Committee on Biological Effects, 1990](#)). The data are not yet available on whether atomic bomb survivors are at risk for adult cancers, but late-occurring carcinogenic effects have been observed in laboratory mice exposed to high radiation doses.

THERAPEUTIC RADIATION. According to the Radiation Therapy Committee Task Group of the American Association of Physics in Medicine, about 4000 pregnant women annually undergo cancer therapy in the United States ([Stovall and colleagues, 1995](#)). They emphasize careful individualization of radiotherapy as a chosen alternative ([Chap. 55, p. 1440](#)). For example, shielding of the fetus can be done for many procedures, and the Task Group has detailed some of those in its report. Despite these precautions, the fetus may be exposed to unacceptable doses of radiation, and thus a carefully designed plan, including dosimetry calculation, must be considered.

DIAGNOSTIC RADIATION. As previously discussed, therapeutic abortion is not indicated because of fetal exposure to a single diagnostic x-ray procedure ([Brent, 1999](#)). To put fetal risk into perspective, it is important to know the dosimetry of x-ray procedures, realizing that averages are crude estimates. **According to the American College of Radiology (Hall, 1991), no single diagnostic procedure results in a radiation dose significant enough to threaten the well-being of the developing embryo and fetus.**

PLAIN FILMS. Doses for standard plain film x-rays are presented in [Table 42-6](#). The most commonly used is the chest x-ray. Fetal exposure is exceptionally small (0.07 mrad), even for two views, and it is far below any significant risk for any gestational age. The single abdominal film has a higher dose because the embryo or fetus is directly in the x-ray beam. Its average exposure is approximately 100 mrad. Three films taken for a lumbosacral spine series increase the exposure to 300 mrad. The intravenous pyelogram may exceed 1 rad because of the number of films taken. For this reason, as discussed in [Chapter 47 \(p. 1259\)](#), the one-shot pyelogram may be useful when urolithiasis or other causes of urinary obstruction are suspected but unproven by ultrasound. Most "trauma series," such as x-rays of an extremity, skull, or rib series, deliver low doses because of the fetal distance from the target area. The single hip film is the highest of these, at 200 mrad.

Fetal indications for plain film studies are very limited; the most common is evaluation of the bony pelvis with breech presentation. As discussed in [Chapter 22 \(p. 512\)](#), this is usually done by computed tomographic scanning. Another example is a suspected fetal skeletal anomaly when the ultrasonic diagnosis is unclear, such as with caudal regression syndrome and sirenomelia.

FLUOROSCOPY AND ANGIOGRAPHY. Dosimetry calculations for fluoroscopy and angiography are much more difficult because of variations in the number of x-ray films obtained, fluoroscopy time, and the amount of fluoroscopy time the fetus is in the radiation field. As shown in [Table 42-7](#), the range is quite variable. Although the Food and Drug Administration limits exposure rate for conventional fluoroscopy such as barium studies, special-purpose systems such as angiography units have potential for much higher exposure.

Commonly performed studies involving routine fluoroscopy are the upper gastrointestinal series and barium enema. Frequently, these are done early in pregnancy during the period of preimplantation or early organogenesis and most often before the woman is aware that she is pregnant. As expected, the upper gastrointestinal series has significantly less exposure to the fetus than a barium enema. Because of this exposure, gastrointestinal endoscopy is commonly used when a pregnant woman needs evaluation ([Chap. 48, p. 1296](#)).

Angiography may occasionally be necessary in pregnancy for some maternal complications. As in the case of plain film x-rays, the farther the distance from the embryo or fetus, the less the exposure risk. Angiographic procedures should be performed when the information obtained alters pregnancy management.

COMPUTED TOMOGRAPHY. Scanning using computed tomography has become an important imaging modality for evaluation of all organ systems. In simple terms, it involves multiple exposures of very thin x-ray beams in a 360-degree circle with computerized interpretations of these exposures. The result is an axial (and occasionally sagittal) image of a body portion, referred to as a slice. Multiple slices of the target body part are obtained along the length of the entire organ or area in question.

Newer-generation tomography equipment is increasingly sensitive; however, higher resolution may be associated with higher radiation exposure. Conversely, because there is less scatter with newer equipment, areas not directly scanned have less exposure. For example, skin exposure from a head tomographic scan will typically be as high as 5 to 6 rad along the area scanned. In the body, doses typically range from approximately 5 rad at the skin surface to 2 rad in the center of the slice.

Spiral computed tomography is a recent advance in tomographic imaging which allows for continuous acquisition of images in a spiral with image reformatting in multiple planes compared with the conventional axial images. The exposure then becomes dependent on the pitch, which is the degree of stretching or tightening of the spiral. The less the pitch, the tighter the spiral, and the greater the exposure. At the present time, a typical pitch (range 1.0 to 2.0) results in radiation from spiral computed tomography exposure that is similar or less than that for conventional computed tomography ([Jurik and colleagues, 1996](#)). Because of its ease and brevity, there is a tendency to increase the number of acquisitions, and this increases radiation exposure ([Zoetelief and Geleijns, 1998](#)).

Many variables in each study affect calculation of radiation doses, especially slice thickness and number of cuts obtained. If a study is performed with and without contrast, twice as many images will be obtained, and the dose to the target area is therefore doubled. Fetal radiation exposure is also dependent on factors such as the size of the mother and the size and position of the fetus ([Ragossino and colleagues, 1986](#)). Finally, the closer the target area is to the fetus, the greater the fetal radiation exposure. Estimated maximal fetal doses from computed tomographic scans are summarized in [Table 42-8](#).

Cranial computed tomographic scanning is the most commonly requested study in pregnant women. Nonenhanced computed tomographic scanning is the preferred imaging technique to detect acute hemorrhage within the epidural, subdural, or subarachnoid spaces, and is usually the initial procedure performed in emergency situations. A contrast scan should not be performed first, because it may mask identification of acute hemorrhage. Cranial computed tomography in women with eclampsia is discussed in [Chapter 24 \(p. 581\)](#).

Computed tomography pelvimetry is performed to evaluate maternal pelvic bony dimension for breech vaginal delivery ([Chap. 18, p. 438](#)). Depending on exposure parameters, fetal dose may approach 1.5 rad, but using a low-exposure technique, this dose can be reduced to 250 mrad ([Moore and Shearer, 1989](#)).

NUCLEAR MEDICINE STUDIES. Ventilation-perfusion lung scans, thyroid scans, and thallium heart scans require the intravenous injection of a radioisotope, which in turn emits radiation that is detected by sensitive cameras. Nuclear medicine studies are performed by "tagging" a radioactive element to a chemical agent. For instance, technetium^{99m} is a radioisotope that can be tagged to red blood cells, sulphur colloid, or pertechnetate, as well as other agents. The method used to tag the agent will determine fetal radiation exposure, particularly if it crosses the placenta, or if it is excreted into urine, whereby fetal proximity to the maternal bladder

increases exposure. The measurement of this radioactive substance is based on its decay, and the units used are the curie (Ci) or the becquerel (Bq). Doses usually are expressed in millicurie (mCi).

Depending on the physical and biochemical properties of a radioisotope, an average fetal exposure can be calculated ([Wagner and co-workers, 1997](#); [Zanzonico, 2000](#)). Commonly used radiopharmaceuticals and the estimated absorbed fetal doses are given in [Table 42-9](#). Recent studies show the exposures will vary with gestational ages and are greatest earlier in pregnancy for most radiopharmaceuticals; an exception is the effect of iodine ¹³¹ on the thyroid. ([Wagner and associates, 1997](#)). Also, the dose of radionuclide can be kept as low as possible ([Adelstein, 1999](#)).

For ventilation-perfusion lung scanning, perfusion is measured with injected ⁹⁹Tc-macroaggregated albumin and ventilation with inhaled xenon ¹²⁷ or xenon ¹³³. Fetal exposure with either is negligible ([Ginsberg and associates, 1989](#); [Mountford, 1997](#)).

Thyroid scanning with iodine ¹²³ or iodine ¹³¹ seldom is indicated in pregnancy. With trace doses used for this, however, fetal risk is minimal. Therapeutic radioiodine in doses to treat Graves disease or thyroid cancer may cause fetal thyroid ablation ([Green and colleagues, 1971](#)).

The sentinel lymphoscintigram for detecting the axillary lymph node most likely to have tumor in the case of breast cancer has emerged as a popular preoperative study to replace lymph node dissection ([DeAngelis and co-workers, 1999](#)). The calculated dose is low and should not preclude its use during pregnancy.

ULTRASOUND

Diagnostic ultrasonography employs sound wave transmission at certain frequencies. At very high intensities, there is a potential for human tissue damage from heat and cavitation ([Dakins, 1991](#); [Merritt, 1989](#)). In the low-intensity range of real-time imaging, however, no fetal risks have been demonstrated in more than 35 years of use ([Maulik, 1997](#); [Miller and colleagues, 1998](#)). [Naumburg and associates \(2000\)](#) recently performed a case-control study of 578 children with leukemia. When compared with healthy controls, a third of each cohort was found to have been exposed to ultrasound in utero.

Recent advances in technology have introduced Doppler-shift imaging coupled with gray-scale imaging to localize spectral waveforms and superimpose color mapping. Higher-energy intensities are used with this duplex Doppler imaging.

As of 1992 ultrasound equipment allows video displays of the thermal index and mechanical index. At the present time, unless ultrasound contrast is employed or temperature increases to the fetus exceed 0.5°C, then no potential risk is expected ([Miller and associates, 1998](#)). The thermal index applies to the Doppler evaluation, most commonly employed to evaluate the fetal heart and in the case of suspected growth restriction. In the case of Doppler, adverse effects reflected in thermal index changes have not been demonstrated in clinical situations ([Maulik, 1997](#)).

There is no contraindication to ultrasound imaging of maternal organs during pregnancy. To date, no documented harmful fetal effects have been reported from ultrasound imaging, nor would such effects be predicted from this nonionizing imaging modality. The wide range of clinical uses of ultrasound in pregnancy are further discussed in [Chapter 41](#) as well as in most other sections of this book.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) has emerged as a major imaging modality in recent years because of high soft-tissue contrast, ability to characterize tissue, and ability to acquire images in any plane—particularly axial, sagittal, and coronal. Rather than ionizing radiation, magnetic resonance imaging employs powerful magnets to temporarily alter the state of hydrogen protons and molecules, especially water. Through a series of acquisitions, information about the location and characteristics of these hydrogen protons can be obtained as they are returned to their normal state. Because of these established attributes, magnetic resonance imaging has become a useful tool in both obstetrical and gynecological imaging. Technological advances have significantly reduced scan times—and thus cost—and they have improved image quality.

PRINCIPLES. Images are based on the radiofrequency signal emitted by hydrogen nuclei after they have been "excited" by radiofrequency pulses in the presence of a strong magnetic field. The radiofrequency signal emitted has characteristics called *relaxation times*. These include the T₁-relaxation time (longitudinal) and the T₂-relaxation time (transverse). In a magnetic field, protons will align themselves in the same direction as the field running through the bore of the magnet. If a radiofrequency pulse is applied, these protons are forced out of alignment and rotate in phase with one another. The T₁-relaxation is the time it takes for protons to realign with the magnetic field after a radiofrequency pulse is applied. T₂-relaxation is the time it takes for the protons to dephase from each other after a radiofrequency pulse is applied. Because these properties vary among tissues, they are the factors principally responsible for contrast among tissues. The signal intensity of one tissue compared with another—contrast—can be manipulated by varying the elapsed time between application of radiofrequency pulses, which is called the *repetition time*. Further manipulation by the time between a radiofrequency pulse and a sampling of the emitted signal is called the *echo-delay time*. The strength of the magnetic field within the bore of the magnet is measured in tesla (T) (1 tesla = 10,000 gauss).

TECHNIQUE. Tomograms are generated by application of radiofrequency pulse sequences in the presence of different external gradient magnetic fields that determine spatial encoding. The signals are interpreted and constructed into a digital image by a computer. Manipulations of the pulse sequence parameters and gradient fields can yield tomograms with different information in any plane through the entire body. Multiple sequences are employed with magnetic resonance imaging to define anatomy, pathology, and physiological properties of tissues. T₁- and T₂-weighted sequences are often part of a magnetic resonance imaging study, yielding tissue characteristics, anatomical detail, and abnormalities such as edema.

SAFETY. There have been three major areas examined concerning the potential effect of magnetic resonance imaging at field strengths used clinically, that is, those less than 2 tesla. These areas include the effects from static magnetic fields, gradient magnetic fields, and radiofrequency magnetic fields ([Wagner and associates, 1997](#)). To date, there are no reported harmful human effects from its use, including any mutagenic effects ([American College of Radiology, 1998](#); [Elster, 1994](#); [Wagner and colleagues, 1997](#)). In the study by [Vadeyar and associates \(2000\)](#), there were no demonstrable fetal heart rate pattern changes during imaging.

Absolute safety cannot be assured until larger studies are available for outcome analysis. The 1998 Standards of the American College of Radiology recommend that each request for a magnetic resonance imaging scan of a pregnant patient should be approved by the attending radiologist who will make the final decision. Indicated magnetic resonance imaging should be performed at any gestational age if no other imaging studies can be performed ([American College of Radiology, 1998](#); [Wagner and colleagues, 1997](#)).

Contraindications to the use of magnetic resonance imaging include internal cardiac pacemakers, neurostimulators, implantable cardiac defibrillators, implantable electronic infusion pumps, cochlear implants, and some other devices. Certain intracranial aneurysm clips and any metallic foreign body in the globe of the eye contraindicate scanning.

MATERNAL INDICATIONS. Magnetic resonance imaging pelvimetry has been performed and is quite accurate in providing appropriate measurements of the pelvic inlet and midpelvis in the case of breech presentation ([Chap. 22, p. 512](#)). Its advantage over computed tomography is the improved resolution of the sagittal plane. Computed tomographic pelvimetry can be performed much more rapidly, however, which is a key advantage for women in labor.

Magnetic resonance imaging in maternal disorders unrelated to pregnancy has the advantage over computed tomography because of the lack of ionizing radiation. In some cases, it may be complementary to computed tomographic imaging, and in others it is preferable. For example, central nervous system abnormalities, such as brain tumors or spinal trauma, are clearly seen with magnetic resonance imaging ([Mantello and associates, 1993](#)). Evaluation of lumbar disc pathology is preferably with magnetic resonance imaging ([LaBan and co-workers, 1995](#)). Due to its greater accessibility, however, cranial computed tomography is the procedure of choice with trauma or if acute hemorrhage is suspected. Magnetic resonance imaging in eclampsia with T₁- and T₂-spin echo acquisitions and magnetic resonance angiography with phase-control imaging has given valuable insights into pathophysiology ([Cunningham and Twickler, 2000](#); [Morris and colleagues, 1997](#)). T₂-weighted images such as that shown in [Figure 42-3](#) thus far demonstrate edema predominantly of the occipital lobes in eclampsia, typically confined to the gray-white matter junction ([Digre and colleagues, 1993](#)). *Magnetic resonance angiography* such as that shown in [Figure 42-4](#), can be used to calculate flow of middle-sized vessels such as the middle and posterior cerebral arteries. This has been useful to measure blood flow alterations induced by vasospasm.

Magnetic resonance imaging is particularly useful to evaluate the abdomen and retroperitoneal space during pregnancy. In this regard, it is preferable to computed tomography, which involves fetal radiation. Some examples include detection and localization of adrenal tumors including pheochromocytoma ([Chap. 50](#)), some gastrointestinal lesions ([Chap. 48](#)), as well as a number of intra-abdominal malignancies, including lymphoma, renal cell carcinoma, and hepatic tumors ([Chap. 55](#)).

Magnetic resonance imaging has been employed as an adjunct to transabdominal and transvaginal sonography in the characterization of uterine and ovarian masses in pregnancy ([Curtis and colleagues, 1993](#); [Kier and co-workers, 1990](#)). Resolution obtained with its use is superior to ultrasonic imaging; however, improved resolution does not alter diagnosis or management in most cases ([Fernandez and colleagues, 1995](#)). As shown in [Figure 42-5](#), magnetic resonance imaging clearly delineates myomas that are associated with pregnancy.

Postpartum complications of infection that include parametrial phlegmon, abscess, uterine dehiscence, and ovarian vein thrombosis can be imaged using either computed tomography or magnetic resonance imaging ([Brown and associates, 1999](#); [Twickler and colleagues, 1997](#); [Woo and co-workers, 1993](#)). Because of the ability of magnetic resonance imaging to project in the sagittal plane, it may provide better visualization of the bladder flap following cesarean section ([Twickler and associates, 1991](#)). A further advantage of magnetic resonance imaging may be the computerized reconstruction of the abdominal venogram ([Fig. 42-6](#)). Magnetic resonance imaging can also be used to further characterize a bladder flap mass, differentiating hematoma from abscess.

FETAL INDICATIONS. Although magnetic resonance imaging has some role in fetal evaluation, ultrasonic imaging remains the mainstay for fetal evaluation. Fast-acquisition sequencing with magnetic resonance imaging now allows it to overcome some of the problems with fetal movement and improved imaging, especially in cases of central nervous system and thoracic abnormalities. This is referred to as **HASTE**—Half-Fourier Acquisition Single slow Turbo spin Echo. [Levine and co-workers \(1999\)](#) found that magnetic resonance images altered the diagnosis in 20 of 66 (40 percent) fetuses with central nervous system abnormalities. In some cases, magnetic resonance imaging may be used to answer very specific questions of fetal anatomy and complex dysmorphism ([Coakley and co-workers, 1999](#)). Recently, a lecithin peak has been observed with magnetic resonance spectroscopy in three term fetuses, raising the possibility of in vivo analysis of lung maturity ([Fenton and associates, 2000](#)).

GUIDELINES FOR DIAGNOSTIC IMAGING DURING PREGNANCY

The [American College of Obstetricians and Gynecologists \(1995\)](#) has reviewed the effects of x-ray, ultrasonography, and magnetic resonance exposure during pregnancy. It has suggested the guidelines given in [Table 42-10](#).

TABLE 42-4. Comparative Aspects of Various Forms of Radiation

Type	Physical Characteristics	Biological Effects
X-rays, γ -rays	Short-wavelength electromagnetic waves, highly penetrating, with the capacity of producing ionization with tissues and subsequent electrochemical reactions.	Electrochemical reaction. Can result in tissue damage with high exposures that result in cell death, mutation, cancer, and developmental defects. Effects are dose related.
Ultrasound	Sound waves with a frequency above the audible range, which produce mechanical compression and rarefactions in matter, and with <i>no</i> capability of producing ionization.	If the energy is high enough, sound waves can cause tissue disruption by cavitation and streaming hyperthermia. None of these effects occur with energies used in diagnostic ultrasonography.
Microwaves (radio frequency), radar, diathermy	Longer electromagnetic waves with variable ability to penetrate, but no ability to produce ionization within tissues.	The primary biological effect is hyperthermia, although possible nonthermal effects are being investigated. Cataract development is the most widely known complication of extensive microwave or radar exposure.
Electromagnetic waves	Very long waves which readily traverse tissue but with insignificant capacity to produce hyperthermia or cytotoxicity.	Electrical and magnetic fields in tissue with no consequences.

TABLE 42-9. Radiopharmaceuticals Used in Nuclear Medicine Studies

Study	Estimated Activity Administered per Examination (mCi)	Weeks' Gestation	Dose to Uterus/Embryo per Pharmaceutical (mrad)	
Brain	20 mCi ^{99m} Tc DTPA	< 12 ^a	880	
		12	700 ^b	
Hepatobiliary	5 mCi ^{99m} Tc sulfur colloid		45	
		5 mCi ^{99m} Tc HIDA	150	
Bone	5 mCi ^{99m} Tc phosphate	< 12	460	
Respiratory				
Perfusion	5 mCi ^{99m} Tc-macroaggregated albumin	< 12	50 ^b	
Ventilation	10 mCi ¹³³ Xe gas		20	
Renal	20 mCi ^{99m} Tc DTPA	< 12	880	
Abscess or tumor	3 mCi ⁶⁷ Ga citrate	< 12	750	
Cardiovascular	20 mCi ^{99m} Tc labeled red blood cells	< 12	500	
		3 mCi ²¹⁰ Tl chloride	< 12	1100
			12	640
		24	520	
		36	300	
	Thyroid	5 mCi ^{99m} Tc O ₄	< 8	240
			0.3 mCi ¹²³ I (whole body)	1.5-6
0.1 mCi ¹³¹ I ^c		Whole body	2-6	15
		Whole body	7-9	88
		Whole body	12-13	160
		Whole body	20	300
		Thyroid-fetal	11	72,000
Thyroid-fetal	12-13	130,000		
Thyroid-fetal	20	590,000		

^aExposures are generally greater prior to 12 weeks' gestation compared with greater gestational age.

^bSome measurements account for placental transfer.

^c¹³¹I is the exception to this rule as its uptake and exposure increases with greater gestational age.

Based on data from Wagner and colleagues (1997).

TABLE 42-10. Guidelines for Diagnostic Imaging During Pregnancy

1. Women should be counseled that x-ray exposure from a single diagnostic procedure does not result in harmful fetal effects. Specifically, exposure to less than 5 rad has not been associated with an increase in fetal anomalies or pregnancy loss.
2. Concern about possible effects of high-dose ionizing radiation exposure should not prevent medically indicated diagnostic x-ray procedures from being performed on the mother. During pregnancy, other imaging procedures not associated with ionizing radiation, such as ultrasonography and magnetic resonance imaging, should be considered instead of x-rays when possible.
3. Ultrasonography and magnetic resonance imaging are not associated with known adverse fetal effects. However, until more information is available, magnetic resonance imaging is not recommended for use in the first trimester.
4. Consultation with a radiologist may be helpful in calculating estimated fetal dose when multiple diagnostic x-rays are performed on a pregnant woman.
5. The use of radioactive isotopes of iodine is contraindicated for therapeutic use during pregnancy.

From the American College of Obstetricians and Gynecologists (1995), with permission.

43. Critical Care and Trauma

Women with a broad spectrum of pathophysiological conditions, some of which may have previously precluded pregnancy, may benefit from technology and expertise in *critical care obstetrics*. Examples include women with structural cardiac lesions or prosthetic heart valves and with functional class III or IV heart disease, women with acute or chronic pulmonary injuries, or those with complications of severe preeclampsia or septic shock syndrome. The pregnant woman is also at risk for trauma, including automobile accidents, attempted suicide, burns, physical abuse, and sexual assaults which may include gunshot and knife wounds. She and her fetus pose unique considerations for critical care, and it is imperative that obstetricians and other members of the health-care team have a working knowledge of these areas.

Because the pregnant woman is usually young and in good health until she suffers from some acute injury, her prognosis will hopefully be better than that of most patients admitted to an intensive care unit. For example, [Lewinsohn and colleagues \(1994\)](#) described 58 obstetrical patients admitted to an intensive care unit with a mean Apache II score of 11 with a mortality risk of 17 percent. Their actual mortality ratio—the ratio between actual and predicted mortality rate—was 0.42, significantly different from the expected 1.0 mortality ratio.

OBSTETRICAL INTENSIVE CARE

In a majority of cases, obstetrical patients who will need intensive care are those with complications specifically related to pregnancy. For example, hemorrhage, along with hypovolemic shock, is a frequent life-threatening complication in a busy obstetrical unit. Uterine atony or lacerations may require hysterectomy to stop hemorrhage ([Chap. 25](#)). It is not unusual for women delivered vaginally to require a surgical procedure to stop bleeding. Examples include vaginal repair of lacerations or laparotomy. Severe preeclampsia and eclampsia are also common obstetrical complications and intensive care is needed antepartum as well as postpartum. Finally, infections with sepsis syndrome are also common in obstetrics.

In many cases, critically ill women will be intensively managed in the obstetrical unit to include the recovery room. In some institutions, there are specialized rooms in the obstetrical suite where necessary equipment and experienced personnel are available. Triage to another specialized unit depends on the acuity of care needed and ability of the facility to provide it. Because of limitations of volume as well as expertise, women who require ventilatory support, invasive monitoring, or pharmacological support of circulation may be better served by transfer to a medical or surgical intensive care unit. The type of unit necessary will be reflected by the medical, surgical, or obstetrical conditions of each patient.

[Mabie and Sibai \(1990\)](#) reported that 0.9 percent of women delivered at the University of Tennessee were admitted to the obstetrical intensive care unit. [Kilpatrick and Matthay \(1992\)](#) reported that only 0.4 percent of obstetrical patients were transferred to the medical-surgical intensive care unit at the University of California, San Francisco. At the University of North Carolina from 1983 through 1990, only 1 of every 400 pregnant or postpartum women required admission to the intensive care unit ([Monaco and colleagues, 1993](#)). At the Medical University of South Carolina only one obstetrical patient was admitted to the intensive care unit every 2 months ([Collop and Sahn, 1993](#)). At Parkland Hospital, 1.7 percent of almost 22,000 women delivered over an 18-month period were admitted to an obstetrical intensive care unit within the labor and delivery unit ([Table 43-1](#)). Only 11, or 3 percent, of these 376 women were transferred to a medical or surgical intensive care unit, usually for intubation and ventilatory support.

For the woman who is undelivered, ideal care is best provided by specially trained obstetricians and obstetrical nurses with experience in critical care medicine. In their absence, a team of physicians and nurses should be assembled to include those with special expertise sufficient to deal with all problem areas. Team members may include obstetricians, anesthesiologists, pulmonologists, cardiologists, and other intensivists.

ORGANIZATION. Patient care standards that have been established for obstetrical as well as intensive care areas must be met. Proper equipment is a basic prerequisite and standard critical care equipment is necessary. Any equipment that may be needed in the obstetrical suite may also be needed in the intensive care unit. The flow-directed pulmonary artery catheter, arterial lines, and ventilators are some mainstays of critical care units. Provisions must also be made for initial neonatal resuscitation and stabilization should delivery occur outside the obstetrical area.

Use of data flow sheets common to intensive care units is recommended. These facilitate quick assessment of the clinical condition. Key components of such flow sheets include hemodynamic parameters, ventilator settings, blood gas analyses, temperature, medications, intake to include specific fluids infused, output, daily weight, and basic laboratory values.

PULMONARY ARTERY CATHETER. In our experiences, invasive hemodynamic monitoring is seldom necessary for the critically ill obstetrical patient. In most of these patients, such monitoring seldom changes management. Some of these women, however, have multiple and complex problems that may be better solved with such monitoring. Pulmonary artery catheterization has been used to diagnose or manage a number of cardiac or pulmonary conditions complicating pregnancy, including myocardial infarction, cardiomyopathy, and mitral stenosis; acute respiratory distress syndrome; amniotic fluid embolism; and severe preeclampsia-eclampsia ([Clark, 1988, 1995, 1997](#); [Cunningham, 1986, 1987](#); [Hankins, 1984, 1985](#), and all of their co-workers). Of equal importance, the information provided by these studies allows for an understanding of the pathophysiology of these as well as other conditions unique to obstetrics. Examples include pulmonary edema associated with the use of β -agonists and hemodynamic alterations of preeclampsia-eclampsia. **With improved understanding of this pathophysiology, the need for invasive monitoring is reduced.** The decision to use invasive monitoring is based on the condition and individual needs of the patient ([Table 43-2](#)).

Invasive monitoring is usually initiated through the internal or external jugular vein or the subclavian vein. The femoral and antecubital veins are used less frequently because of greater difficulty in positioning the catheter. In the woman with a coagulopathy, however, the antecubital approach may be prudent. The method is described in detail by [Clark and colleagues \(1997\)](#).

DATA COLLECTION. Continuous central venous and pulmonary artery pressures and intermittent pulmonary capillary wedge pressure measurements are obtained with the pulmonary artery catheter. Cardiac output can be measured by thermodilution. Heart rate and rhythm are monitored and may be continuously recorded. Systemic arterial pressure can be measured noninvasively by manual or automatic sphygmomanometers or by arterial catheterization.

Several mean pressures are measured: *filling pressures* include central venous and pulmonary capillary wedge pressures; arterial pressures are those of the pulmonary and systemic circulations. Formulas for deriving various cardiopulmonary parameters are shown in [Table 43-3](#). Cardiac output, stroke volume, and systemic and pulmonary vascular resistance can be corrected for body size by division of the values by body surface area to obtain **index values**. Specific body surface area nomograms have not been developed for pregnant women; thus nomograms for nonpregnant adults are used. [Clark and colleagues \(1989\)](#) have determined hemodynamic parameters for healthy nonpregnant and pregnant women at term ([Table 43-4](#) and [Fig. 43-1](#)). Increased blood volume and cardiac output are accommodated by decreased vascular resistance and increased pulse rate.

As emphasized by [Van Hook and Hankins \(1997\)](#), hemodynamic information gained by pulmonary artery monitoring does not always reflect uteroplacental perfusion. Assessment of fetal heart rate pattern is more reliable for this purpose.

DATA INTERPRETATION. Cardiac function is assessed in four areas: **Preload** is determined by intraventricular pressure and volume, thus setting the initial myocardial muscle fiber length. Clinically, the right and left ventricular end-diastolic filling pressures are assessed by central venous pressure and pulmonary capillary wedge pressure, respectively. Cardiac output plotted against central venous or pulmonary capillary wedge pressure constructs a cardiac function curve for the respective ventricle. The ventricular function curve demonstrates that a failing heart requires a higher preload or filling pressure to achieve the same cardiac output as a normally functioning heart ([Fig. 43-1](#)). Therapeutic manipulation of ventricular filling pressures and simultaneous measurement of cardiac output allows calculation of optimal preload at the bedside. Preload can be increased by the administration of crystalloid, colloid, or blood, and it can be decreased by the use of a diuretic or a vasodilator or by phlebotomy.

Afterload is defined as ventricular wall tension during systole and is dependent on end-diastolic ventricular radius, aortic diastolic pressure, and ventricular wall thickness. The extent to which right or left intraventricular pressures rise during systole depends primarily on the pulmonary or systemic vascular resistance ([Fig. 43-2](#)). With heart failure, increases in afterload such as with preeclampsia worsen failure by decreasing both stroke volume and cardiac output. Afterload, like preload, can be increased or decreased therapeutically. Increases are mediated through α -adrenergic stimulation, for example, with phenylephrine. Decreases in afterload or systemic vascular resistance can be achieved with numerous agents. The intermittent intravenous administration of small incremental doses of hydralazine with intermittent arterial pressure monitoring has been proven safe for both mother and fetus. Sodium nitroprusside by continuous intravenous infusion is commonly used in medical intensive care units.

The **inotropic state** of the heart is defined as the force and velocity of ventricular contractions when preload and afterload are held constant. In low-output cardiac failure, both preload and afterload should be optimized. If this fails to restore cardiac output to an acceptable level, attention should be directed to improving myocardial contractility. Beta-agonists such as dopamine, dobutamine, and isoproterenol are effective in improving cardiac output acutely. Digitalis may be used either short term or long term.

Heart rate is important, and either tachycardia or bradycardia may cause problems. If cardiac output is compromised because of bradycardia, treatment either with atropine or cardiac pacing is indicated. Sustained tachycardia can lead to congestive heart failure because of shortened systolic ejection and diastolic filling times or myocardial ischemia, especially with valvar heart disease ([Clark and colleagues, 1985](#)). The pathophysiological basis of tachycardia should be determined and corrected; common causes include fever, hypovolemia, and pain.

COMPLICATIONS. An all-important risk of invasive monitoring is over-interpretation or misinterpretation of data. As emphasized by [Van Hook and Hankins \(1997\)](#), mere placement of the catheter is not beneficial, and it may be harmful. Other complications arise from gaining venous access and can be reduced by attention to detail and by experience. The most common is **pneumothorax**, which complicates 5 percent of subclavian and 0.01 percent of internal jugular vein insertions. Lethal **intrathoracic bleeding** has been reported during attempts at subclavian vein cannulation with injuries to either arteries or veins. The pulmonary artery catheter itself may incite a variety of ventricular and supraventricular **arrhythmias** as it passes through the right side of the heart. Disconnection of the catheter or introducer from the associated intravenous lines causes massive **hemorrhage**. Rare complications include pulmonary artery rupture, pulmonary infarction, sepsis, knotting of the catheter, thromboembolism, and balloon rupture. Given a broad range of medical and surgical patients with conditions necessitating invasive monitoring, 3 percent will sustain a major complication, including death.

CONTROVERSIES. There are no data from large studies in nonpregnant patients that pulmonary arterial catheterization improves outcome. In one of several studies of myocardial infarction, [Connors and colleagues \(1996\)](#) found excessive mortality in patients undergoing catheterization, despite adjusting for severity of disease. In 1997, the [Pulmonary Artery Catheter Consensus Conference](#) was convened by the National Institutes of Health and the Food and Drug Administration. Although this committee did not call for a moratorium on the use of pulmonary arterial catheterization, it acknowledged the need for randomized, controlled trials.

ARTERIAL LINES. Indwelling arterial catheters allow continuous monitoring of systemic blood pressure as well as provide easy access for arterial blood gas samples. Cannulation may be complicated by hematoma, infection, and vessel thrombosis. Serious complications from use of arterial lines, viz., gangrene and loss of a digit or extremity, develop in less than 1 percent of cases.

ACUTE PULMONARY EDEMA

There are two general causes of acute pulmonary edema. Alveolar flooding is caused by either heart failure or permeability edema from alveolar-capillary injury. In many obstetrical cases, a combination of the two is present. In a review of 45,000 pregnancies at the Medical Center of Delaware, [Largoza and colleagues \(1997\)](#) found 40 pregnant women with acute pulmonary edema. Of these, 11 were due to cardiac failure, 11 to tocolytic therapy, 10 to iatrogenic fluid overload, four to preeclampsia, two to infection, and two to renal or hepatic failure. From the University of California, San Francisco, [DiFederico and associates \(1998\)](#) reported that pulmonary edema complicated 0.5 percent of 16,810 deliveries. Commonly associated conditions were preeclampsia (28 percent), preterm labor (24 percent), fetal surgery (17 percent), and infection (14 percent). [Karetzky and Ramirez \(1998\)](#) described 19 cases in 10,852 deliveries, and noncardiogenic pulmonary edema predominated.

In our experiences at Parkland Hospital, in which tocolytic therapy is not used and intravenous crystalloid is administered conservatively in preeclampsia, most cases of pulmonary edema develop in older, usually obese women with chronic hypertension that is further complicated by preeclampsia. These cases often are precipitated by operative delivery with acute blood loss, anemia, and infection ([Cunningham and associates, 1986](#); [Sibai and colleagues, 1987](#)). Of 376 women admitted over an 18-month period to the Obstetrical Intensive Care Unit at Parkland Hospital and shown in [Table 43-1](#), less than 5 percent had pulmonary edema.

A number of disorders that have been associated with acute pulmonary injury and permeability edema in pregnancy are listed in [Table 43-5](#). Although most of these are coincidental, some are unique to pregnancy. For example, pulmonary complications, including aspiration pneumonia and pulmonary edema, are common with eclampsia ([Bhagwanjee and associates, 2000](#); [Mattar and Sibai, 2000](#)). Although questionably a sole cause, the use of β -agonists to forestall labor is associated with pulmonary edema. Occult chorioamnionitis and sepsis may be the primary cause with amplification by β -mimetics. [Amon and associates \(2000\)](#) described a 5 percent incidence of pulmonary edema with tocolytic therapy given to 257 women.

ACUTE RESPIRATORY DISTRESS SYNDROME

This syndrome is the worst form of respiratory failure. It has a mortality rate of 40 to 50 percent in nonpregnant patients, and this increases to 90 percent if acute respiratory insufficiency was triggered or complicated by sepsis. In a series of 31 pregnant women with acute respiratory failure, [Perry and colleagues \(1996\)](#) reported a maternal mortality rate of 25 percent. There is no evidence that delivery improves maternal oxygenation ([Tomlinson and associates, 1998](#)).

Acute respiratory distress syndrome (ARDS) is a pathophysiological diagnosis. It includes both pulmonary alveolar epithelial injuries sustained via the airways and endothelial injuries sustained via the pulmonary vasculature. After recruitment to the site of inflammation by chemokines, neutrophils accumulate and initiate tissue injury by secretion of cytokines. This results in increased pulmonary capillary permeability, loss of lung volume, and shunting with resultant arterial hypoxemia. This has been reviewed recently by [Luster \(1998\)](#) and [Ware and Matthay \(2000\)](#).

Physiological criteria required for diagnosis of the syndrome differ, but it is important to remember that respiratory failure is a continuum from mild pulmonary insufficiency to total mechanical ventilatory dependence. For research purposes, most investigators define acute respiratory distress syndrome as diffuse pulmonary infiltrates on chest x-ray, ratio of arterial oxygen tension to the fraction of inspired oxygen ($\text{PaO}_2/\text{FiO}_2$) of less than 200 to 250, and no evidence for heart failure ([Ware and Matthay, 2000](#); [Weg and colleagues, 1998](#)).

In nonpregnant patients, sepsis and diffuse infectious pneumonia are the most common single-agent causes of pulmonary failure. In pregnancy, infection, preeclampsia-eclampsia, and hemorrhage are commonly found ([Catanzarite and Willms, 1997](#); [Clark and associates, 1997](#)). [Perry and colleagues \(1996\)](#) reported that almost 40 percent of obstetrical cases were caused by infection or sepsis. Importantly, more than 70 percent of women with pulmonary insufficiency have some combination of sepsis, shock, trauma, and fluid overload. Thus, multiplicity of causes is the rule with acute and severe lung injury.

CLINICAL COURSE. With pulmonary injury, the clinical condition depends largely on the magnitude of the insult, the ability to compensate for it, and the stage of the disease. For example, if the woman presents soon after the initial injury, there commonly are no physical findings except hyperventilation, and arterial oxygenation usually is adequate. Normal pregnancy-induced metabolic alkalosis may be accentuated because of hyperventilation. With continued insult, or with time, auscultatory and radiological evidence for pulmonary disease becomes more obvious. There will usually be decreased lung compliance and increased intrapulmonary blood shunting. There is progressive alveolar and interstitial edema along with extravasation of inflammatory cells and erythrocytes.

Ideally, pulmonary injury will be identified at this early stage, the insult terminated, and specific therapy directed at the injury. If not, then further progression results in acute respiratory failure characterized by marked dyspnea, tachypnea, and hypoxemia. Further loss of lung volume results in worsening of both pulmonary compliance and increasing intrapulmonary shunts. There are diffuse abnormalities by auscultation, and the chest radiograph characteristically demonstrates bilateral lung involvement ([Fig. 43-3](#)). At this phase, injury has progressed to a point that ordinarily will be lethal in the absence of treatment with high inspired oxygen concentrations. Positive airway pressure, whether by mask or by intubation, is frequently necessary at this stage for airspace recruitment.

During the final phase of the respiratory distress syndrome, **intrapulmonary shunts** in excess of 30 percent result in severe and refractory hypoxemia. The marked increase in dead space, often exceeding 60 percent of tidal volume, leads to hypercapnia and an inability to provide ventilation and oxygenation. Metabolic and respiratory acidosis can result in myocardial irritability and dysfunction, which often leads to cardiac arrest. Microscopically, during end-stage disease, intra-alveolar fibrosis and fibroblastic infiltration of the alveolar septum combine to form massive tissue plates that completely mask the original architecture of the lung parenchyma.

MANAGEMENT. In acute and severe lung injury, attempts are made to provide adequate oxygenation of peripheral tissues while ensuring that therapeutic maneuvers do not further aggravate lung injury. While, at least intuitively, increasing oxygen delivery should produce a corresponding increase in tissue uptake, this is difficult to measure ([Evans and Smithies, 1999](#)). Support of systemic perfusion with intravenous crystalloid and blood is imperative ([Chap. 25](#), p. 653). Because sepsis is so commonplace in lung injury, empirical antimicrobial therapy is considered.

Three critical points merit emphasis:

1. Oxygen delivery is directly proportional to cardiac output.
2. The overwhelming majority of transported oxygen is bound to hemoglobin and is *not* in solution. Accordingly, oxygen delivery can be greatly improved by correction of anemia because each gram of hemoglobin carries 1.25 mL of oxygen when 90 percent saturated.
3. Increasing the arterial P_{O_2} from 100 to 200 mm Hg will result in the transport of only 0.1 mL of additional oxygen for each 100 mL of blood.

Reasonable goals in caring for the woman with severe lung injury are to obtain a PaO_2 of 60 mm Hg or 90 percent oxyhemoglobin saturation at an inspired oxygen content of less than 50 percent, and with positive end-expiratory pressures of less than 15 mm Hg. According to [Tomlinson and colleagues \(1998\)](#), delivery of the fetus does not improve maternal oxygenation.

OXYHEMOGLOBIN DISSOCIATION CURVE. The propensity of the hemoglobin molecule to release oxygen is described by the oxyhemoglobin dissociation curve. Simplistically, the curve can be divided into an upper oxygen association curve representing the alveolar-capillary environment, and a lower oxygen dissociation portion representing the tissue capillary environment ([Fig. 43-4](#)). Shifts of the curve have their greatest impact at the steep portion because they affect oxygen delivery. A rightward shift is associated with decreased hemoglobin affinity for oxygen and hence increased tissue-capillary oxygen interchange. Rightward shifts are produced by hypercapnia, metabolic acidosis, increased body temperature, and increased 2,3-diphosphoglycerate levels. During pregnancy, the erythrocyte concentration of 2,3-diphosphoglycerate is increased by approximately 30 percent. This favors oxygen delivery to both the fetus and peripheral maternal tissues ([Rorth and Bille-Brahe, 1971](#)).

Fetal hemoglobin has a higher oxygen affinity than adult hemoglobin and its curve is positioned to the left of the adult curve ([Fig. 43-4](#)). At a level of 50 percent hemoglobin saturation, the maternal PaO_2 is 27 mm Hg compared with 19 mm Hg in the fetus. Under normal physiological conditions, the fetus is constantly on the dissociation, or tissue, portion of the curve. Even with severe maternal lung disease with very low PaO_2 levels, oxygen displacement to fetal tissues is favored. This has been confirmed by studies of pregnant women and their fetuses at high altitude, where despite a maternal PaO_2 of only 60 mm Hg, the fetal PaO_2 is equivalent to that at sea level ([Subrevilla and colleagues, 1971](#)).

MECHANICAL VENTILATION. In some patients, positive pressure ventilation by face mask may be effective in early stages of pulmonary insufficiency ([Wyncoll and Evans, 1999](#)). In an attempt to maximize the fetal environment, however, early intubation and assisted ventilation is indicated in the pregnant woman if respiratory failure appears to be imminent. Mechanical ventilation usually requires a volume-cycled ventilator. The ventilator is adjusted to obtain a PaO_2 greater than 60 mm Hg, or a hemoglobin saturation of 90 percent and a $Paco_2$ of 35 to 45 mm Hg. This is the normal $Paco_2$ for pregnancy, and lower levels should be avoided because they can lower placental perfusion ([Levinson and co-workers, 1974](#)).

POSITIVE END-EXPIRATORY PRESSURE. With severe lung injury and high intrapulmonary shunt fractions, it may not be possible to provide adequate oxygenation with usual pressures, even with 100 percent oxygen. Positive end-expiratory pressure (PEEP) is usually successful in decreasing the shunt by recruiting collapsed alveoli. At low levels—for example, 5 to 15 mm Hg—positive pressure can usually be employed safely without invasive cardiovascular monitoring. At the higher levels, however, right-sided venous return can be impaired, resulting in decreased cardiac output and decreased uteroplacental circulation. Because positive pressure ventilation raises pulmonary capillary wedge pressure, it must be discontinued during such measurements. High levels can also result in overdistention of alveoli, falling compliance, and barotrauma.

FLUID THERAPY. Treatment of critically ill women with acute respiratory failure requires assiduously detailed attention to fluid balance because fluid overload further compromises pulmonary status ([Wyncoll and Evans, 1999](#)). In the intensive care setting, intake and output records should be supplemented with daily weights. A mechanically ventilated patient retains an extra liter of fluid daily. Because respiratory distress syndrome is characterized by a pulmonary permeability defect, fluid leaks into the interstitium, even at normal pressures. Thus, it is best to maintain the lowest pulmonary capillary wedge pressure possible while avoiding decreased cardiac output.

Some pregnancy-induced physiological changes may predispose the woman to greater risk of lung injury from fluid therapy. [Robertson \(1969\)](#) demonstrated a continuous decline in the colloid oncotic pressure (COP) across pregnancy; it fell from 28 mm Hg in the nonpregnant woman to 23 mm Hg at term. [Benedetti and Carlson \(1979\)](#) reported a further decline to 17 mm Hg in the puerperium. In women with preeclampsia, oncotic pressure was 16 mm Hg antepartum and 14 mm Hg postpartum ([Zinaman and co-workers, 1985](#)). The importance of these changes is their impact on the **colloid oncotic pressure/wedge pressure gradient**. Under normal conditions, this gradient exceeds 8 mm Hg; however, reductions to 4 mm Hg or less are associated with increased risks for pulmonary edema.

OTHER THERAPY. After promising preliminary data of **artificial or replacement surfactant therapy**, [Anzueto and colleagues \(1996\)](#) performed a prospective study of 725 patients with sepsis-induced lung failure. Continuous administration of aerosolized surfactant had no significant effect on 30-day survival or duration of mechanical ventilation. In another study, inhalation of **nitric oxide** caused early improvement, but mortality was unchanged ([Wyncoll and Evans, 1999](#)). In a small preliminary study, **prolonged methylprednisolone** therapy begun in patients with no improvement on day 7 demonstrated improved lung injury and reduced mortality ([Meduri and associates, 1998](#)).

Other specific therapies to include **immunotherapy** with anti-CD blocking antibodies, **lipid mediator antagonists** to arachidonic acid, and **antioxidants** are under current investigation ([Clark and colleagues, 1997](#)).

BACTEREMIA AND SEPTICEMIC SHOCK

Infections that most commonly cause bacteremia and septicemic shock in obstetrical patients are antepartum pyelonephritis ([Chap. 47](#) p. 1255), chorioamnionitis and puerperal sepsis ([Chap. 26](#)), septic abortion ([Chap. 33](#) p. 877), and necrotizing fasciitis ([Chap. 26](#), p. 678). At least in nonpregnant patients, and regardless of etiology of septic shock, mortality is high. In two recent multicenter studies totaling nearly 2400 patients, the mortality rate at 28 days was 35 to 40 percent with severe sepsis and shock ([Abraham and colleagues, 1997, 1998](#)). [Annane and co-workers \(2000\)](#) recently published interesting observations in 189 nonpregnant patients with sepsis admitted to two French hospitals. Serum cortisol levels before and after corticotropin administration were predictive of survival. In the largest study of septic shock in pregnancy, [Mabie and associates \(1997\)](#) reported a 28 percent mortality in 18 women.

ETIOLOGY AND PATHOGENESIS

Because pelvic infections are polymicrobial, septic shock may be caused by any of a number of pathogens. Most commonly, bacteria that cause shock are from members of the endotoxin-producing *Enterobacteriaceae* family, especially *Escherichia coli*. Pathogens that less often cause shock are aerobic and anaerobic streptococci and *Bacteroides* and *Clostridium* species. Group A β -hemolytic streptococci, as well as *Staphylococcus aureus*, produce virulent exotoxins that cause all features of the sepsis syndrome ([Chap. 26](#), p. 674). In pyelonephritis, *E coli* and *Klebsiella* species most likely cause bacteremia or septicemia ([Cunningham and associates, 1987](#); [Mabie and colleagues, 1997](#)).

Sepsis is caused by an inflammatory response to a trigger—most often microbial endotoxins and exotoxins. These and other toxins stimulate inflammatory cytokine production by vascular endothelium. These cytokines include tumor necrosis factor and interleukin-1 and -8. Neutrophil adherence to endothelium follows, and leukocytes produce a number of toxic substances including proteases and cytokines ([Wheeler and Bernard, 1999](#)).

Endotoxin is a lipopolysaccharide that is released upon lysis of the cell wall of gram-negative bacteria. There are probably other bacterial substances that result in mediator release with activation of complement, kinins, or the coagulation system ([Chap. 25](#), p. 657). According to [Levi and ten Cate \(1999\)](#), 30 to 50 percent of nonpregnant patients with gram-negative sepsis have **disseminated intravascular coagulation**.

Bacterial **exotoxins** released by organisms can also cause shock and death. Examples include exotoxin A from *Pseudomonas aeruginosa* or toxic-shock-syndrome-toxin from *S aureus*. We, as well as others, have encountered a virulent toxic-shock-like syndrome caused by group A streptococcal infection ([Nathan and colleagues, 1993](#)). Extensive tissue necrosis and gangrene, especially of the postpartum uterus, may cause profound cardiovascular collapse and maternal death ([Chap. 26](#), p. 685).

Release of vasoactive mediators produces selective vasodilation with maldistribution of blood flow. Leukocyte and platelet aggregation cause capillary plugging. Vascular endothelial injury causes profound capillary leakage and interstitial fluid accumulation. Depending on the injury and inflammatory response, there is a

spectrum of clinical disease that is schematically depicted in [Figure 43-5](#). Thus, sepsis is a clinical as well as pathophysiological continuum. The end results of this cascade of pathophysiological events cause the **septic shock syndrome**. In its early stages, clinical shock results primarily from decreased systemic vascular resistance that is not compensated fully by increased cardiac output. Hypoperfusion results in lactic acidosis, decreased tissue oxygen extraction, and end-organ dysfunction. This is also referred to as **multiple organ failure syndrome** ([Table 43-6](#)).

HEMODYNAMIC CHANGES IN SEPTIC SHOCK

A greater understanding of the septic shock syndrome has been made possible by direct hemodynamic measurements. The pathophysiology of sepsis has been elucidated by the elegant clinical studies of [Parker \(1987\)](#) and [Parrillo \(1990\)](#) and their colleagues from the National Institutes of Health. If circulating volume is initially restored, then septic shock can be characterized as a high cardiac output, low systemic vascular resistance condition. This is often referred to as the *warm phase* of septic shock. Concomitantly, pulmonary hypertension develops. Paradoxically, patients with severe sepsis are likely to have myocardial depression despite high cardiac output ([Ognibene and co-workers, 1988](#)). An elevated cardiac index with decreased systemic vascular resistance are the most common cardiovascular manifestations of septic shock and often have prognostic significance.

Most previously healthy women with sepsis complicating obstetrical infections respond well to fluid resuscitation, given along with intensive antimicrobial therapy and, if indicated, removal of infected tissue. If hypotension is not corrected following vigorous fluid infusion, then the prognosis is guarded. If there is no response to β -adrenergic inotropic agents, then there is severe and unresponsive vascular insufficiency or overwhelming myocardial depression. Oliguria and continued peripheral vasoconstriction characterize a secondary, *cold phase* of septic shock, from which survival is uncommon. Another poor prognostic sign with sepsis is continued end-organ dysfunction; that is, renal, pulmonary, and cerebral failure once hypotension has been corrected. The average risk of death increases by 15 to 20 percentage points with failure of each organ system ([Wheeler and Bernard, 1999](#)).

DIAGNOSIS AND TREATMENT

Whenever serious bacterial infection is suspected, blood pressure and urine flow should be monitored closely. Septic shock, as well as hemorrhagic shock, should be considered whenever there is evidence of hypotension or oliguria. When shock from sepsis is suspected, prompt and aggressive treatment includes:

1. Careful monitoring of vital signs and urinary output.
2. Vigorous intravenous fluid infusion to restore circulating volume.
3. Administration of empirical antimicrobial drugs selected to provide coverage that includes all suspected pathogens.
4. Oxygen and ventilatory support if needed.
5. And, if indicated, surgical intervention after the clinical condition has been stabilized.

Shown in [Table 43-7](#) is a scheme for treatment of sepsis syndromes. Rapid infusion with 2 L and sometimes as many as 4 to 6 L of crystalloid fluids may be required to restore renal perfusion in severely affected women. Because of the vascular leak, these women usually are hemoconcentrated, and if the hematocrit is 30 volume percent or less, then blood is given along with crystalloid to maintain the hematocrit at about 30 volume percent or perhaps slightly higher ([Chap. 25](#), p. 653). The use of colloid solution, for example, 5 percent human albumin, is controversial ([Clark and colleagues, 1997](#); [Ware and Matthay, 2000](#)). If aggressive volume replacement is not promptly followed by urinary output of at least 30 and preferably 50 mL/hr, as well as other indicators of improved perfusion, then consideration is given for insertion of a pulmonary artery catheter. Mortality is high when sepsis is further complicated by renal failure ([Alexopoulos and colleagues, 1993](#)). In women who are seriously ill, pulmonary capillary endothelium is also likely damaged, with alveolar leakage and pulmonary edema occurring even with low or normal pulmonary capillary wedge pressures—the **acute respiratory distress syndrome** described earlier (pp. 1164 to 1165). This must be differentiated from circulatory overload from overly vigorous fluid therapy, with which wedge pressures will be abnormally high.

Broad-spectrum antimicrobials are administered in maximal doses after appropriate cultures are taken. These include blood cultures, along with specimens of exudates that are not contaminated by normal flora. For women with infected abortions or those with deep fascial infections, a Gram-stained smear may be helpful in identifying *Clostridium perfringens* or group A streptococcal organisms. Generally, empirical coverage with regimens such as ampicillin plus gentamicin plus clindamycin suffices.

SURGICAL TREATMENT. Continuing sepsis may prove fatal, and debridement of necrotic tissue or drainage of purulent material is crucial. Of 18 pregnant women with septic shock, [Mabie and colleagues \(1997\)](#) reported that eight required surgical therapy to control the source of infection. A meticulous search is made for such foci. For women with an infected abortion, the uterine contents must be removed promptly by curettage. Hysterectomy is seldom indicated unless the uterus has been lacerated or is obviously intensely infected ([Fig. 43-6](#)). Bacterial shock may become clinically apparent several hours after evacuation of infected products from the uterus.

For women with pyelonephritis, continuing sepsis usually is from urinary obstruction caused by calculi or a perinephric abscess or phlegmon. With obstruction, ureteral catheterization or percutaneous nephrostomy may be lifesaving, and flank exploration with debridement may be indicated ([Chap. 47](#), p. 1258). In some cases, end-stage pyonephrosis is found as a source of continuing sepsis and nephrectomy must be performed.

Puerperal infections causing sepsis that may be amenable to surgical treatment are those in which there are appreciable amounts of infected or devitalized tissue, or both. In addition to clostridial infections, there have been reports in the past 10 years of women with massive uterine myonecrosis from group A β -hemolytic streptococci. The mortality rate in these women has been high ([Mabie and co-workers, 1997](#); [Nathan and colleagues, 1993](#)). Other causes of sepsis are deep myofascial infections of the episiotomy site or abdominal surgical incision (see necrotizing fasciitis in [Chap. 26](#), p. 684). These infections must be promptly recognized and aggressively treated ([Feinberg and colleagues, 1996](#)). In women with persistent infections following cesarean delivery, the uterine incision may undergo necrosis and dehiscence with subsequent peritonitis. Hysterectomy has been necessary following overwhelming sepsis due to a gas-forming *E coli* chorioamnionitis ([Catanzarite and associates, 1994](#)). Another source may be from a ruptured parametrial or intra-abdominal abscess. **Any woman with a puerperal infection who is suspected of developing peritonitis should be carefully evaluated for uterine incisional necrosis and separation or for bowel perforation.**

ADJUNCTIVE THERAPY PRESSOR AGENTS. Vasoactive drugs are not given unless aggressive fluid treatment fails to correct hypotension and perfusion abnormalities. One commonly used agent is dopamine hydrochloride, which when given in doses of 2 to 10 μ g/kg/min stimulates cardiac α -receptors to increase cardiac output. Doses of 10 to 20 μ g/kg/min cause β -receptor stimulation, an increase in systemic vascular resistance, and an increase in blood pressure. At doses of more than 20 μ g/kg/min, α -receptor stimulation predominates, but dopamine is seldom needed at these higher doses. If there is no response to dopamine, then dobutamine, 5 to 15 μ g/kg/min or norepinephrine, 5 to 20 μ g/min, may be of benefit ([Wheeler and Bernard, 1999](#)).

OXYGENATION AND VENTILATION. Oxygen is administered in an attempt to improve tissue oxygenation. As the septic shock syndrome progresses and intravascular volume is restored, there may be substantive pulmonary capillary endothelial damage with leakage into alveoli. Resultant pulmonary edema causes hypoxemia, which worsens tissue hypoxia and acidosis. When this is severe and adequate oxygenation cannot be maintained by increased oxygen delivered via a nonbreathing mask or by a continuous positive airway pressure mask, then tracheal intubation and mechanical ventilation that delivers positive pressure may prove to be lifesaving (see p. 1165).

ANTI-INFLAMMATORY AGENTS. Methylprednisolone given in large doses within a few hours of sepsis does not improve early or late morbidity or mortality ([Bone and colleagues, 1987](#); [Veterans Administration Systemic Sepsis Cooperative Study Group, 1987](#)). Similarly, in 455 patients given intravenous ibuprofen or placebo for sepsis, there was no improvement in prevention of shock, respiratory failure, or mortality ([Bernard and co-workers, 1997](#)).

IMMUNOTHERAPY. There have been several studies using **antiendotoxin antibody** serum for gram-negative sepsis or septic shock. Although preliminary results were promising with a human monoclonal IgM antibody to lipid A, the observations of the [French National Registry of HA-1A in Septic Shock \(1994\)](#) were not. This cohort study of 600 patients showed that mortality was not decreased with treatment and suggested excess mortality in patients with non-gram-negative bacteremia.

A number of studies with **E5 murine monoclonal IgM antiendotoxin antibody** for gram-negative sepsis showed no improvement of mortality ([Angus and associates, 2000](#); [Bone and colleagues, 1995](#)). E5 antibodies did result in prevention of acute respiratory distress syndrome and greater resolution of organ failure in patients with sepsis—an important finding because patients with suspected sepsis can be identified without waiting for culture results.

Because certain cytokines have been shown to mediate the inflammatory response in sepsis, **anticytokine antibodies** have been used in clinical trials. [Abraham and colleagues \(1998\)](#) used murine monoclonal antibody against tumor necrosis factor- α (TNF- α Mab) in 948 patients with septic shock. While the incidence of coagulopathy in the treated group was significantly decreased (19 versus 27 percent), there were no other benefits, including the 28-day mortality rate of about 40 percent in both groups.

[Abraham and co-workers \(1997\)](#) studied a recombinant **fusion protein of p55 tumor necrosis factor receptor** to competitively block TNF- α binding with cell-associated receptors. They treated 498 patients with severe sepsis and found a similar 28-day mortality in treated (35 percent) versus placebo-group patients (39 percent).

TRAUMA IN PREGNANCY

Trauma, homicide, and similar violent events are a leading cause of death in young women. According to the [American College of Obstetricians and Gynecologists \(1998\)](#), 1 in 12 pregnancies is associated with physical trauma. Indeed, injury-related deaths are the most commonly identified cause of maternal morbidity in Cook County, Illinois; New York City; Massachusetts; Utah; and North Carolina ([Dannenberg, 1995](#); [Fildes, 1992](#); [Jacob, 1998](#); [Sachs, 1987](#), and all their colleagues; [Harper and Parsons, 1997](#)). Although motor vehicle accidents, falls, and homicides are clearly sources of significant trauma in pregnancy, by far the most frequent form of trauma involves physical or sexual abuse. In many cases, trauma arises from domestic abuse or battering ([Eisenstat and Bancroft, 1999](#); [Kurzel and associates, 2000](#)). Interestingly, [Dietz and associates \(1999\)](#) reported that women who were psychologically and physically abused in childhood frequently had an unintended first pregnancy.

BLUNT TRAUMA

PHYSICAL ABUSE. It is estimated that 5 million women each year are physically assaulted by their male partners ([American College of Obstetricians and Gynecologists, 1999](#)). Even more appalling is that pregnant women are not immune to such physical violence. In a recent mail survey, [Horan and colleagues \(1998\)](#) ascertained that ACOG Fellows routinely screen 27 percent of nonpregnant women for domestic violence at the first office visit. For pregnant women, 39 percent routinely screened at the first prenatal visit. While only a third of these physicians had received instruction on domestic violence during residency, two thirds learned through continuing education.

Most data concerning this subject are from public institutions. For example, a third of injuries to pregnant women cared for at the University of Mississippi Medical Center were intentionally inflicted ([Poole and colleagues, 1996](#)). [McFarlane and colleagues \(1992\)](#) and [Berenson and co-workers \(1991\)](#) questioned women attending public clinics and reported that almost a fourth had been physically or sexually abused during pregnancy. [Cokkinides and colleagues \(1999\)](#) found that 11 percent of 6000 pregnant women reported physical violence. Importantly, this was linked to poverty, poor education, and use of tobacco and alcohol. [Kurzel and associates \(2000\)](#) reported that drug use was associated with half of instances of battered pregnant women. Similar risk factors were reported from two multicenter emergency department studies of nonpregnant women ([Grisso and co-workers, 1999](#); [Kyriacou and associates, 1999](#)).

The woman who is physically abused tends to present late, if at all, for prenatal care. Her risk of preterm labor and of chorioamnionitis is twice that of control women ([Berenson and co-workers, 1994](#)). Women abused during pregnancy are also at increased risk for low-birthweight infants as well as a higher cesarean delivery rate ([Curry and colleagues, 1998](#); [Parker and associates, 1994](#)).

Risk factors for physical abuse in pregnancy have been generally subdivided into three categories ([Stewart and Cecutti, 1993](#)). *Social instability* includes such factors as young age; unmarried, divorced, or separated; lower level of education or unemployment; and unplanned pregnancy. *Unhealthy lifestyle* includes poor diet; substance abuse including alcohol, tobacco, and illicit drugs; and emotional problems. *Physical health problems* include acute and chronic medical conditions and use of prescription medications. Unfortunately, the abused pregnant woman tends to stay with the abuser, and 60 percent report two or more episodes of physical assault during pregnancy ([McFarlane and colleagues, 1992](#)). The woman who is physically or sexually abused in pregnancy should also be considered to be emotionally abused. Finally, [Stewart \(1994\)](#) observed the tendency for physical abuse to increase in the first several months following delivery.

SEXUAL ASSAULT. According to the [Federal Bureau of Investigation \(1998\)](#), there were nearly 100,000 forcible rapes of women reported in 1997. It generally is held that only 10 to 20 percent of sexual assaults are reported. [Satin and co-workers \(1991\)](#) reviewed over 5700 sexual assaults against women committed in Dallas County over 6 years, and found that 2 percent of the victims were pregnant. Associated physical trauma was less common than in nonpregnant rape victims, and only a third of assaults took place after 20 weeks. From a forensic standpoint, evidence collection was not altered.

[Satin and co-workers \(1992\)](#) also interviewed 2404 women postpartum and found that the lifetime prevalence of forced sexual contact was 5 percent. Compared with nonvictims, rape victims had a higher incidence of sexually transmitted diseases, urinary infections, vaginitis, drug use, and multiple hospitalizations. [Berenson and colleagues \(1992\)](#) reported that 8 percent of pregnant adolescents had been sexually assaulted. A member of their family was the perpetrator in 46 percent of cases, and a spouse or boyfriend in 33 percent.

The importance of psychological counseling for the rape victim and her family cannot be overemphasized. In addition to attention to physical and psychological injuries, exposure to sexually transmitted diseases must be considered. Shown in [Table 43-8](#) are the current recommendations for prophylaxis recommended by the [Centers for Disease Control and Prevention \(1998\)](#).

AUTOMOBILE ACCIDENTS. According to the [National Highway Traffic Safety Administration \(1998\)](#), vehicular deaths are the leading cause of deaths in females 8 to 28 years old. Most cases of significant blunt trauma during pregnancy are caused by vehicle accidents, falls, and direct assault ([Connolly and co-workers, 1997](#); [Pak and colleagues, 1998](#)). Car accidents account for the majority of these deaths, which might be prevented with the use of three-point restraints ([American College of Obstetricians and Gynecologists, 1998](#); [Crosby, 1996](#)). Indeed, [Pearlman and associates \(2000\)](#) found that proper seatbelt use and crash severity were the best predictors of maternal-fetal outcomes. Despite this, [Pearlman and Phillips \(1996\)](#) found that a third of women did not use seat restraints or used them incorrectly during pregnancy. Similarly, [Tyroch and associates \(1999\)](#) reported that while 86 percent used restraints while pregnant, almost half used them incorrectly.

Effects of deployment of airbags in pregnant drivers or passengers have not been widely reported. [Sims and associates \(1996\)](#) reported three third-trimester women whose driver-side airbag deployed in 10 to 25 mph collisions. They reported no injuries. [Schultze and colleagues \(1998\)](#) reported a 20 percent placental abruption that caused a stillborn 28-week fetus in a woman whose airbag deployed in a 40 mph collision. Even less is known concerning passenger-side bags or doorbags.

OTHER BLUNT TRAUMA. Some other common causes of blunt trauma are falls and aggravated assaults ([Luger and associates, 1995](#)). Less common forms of blunt trauma include blast injury or crush injury ([Awwad and co-workers, 1994a](#); [Schoenfeld and colleagues, 1995](#)). Serious intra-abdominal injuries are of particular concern and, probably related to the markedly increased pelvic and abdominal vascularity, retroperitoneal hemorrhage is encountered more commonly compared with nonpregnant women. Conversely, bowel injuries are less frequent because of the protective effect of the large uterus. Diaphragmatic, splenic, liver, and kidney injuries may also be sustained ([Flick and colleagues, 1999](#); [Icely and Chez, 1999](#)).

TRAUMATIC PLACENTAL ABRUPTION. Placental separation is likely caused by deformation of the elastic myometrium around the relatively inelastic placenta ([Crosby and associates, 1968](#)). Abruption complicates 1 to 6 percent of "minor" injuries and up to 50 percent of major injuries ([Goodwin and colleagues, 1990](#); [Pearlman and co-workers, 1990](#)). [Reis and colleagues \(2000\)](#) found that abruption was more likely in car accidents occurring at over 30 mph.

In many cases, findings with traumatic abruption are similar to those discussed in [Chapter 25](#) (p. 624). [Stettler and associates \(1992\)](#) reviewed our experiences with 13 such women at Parkland Hospital and reported that although 11 had uterine tenderness, only five had vaginal bleeding. Other common findings are uterine contractions; evidence for fetal compromise such as fetal tachycardia, late decelerations, and acidosis; and fetal death. Because placental abruption associated with trauma may be concealed, the incidence of associated severe coagulopathy is probably higher than with nontraumatic abruption.

[Kettel and co-workers \(1988\)](#) emphasize that abruption may be occult and not associated with uterine pain, tenderness, and bleeding. According to [Pearlman and associates \(1990\)](#), detection of uterine contractile activity using electronic monitoring is suggestive of abruption. If tocolytics are used, they may obfuscate clinical findings of placental abruption.

UTERINE RUPTURE. This is uncommon with blunt trauma and is found in less than 1 percent of severe cases ([American College of Obstetricians and Gynecologists, 1998](#)). It is usually associated with a direct impact of substantive force. Findings may be identical to those for placental abruption, and maternal and fetal deterioration are soon inevitable. [Dash and Lupetin \(1991\)](#) described a 24-week pregnancy in which traumatic uterine rupture was confirmed using computed tomography.

FETAL-MATERNAL HEMORRHAGE. If there is considerable abdominal force associated with trauma, and especially if the placenta is lacerated, life-threatening fetal-maternal hemorrhage may be encountered ([Pritchard and associates, 1991](#)). Some degree of bleeding from the fetal to maternal circulation is found in 10 to 30 percent of trauma cases ([Goodwin and Breen, 1990](#); [Pearlman and associates, 1990](#)). In 90 percent of these cases, however, hemorrhage is less than 15 mL. We encountered three cases of massive fetal-maternal hemorrhage in eight women with a traumatic abruption ([Stettler and associates, 1992](#)). It seems likely that this is not due to placental separation because there usually is no fetal bleeding into the intervillous space. More likely fetal hemorrhage is associated with a placental tear or "fracture" caused by stretching. In the three cases of massive fetal bleeding described above, two were associated with a placental laceration and the infants were stillborn ([Fig. 43-7](#)).

FETAL INJURY. According to [Kissinger and co-workers \(1991\)](#), the risk of fetal death with trauma is significant when there is direct fetoplacental injury, maternal shock, pelvic fracture, maternal head injury, or hypoxia. Although fetal injury and death are uncommon, there are many interesting case reports that describe it. Fetal skull and brain injury are most common. These injuries are more likely if the head is engaged, and the maternal pelvis is fractured on impact ([Palmer and Sparrow, 1994](#)). Conversely, fetal head injuries, presumably from a *contrecoup* effect, may be sustained in unengaged vertex or nonvertex presentations. [Weyerts and colleagues \(1992\)](#) described a newborn with paraplegia and contractures associated with a motor vehicle accident sustained several months before birth.

PENETRATING TRAUMA

Knife and gunshot wounds are the most common penetrating injuries and may be associated with aggravated assaults, suicide attempts, or attempts to cause abortion. The incidence of visceral injury with penetrating trauma is only 15 to 40 percent compared with 80 to 90 percent in nonpregnant individuals ([Stone, 1999](#)). When the uterus sustains penetrating wounds, the fetus is more likely than the mother to be seriously injured ([Fig. 43-8](#)). Indeed, although the fetus sustains injury in two thirds of such cases, visceral injuries to the mother are seen in only 20 percent ([Buchsbaum, 1979](#)). [Awwad and colleagues \(1994b\)](#) reported unique experiences with high-velocity penetrating wounds of the pregnant uterus collected over 16 years of civil war in Lebanon. Among 14 women, two died, but neither was as a direct result of intra-abdominal injury. Three observations were made:

1. Visceral injuries were present when the entrance wound was in either the upper abdomen or back.
2. When the entry wound site was anterior and below the uterine fundus, visceral injuries were absent in all six women.
3. Perinatal death ensued in half and was due to either maternal shock, uteroplacental injury, or direct fetal injury.

MANAGEMENT OF TRAUMA

With few exceptions, treatment priorities are directed toward the injured pregnant woman as they are for nonpregnant patients. Primary goals are evaluation and stabilization of maternal injuries. Attention to fetal assessment during the acute evaluation may divert attention from life-threatening maternal injuries ([American College of Obstetricians and Gynecologists, 1998](#)). Basic rules are applied to resuscitation, including establishing ventilation and arrest of hemorrhage along with treatment for hypovolemia with crystalloid and blood products. **An important aspect of management is deflection of the large uterus away from the great vessels to diminish their effect on decreased cardiac output.** [Hoff and associates \(1991\)](#), as well as [Scorpio and colleagues \(1992\)](#), documented that fetal death is related to the severity of maternal injury. They found close correlation of low maternal serum bicarbonate level with fetal demise. Biester and co-workers (2000) did not find the Revised Trauma Score predictive of adverse pregnancy outcome.

Following emergency resuscitation, evaluation is continued for fractures, internal injuries, bleeding sites, as well as uterine and fetal injuries. If indicated, open peritoneal lavage should be performed in the pregnant woman ([Scorpio and colleagues, 1992](#)). Penetrating injuries in most cases must be evaluated using radiography ([Chap. 42](#)). Because clinical response to peritoneal irritation is blunted during pregnancy, an aggressive approach to exploratory laparotomy is pursued for abdominal trauma. Whereas exploration is mandatory for abdominal gunshot wounds, some advocate close observation for selected stab wounds ([Grubb, 1992](#)).

CESAREAN DELIVERY. The necessity for cesarean delivery of a live fetus depends on several factors. Laparotomy itself is not an indication for hysterectomy. Some considerations include gestational age, fetal condition, extent of uterine injury, and whether the large uterus hinders adequate treatment or evaluation of other intra-abdominal injuries ([Awwad and colleagues, 1994a](#)).

ELECTRONIC MONITORING. As for many other acute or chronic maternal conditions, fetal well-being may reflect the status of the mother, and thus fetal monitoring is another "vital sign" to help evaluate the extent of maternal injuries. Even if the mother is stable, the use of electronic monitoring may be predictive of placental abruption. [Pearlman and associates \(1990\)](#) reported no abruptions if uterine contractions were less often than every 10 minutes within 4 hours after trauma was sustained. **Importantly, 20 percent of women who had more frequent contractions had an associated placental abruption.** In these cases, abnormal tracings were common and included fetal tachycardia and late decelerations. [Connolly and co-workers \(1997\)](#) reported no adverse outcomes in women who had normal monitor tracings.

Because placental abruption usually develops early following trauma, fetal monitoring is begun as soon as the maternal condition is stabilized. The duration that post-trauma monitoring should be performed is not precisely known. According to [Goodwin and Breen \(1990\)](#), an observation period of 2 to 6 hours is sufficient if there are no other ominous signs such as contractions, uterine tenderness, or bleeding. It seems reasonable to continue monitoring as long as there are uterine contractions, a nonreassuring fetal heart pattern, vaginal bleeding, uterine tenderness or irritability, serious maternal injury, or ruptured membranes ([American College of Obstetricians and Gynecologists, 1998](#)). In very rare cases, abruptio placentae has developed days after trauma ([Higgins and Garite, 1984](#)).

FETAL-MATERNAL HEMORRHAGE. Routine use of the Kleihauer-Betke or an equivalent test in pregnant trauma victims is controversial ([Pak and associates, 1998](#)). It is unclear if their routine use will modify adverse outcomes associated with fetal anemia, cardiac arrhythmias, and death. In a retrospective review of 125 pregnant women with blunt injuries admitted to a level I trauma center, the Kleihauer-Betke test had a sensitivity of 56 percent, a specificity of 71 percent, and an accuracy of 27 percent ([Towery and co-workers, 1993](#)). These investigators concluded that the test was of little use in the setting of acute trauma, and electronic fetal monitoring or ultrasound, or both, are more useful in detecting fetal or pregnancy-associated complications. [Dupre and associates \(1993\)](#) reached similar conclusions, and while they found evidence for fetal-maternal hemorrhage in 22 percent of women studied, it was of no prognostic significance. Likewise, [Connolly and co-workers \(1997\)](#) performed 289 Kleihauer-Betke tests in traumatic injuries in pregnant women and in only one case was management affected.

For the woman who is D-negative, administration of anti-D immunoglobulin should be considered. This may be omitted if the test for fetal bleeding is negative. Isoimmunization may still develop if the fetal-maternal hemorrhage exceeds 15 mL of fetal cells.

Another important aspect of care for the pregnant trauma patient is to ensure that her tetanus immunization is current.

THERMAL INJURY

Although Parkland Hospital is a major burn center for the United States, we have not seen a large number of pregnant women with severe burns. Fetal prognosis is poor with severe burns. Usually the woman enters labor spontaneously within a few days to a week, and often delivers a stillborn infant. Contributory factors are hypovolemia, pulmonary injury, septicemia, and the intensely catabolic state associated with burns.

PROGNOSIS. From their review, [Polko and McMahon \(1998\)](#) concluded that pregnancy does not alter maternal outcome compared with nonpregnant women of similar age. A number of investigators have reported that maternal and fetal survival parallels the percentage of burned surface area ([Table 43-9](#)). In general, prognosis worsens when burns exceed 40 to 50 percent of body surface area. For instance, there was a 50 percent maternal and fetal loss in the 40 to 60 percent burn group compared with 11 percent fetal and no maternal losses with a 20 to 40 percent area burn. In the 170 pregnant burned women reported in [Table 43-9](#), as the total burned body surface area reaches or exceeds 50 percent, both maternal and fetal morbidity invariably exceeds 50 percent.

SKIN CONTRACTURES. Following serious abdominal burns, skin contractures that develop may be painful during a subsequent pregnancy and may even necessitate surgical decompression and split skin autografts ([Matthews, 1982](#)). [Widgerow and colleagues \(1991\)](#) described two women in whom surgical release without covering the resulting defect was sufficient. [McCauley and colleagues \(1991\)](#) followed seven women with severe circumferential truncal burns sustained at a mean age of 7.7 years. All of 14 subsequent pregnancies were delivered at term without major complications. Loss or distortion of nipples may cause problems in breast feeding.

ELECTRIC SHOCK

Earlier case reports were suggestive of a high fetal mortality with electric shock ([Fatovich, 1993](#)). In a prospective cohort study, however, [Einarson and colleagues \(1997\)](#) showed similar perinatal outcomes in 31 exposed women compared with normal pregnant controls. They concluded that traditional 110-volt North American electric current likely is less dangerous than 220-volt currents available in Europe. [Fish \(2000\)](#) has described neurological and vascular effects of lightning injury.

CARDIOPULMONARY RESUSCITATION

Cardiac arrest fortunately is rare during pregnancy. There are special considerations for cardiopulmonary resuscitation (CPR) conducted in the second half of pregnancy. In nonpregnant women, external chest compression results in a cardiac output of only 30 percent of normal ([Clark and colleagues, 1997](#)). Cardiac output is even less in advanced pregnancy, when aortocaval compression from the enlarged uterus may impede resuscitative efforts by diminishing forward flow as well as venous return. **Thus, uterine displacement is paramount to accompany other resuscitative efforts.** Left lateral displacement can be accomplished manually by a member of the team, by tilting the operating table laterally, by placing a wedge under the right hip, or by using the Cardiff resuscitation wedge. [Rees and Willis \(1988\)](#) showed with a manikin that resuscitation with the Cardiff wedge was as efficient as resuscitation in the supine position.

Over the past few years, the recommendation by many authors is to perform cesarean delivery within 4 to 5 minutes of beginning cardiopulmonary resuscitation if the fetus is viable ([Moise and Belfort, 1997](#)). Certainly there is an inverse correlation between neurologically intact neonatal survival and the cardiac arrest-to-delivery interval in women delivered by perimortem cesarean. According to [Clark and co-workers \(1997\)](#) 98 percent of infants delivered before 5 minutes will be neurologically intact. From 6 to 15 minutes it is 83 percent; from 16 to 25 minutes, 33 percent; and 26 to 35 minutes, 25 percent. Based on theory and a few anecdotal case reports, delivery may also enhance maternal resuscitative efforts, which must be continued throughout surgery. For all of these reasons, the [American College of Obstetricians and Gynecologists \(1998\)](#) advises consideration for cesarean delivery in third-trimester pregnancy within 4 minutes of cardiac arrest. Unfortunately, as emphasized by [Clark and associates \(1997\)](#), these goals rarely can be met in actual practice. [Whitten and Irvine \(2000\)](#) recently reviewed indications for postmortem and perimortem cesarean delivery.

TABLE 43-2. Some Indications for Invasive Hemodynamic Monitoring

Sepsis with refractory hypotension or oliguria
Unexplained or refractory pulmonary edema, heart failure, or oliguria
Severe pregnancy-induced hypertension with persistent pulmonary edema or oliguria
Unexplained intraoperative or intrapartum cardiovascular decompensation
Selected cases with massive blood and volume loss or replacement
Acute respiratory distress syndrome
Persistent shock of undefined etiology
Amnionic fluid embolism
Some chronic conditions, particularly when associated with labor or major surgery
NYHA class III or IV cardiac disease
Peripartum or perioperative coronary artery disease
Pulmonary hypertension

NYHA = New York Heart Association.

Modified from American College of Obstetricians and Gynecologists (1992).

TABLE 43-3. Formulas for Deriving Various Cardiopulmonary Parameters

Mean arterial pressure (MAP) (mm Hg) = [systolic pressure + 2 (diastolic pressure)] ÷3

Cardiac output (CO) (L/min) = heart rate × stroke volume

Stroke volume (SV) (mL/beat) = CO/HR

Stroke index (SI) (mL/beat/m²) = stroke volume/BSA

Cardiac index (CI) (L/min/m²) = CO/BSA

Systemic vascular resistance (SVR) (dynes × sec × cm⁻⁵) = [(MAP - CVP)/CO] × 80

Pulmonary vascular resistance (PVR) (dynes × sec × cm⁻⁵) = [(MPAP - PCWP)/CO] × 80

Lung compliance:

Static = $\frac{\text{Tidal volume}}{\text{Plateau inspiratory pressure}}$

Dynamic = $\frac{\text{Tidal volume}}{\text{Peak inspiratory pressure}}$

BSA = body surface area (m²); CO = cardiac output (L/min); CVP = central venous pressure (mm Hg);
HR = heart rate (beats/min); MAP = mean systemic arterial pressure (mm Hg); MPAP = mean
pulmonary artery pressure (mm Hg); PCWP = pulmonary capillary wedge pressure (mm Hg).

44. Cardiovascular Diseases

Heart disease is the third leading cause of death in 25- to 44-year-old women ([Martin and colleagues, 1999](#)). Because it is relatively common in women of childbearing age, heart disease of varying severity complicates about 1 percent of pregnancies. In the past, **rheumatic heart disease** accounted for the majority of cases, but over the past three decades, it has almost disappeared in this country. [Meyer and colleagues \(1994\)](#) described 74 pregnancies over 10 years complicated by cardiac disease, and only a few were caused by rheumatic fever. Similarly, [Tan and de Swiet \(1998\)](#) reported that only 12 percent of 73 women had cardiac disease caused by rheumatic lesions. Better medical management, together with a number of newer surgical techniques, has enabled more girls with **congenital heart disease** to reach childbearing age ([Brickner and co-workers, 2000](#)). Congenital heart lesions now constitute at least half of all cases of heart disease encountered during pregnancy ([Bitsch and colleagues, 1989](#); [McFaul and associates, 1988](#)). **Hypertensive heart disease**, frequently complicated by heart disease of obesity, has become a relatively common cause of peripartum heart failure at Parkland Hospital ([Cunningham and co-workers, 1986](#)). Other varieties are even less common and include coronary, thyroid, syphilitic, and kyphoscoliotic cardiac disease, as well as idiopathic cardiomyopathy, cor pulmonale, constrictive pericarditis, various forms of heart block, and isolated myocarditis.

Maternal mortality related to heart disease has decreased remarkably over the past 50 years. [Sachs and associates \(1988\)](#) reported that maternal mortality from cardiac disease fell from 5.6 to 0.3 per 100,000 live births in Massachusetts from 1954 through 1985. Unfortunately, heart disease still contributes significantly to maternal mortality, both in the United States and throughout the world. [Koonin and colleagues \(1997\)](#) reported that heart disease was responsible for 5.6 percent of 1459 pregnancy-related deaths in the United States from 1987 to 1990. In the United Kingdom from 1994 through 1996, cardiac disease accounted for 40 of 105 indirect maternal deaths ([de Swiet, 2000](#)). [Dorfman \(1990\)](#) reported that 8 percent of maternal deaths in New York City from 1981 through 1983 were caused by cardiac disease. Similarly, [Jacob and associates \(1998\)](#) found that heart disease accounted for 15 percent of maternal mortality in Utah from 1982 through 1994.

PHYSIOLOGICAL CONSIDERATIONS WITH HEART DISEASE IN PREGNANCY

The marked hemodynamic changes stimulated by pregnancy have a profound effect on underlying heart disease in the pregnant woman. These physiological changes are detailed in [Chapter 8 \(p. 183\)](#). The most important consideration is that during pregnancy cardiac output is increased by as much as 30 to 50 percent. [Capeless and Clapp \(1989\)](#) have shown that almost half of the total increase has occurred by 8 weeks, and it is maximized by midpregnancy. The early increase can be attributed to augmented stroke volume that apparently results from decreased vascular resistance and is accompanied by diminished blood pressure. Later in pregnancy there is also an increased resting pulse, and stroke volume increases even more, presumably related to increased diastolic filling from augmented blood volume. These changes were reviewed by [van Oppen and colleagues \(1996\)](#) and [McLaughlin and Roberts \(1999\)](#).

An important study by [Clark and colleagues \(1989\)](#) contributed to the understanding of cardiovascular physiology during pregnancy. Using right-sided heart catheterization, these investigators measured hemodynamic function in 10 healthy primigravid women. Pregnancy values were compared with values measured again 11 to 13 weeks postpartum ([Table 44-1](#)). At or near term, cardiac output in the lateral recumbent position was increased 43 percent by virtue of elevated pulse rate and stroke volume. Systemic and pulmonary vascular resistance concomitantly decreased, and no change was observed in intrinsic left-ventricular contractility. As shown in [Figure 44-1](#), pregnancy is characterized by normal left-ventricular function, and not hyperdynamic function as once thought. The investigators concluded that maintenance of normal left-ventricular filling pressures comes about as the result of ventricular dilatation.

Because significant hemodynamic alterations are apparent early in pregnancy, women with severe cardiac dysfunction may experience worsening of heart failure before midpregnancy. In others, heart failure develops when hypervolemia of pregnancy is maximal after 28 weeks. In the majority, heart failure develops peripartum when there are additional hemodynamic burdens. This is when the physiological capability for rapid changes in cardiac output is frequently overwhelmed in the presence of structural cardiac disease. For example, in 542 women whose pregnancies were complicated by heart disease, 8 of 10 maternal deaths were during the puerperium ([Etheridge and Pepperell, 1977](#)).

PROGNOSIS. The likelihood of a favorable outcome for the mother with heart disease depends upon the functional cardiac capacity, other complications that further increase cardiac load, and quality of medical care provided. Psychological and socioeconomic factors may also assume great importance, because for some women, bed rest may be required throughout pregnancy.

CONGENITAL HEART DISEASE IN OFFSPRING. Many congenital heart lesions appear to be inherited as polygenic characteristics ([Chap. 36, p. 957](#)). Thus, it might be expected that some women with congenital lesions would give birth to similarly affected infants. [Whitte-more and co-workers \(1982\)](#) found a 10 percent incidence of fetal congenital heart disease in women born with cardiac anomalies. Only half of mother-fetus pairs were concordant for the same anomaly. [Shime and colleagues \(1987\)](#) found congenital cardiovascular lesions, including Marfan syndrome, in 3 percent of 87 infants born to women with congenital heart lesions.

DIAGNOSIS OF HEART DISEASE

Many of the physiological changes of normal pregnancy tend to make the diagnosis of heart disease more difficult ([Chap. 8, p. 181](#)). For example, in normal pregnancy, functional systolic heart murmurs are quite common. Respiratory effort in normal pregnancy is accentuated, at times suggesting dyspnea. Edema is generally present in the lower extremities during the latter half of pregnancy. It is important not to diagnose heart disease during pregnancy when none exists, and at the same time not fail to detect and appropriately treat heart disease when it does exist. Listed in [Table 44-2](#) are a number of symptoms and clinical findings that may indicate heart disease. Pregnant women who have none of these findings rarely have serious heart disease.

DIAGNOSTIC STUDIES

Most diagnostic cardiovascular studies are noninvasive and can be conducted safely in pregnant women. In most cases, conventional testing including electrocardiography, echocardiography, and chest radiography will provide necessary data. If indicated, right-heart catheterization can be performed with limited x-ray fluoroscopy. On rare occasions, it may be necessary to perform left-heart catheterization. Technetium^{99m}-labeled albumin or red cells are often used to evaluate ventricular function. The estimated fetal radiation exposure for a 20-mCi dose study is 120 mrad, well below the accepted level for significant teratogenic or oncogenic effect ([Chap. 42, p. 1153](#)). Thallium²⁰¹, used to evaluate regional coronary perfusion, yields a fetal exposure of 300 to 1100 mrad, depending on the stage of gestation. In cases with clear indications, any minimal theoretical risk will be outweighed by maternal benefits.

ELECTROCARDIOGRAPHY. As the diaphragm is elevated in advancing pregnancy, there is an average 15-degree left-axis deviation in the electrocardiogram, and mild ST changes may be seen in the inferior leads. Atrial and ventricular premature contractions are relatively frequent ([Carruth and colleagues, 1981](#)). Pregnancy does not alter voltage findings.

CHEST X-RAY. Anterior-posterior and lateral chest radiographs may be very useful when heart disease is suspected clinically. When used with a lead apron shield, fetal radiation exposure is minimized ([Chap. 42, p. 1148](#)). Slight heart enlargement cannot be detected accurately by x-ray because the heart silhouette normally is larger in pregnancy; however, gross cardiomegaly can be excluded.

ECHOCARDIOGRAPHY. The widespread use of echocardiography has allowed accurate diagnosis of most heart diseases during pregnancy. It allows noninvasive evaluation of structural and functional cardiac factors. Its use has also provided data on normal pregnancy-induced hemodynamic and cardiovascular changes. Some normal pregnancy-induced changes include tricuspid regurgitation and significantly increased left-atrial size and left-ventricular outflow cross-sectional area ([Limacher and co-workers, 1985](#)).

CLINICAL CLASSIFICATION

There is no clinically applicable test for accurately measuring functional cardiac capacity. A helpful clinical classification was first published in 1928 by the New York Heart Association, and was revised for the eighth time in 1979. One important change was the addition of an assessment of cardiac status after all data have been reviewed. Thus, the classification is no longer based only on clinical symptoms. The following is based on past and present disability and is uninfluenced by physical signs.

- **Class I.** Uncompromised: Patients with cardiac disease and *no limitation of physical activity*. They do not have symptoms of cardiac insufficiency, nor do they experience anginal pain.

- **Class II.** Slightly compromised: Patients with cardiac disease and *slight limitation of physical activity*. These women are comfortable at rest, but if ordinary physical activity is undertaken, discomfort results in the form of excessive fatigue, palpitation, dyspnea, or anginal pain.
- **Class III.** Markedly compromised: Patients with cardiac disease and *marked limitation of physical activity*. They are comfortable at rest, but less than ordinary activity causes discomfort by excessive fatigue, palpitation, dyspnea, or anginal pain.
- **Class IV.** Severely compromised: Patients with cardiac disease and *inability to perform any physical activity without discomfort*. Symptoms of cardiac insufficiency or angina may develop even at rest, and if any physical activity is undertaken, discomfort is increased.

PRECONCEPTIONAL COUNSELING

The woman with significant heart disease may benefit from counseling before the decision to become pregnant (see also [Chap. 9, p. 213](#)). Maternal mortality generally varies directly with functional classification at pregnancy onset; however, this relationship may change as pregnancy progresses. [Siu and colleagues \(1997\)](#) observed a 10 percent incidence of heart failure in 250 women with class I or II disease. Their experiences, as well as those of [McFaul and co-workers \(1988\)](#), were that there were no maternal deaths in over 700 women in classes I or II. In some women, life-threatening cardiac abnormalities can be reversed by corrective surgery and subsequent pregnancy is less dangerous. In other cases, fetal considerations predominate. For example, women with a mechanical prosthetic valve generally take warfarin compounds, which are known to be teratogenic. Therefore, during pregnancy, heparin is usually substituted for warfarin.

The [American College of Obstetricians and Gynecologists \(1992a\)](#) had adopted the three-tiered classification according to risks for death during pregnancy. These risks, shown in [Table 44-3](#), were developed to aid in counseling the woman regarding advisability of conception or continuation of pregnancy. As emphasized by [Clark and colleagues \(1997\)](#), common contemporaneous cardiac causes of maternal mortality are pulmonary complications, cardiomyopathy, infective endocarditis, coronary artery disease, and sudden arrhythmias.

GENERAL MANAGEMENT

Although a number of generalizations regarding management may be drawn, in clinical practice few women actually fit any "classic" pattern of structural cardiac disease. [Siu and associates \(1997\)](#) studied outcomes of 276 pregnancies involving 221 women with a variety of heart disorders. They found that poor maternal functional class or cyanosis, myocardial dysfunction, left-heart obstructive lesions, prior arrhythmia, and prior cardiac events were prognostic of complications during pregnancy. The likelihood of cardiac complications during pregnancy was 3, 30, and 66 percent when none, one, or more than one of these were present. Thus, individualization is essential in assuring optimal outcome. In most instances, management is with a team approach, involving obstetrician, cardiologist, anesthesiologist, and other specialists. Cardiovascular changes likely to be poorly tolerated by an individual woman are identified, and a plan is formulated to minimize such changes.

Four concepts that affect management are emphasized by the [American College of Obstetricians and Gynecologists \(1992a\)](#):

1. The 50 percent increase in blood volume and cardiac output by the early third trimester.
2. Further fluctuations in volume and cardiac output in the peripartum period.
3. A decline in systemic vascular resistance, reaching a nadir in the second trimester, and then rising to 20 percent below normal by late pregnancy.
4. Hypercoagulability, of special importance in women requiring anticoagulation in the nonpregnant state with coumarin derivatives.

Within this framework, both prognosis and management are influenced by the nature and severity of the specific lesion, in addition to the functional classification.

MANAGEMENT OF CLASSES I AND II

With rare exceptions, women in class I and most in class II go through pregnancy without morbidity. Throughout pregnancy and the puerperium, however, special attention should be directed toward both prevention and early recognition of heart failure. While infrequent today, in the past when severe mitral stenosis was common, heart failure developed in a third of these women ([Sugrue and colleagues, 1981](#)). By contrast, in nearly 250 pregnancies in women with class I or II heart disease in Toronto, only 10 percent developed failure ([Siu and co-workers, 1997](#)). Maternal mortality is low in classes I and II. Indeed, [McFaul and co-workers \(1988\)](#) and [Siu and associates \(1997\)](#) reported no maternal deaths in 726 pregnancies.

Infection has proved to be an important factor in precipitating cardiac failure. Each woman should receive instructions to avoid contact with persons who have respiratory infections, including the common cold, and to report at once any evidence for infection. Bacterial endocarditis is a deadly complication of valvar heart disease. Pneumococcal and influenza vaccines are recommended.

Cigarette smoking is prohibited, both because of its cardiac effects as well as the propensity to cause upper respiratory infections. Illicit drug use may be particularly harmful, as with the cardiovascular effects of cocaine or amphetamines, in addition to the propensity for intravenous use of any illegal substance to cause infective endocarditis.

The onset of congestive heart failure is generally gradual. The first warning sign is likely to be persistent basilar rales, frequently accompanied by a nocturnal cough. A sudden diminution in ability to carry out usual duties, increasing dyspnea on exertion, or attacks of smothering with cough are symptoms of serious heart failure. Clinical findings may include hemoptysis, progressive edema, and tachycardia.

LABOR AND DELIVERY. In general, delivery should be accomplished vaginally unless there are obstetrical indications for cesarean delivery. In some women with severe heart disease, **pulmonary artery catheterization** may be indicated for continuous hemodynamic monitoring ([American College of Obstetricians and Gynecologists, 1992b](#)). This may be performed electively when labor begins or planned cesarean delivery is performed. In our experiences, such monitoring is rarely indicated in women who have remained in functional class I or II throughout pregnancy.

Relief from pain and apprehension is especially important. While intravenous analgesics provide satisfactory pain relief for some women, continuous epidural analgesia is recommended for most situations. The major danger of conduction analgesia is maternal hypotension ([Chap. 15, p. 372](#)). This is especially dangerous in women with intracardiac shunts, in whom flow may be reversed with blood passing from the right-to-left within the heart or aorta, thereby bypassing the lungs. Hypotension can be very hazardous with pulmonary hypertension or aortic stenosis because ventricular output is dependent upon adequate preload. In women with these conditions, narcotic conduction analgesia or general anesthesia may be preferable.

During labor, the mother with significant heart disease should be kept in a semirecumbent position with lateral tilt. Vital signs should be taken frequently between contractions. Increases in pulse rate much above 100 per minute or in the respiratory rate above 24, particularly when associated with dyspnea, may suggest impending ventricular failure. With any evidence of cardiac decompensation, intensive medical management must be instituted immediately. It is essential to remember that delivery itself will not necessarily improve the maternal condition. Moreover, emergency operative delivery may be particularly hazardous. Clearly, both maternal and fetal conditions must be considered in the decision to hasten delivery under these circumstances.

For vaginal delivery in women with only mild cardiovascular compromise, epidural analgesia given along with intravenous sedation often suffices. This has been shown to minimize intrapartum cardiac output fluctuations and allows forceps or vacuum-assisted delivery. Subarachnoid blockade—spinal analgesia or saddle block—is not generally recommended in women with significant heart disease. For cesarean delivery, epidural analgesia is preferred by most clinicians with caveats for its use with pulmonary hypertension. Spinal analgesia is contraindicated with some lesions. Finally, general endotracheal anesthesia with thiopental, succinylcholine nitrous oxide, and at least 30 percent oxygen has also proved satisfactory ([Chap. 15, p. 362](#)).

INTRAPARTUM HEART FAILURE. Cardiovascular decompensation during labor may manifest as pulmonary edema and hypoxia, hypotension, or both. The proper therapeutic approach will depend upon the specific hemodynamic status and the underlying cardiac lesion. For example, decompensated mitral stenosis with pulmonary edema due to absolute or relative fluid overload is often best approached with aggressive diuresis, or if precipitated by tachycardia, by heart rate control with β -blocking agents. On the other hand, the same treatment in a woman suffering decompensation and hypotension due to aortic stenosis could prove fatal.

Unless the underlying pathophysiology is understood and the cause of the decompensation clear, empirical therapy is hazardous.

PUERPERIUM. Women who have shown little or no evidence of cardiac distress during pregnancy, labor, or delivery may still decompensate after delivery. Therefore, it is important that meticulous care be continued into the puerperium. Postpartum hemorrhage, anemia, infection, and thromboembolism are much more serious complications with heart disease. Indeed, these factors frequently act in concert to precipitate postpartum heart failure in women with underlying disease (Cunningham and associates, 1986).

If tubal sterilization is to be performed after vaginal delivery, it may be best to delay the procedure until it is obvious that the mother is afebrile, not anemic, and has demonstrated that she can ambulate without evidence of distress. Women who do not undergo tubal sterilization should be given detailed contraceptive advice. There are special considerations for contraception in women with various types of cardiac disorders. These are discussed in some of the following sections and in [Chapter 58](#). The [American College of Obstetricians and Gynecologists \(2000\)](#) has also recently considered some of these specific situations.

MANAGEMENT OF CLASSES III AND IV

These severe cases are uncommon today. In the Toronto study cited earlier, only 2 percent of 221 women had class III or IV heart disease ([Siu and associates, 1997](#)). In their experiences with 445 pregnant women with heart disease, [McFaul and colleagues \(1988\)](#) reported 4 percent with class III and 7 percent with class IV. The important question in these women is whether pregnancy should be undertaken. If women choose to become pregnant, they must understand the risks and cooperate fully with planned care. If seen early enough, women with some types of severe cardiac disease should consider pregnancy interruption. If the pregnancy is continued, prolonged hospitalization or bed rest will often be necessary.

As for less severe disease, epidural analgesia for labor and delivery is usually recommended. Vaginal delivery is preferred in most cases, and cesarean delivery is limited to obstetrical indications. The decision for cesarean delivery must take into account the specific cardiac lesion, overall maternal condition, availability and experience of anesthetic support, as well as physical facilities. These women often tolerate major surgical procedures poorly, and should be delivered in a facility with experience with complicated cardiac disease.

SURGICALLY CORRECTED HEART DISEASE

The majority of clinically significant lesions are repaired during childhood. [Morris and Menashe \(1991\)](#) reviewed mortality statistics for over 2700 children having corrective cardiac surgery in Oregon from 1958 through 1989. At 25 years, more than 75 percent were still alive. In referral centers for congenital heart disease in adults, only 15 to 20 percent have not had previous surgical intervention ([Perloff, 1997](#)). Examples of defects not diagnosed until adulthood include atrial septal defects, pulmonic stenosis, bicuspid aortic valve, and aortic coarctation ([Brickner and colleagues, 2000](#)). In some cases, the defect is mild and surgery is not required. In others a significant structural anomaly is amenable to surgical correction. With successful repair, many women will attempt pregnancy. In some instances, surgical corrections have been performed during pregnancy.

VALVE REPLACEMENT

A number of reproductive-age women have had a cardiac valvar prosthesis implanted to replace a severely damaged mitral or aortic valve. Reports of subsequent pregnancy outcomes are now quite numerous, and indeed, successful pregnancies have followed prosthetic replacement of even three heart valves ([Nagorney and Field, 1981](#)).

EFFECT ON PREGNANCY. Pregnancy is to be undertaken in these women only after serious consideration. Women with a **mechanical valve prosthesis** must be anticoagulated, and when not pregnant, warfarin is recommended. As shown in [Table 44-4](#), a number of serious complications can develop, especially with mechanical valves. Thromboembolism involving the prosthesis and hemorrhage from anticoagulation are of extreme concern. Also, there may be deterioration in cardiac function. Maternal mortality is 3 to 4 percent with mechanical valves and fetal loss is common. The critical issue is anticoagulation, and there is a suggestion that heparin may be less effective than warfarin in preventing thromboembolic events. Unfortunately, there are known adverse fetal effects of warfarin ([Caulin-Glaser and Setaro, 1999](#)). Spontaneous abortions, stillbirths, and malformed fetuses are more common if warfarin is used ([Chap. 38, p. 1014](#)).

The results shown in [Table 44-4](#) are similar to those reported by [Chan and colleagues \(2000\)](#) in their review of 28 studies published through 1997. They concluded that better maternal outcomes were achieved with continuation of warfarin throughout pregnancy; however, the embryopathy rate was 6.4 percent. While heparin substitution from 6 to 12 weeks eliminated embryopathy, it was associated with significantly increased thromboembolic complications. Low-dose heparin is definitely inadequate and in the study by [Iturbe-Alessio and colleagues \(1986\)](#), 3 of 35 women taking low-dose heparin suffered massive thrombosis of a mitral prosthesis, and two of them died. Overall, [Chan and co-workers \(2000\)](#) found a 2.9 percent maternal mortality rate.

Porcine tissue valves are much safer during pregnancy ([Table 44-4](#)). This is primarily because anticoagulation is not required. [Deviri and colleagues \(1985\)](#) reported no thrombi in 22 pregnancies in 11 unanti-coagulated women with porcine xenografts. [Lee and associates \(1994\)](#) described generally good outcomes in 95 pregnancies in 57 women with a porcine graft. Four of these developed valve dysfunction. Unfortunately, although less thrombogenic, such bioprostheses are not as durable as mechanical prostheses. Their use necessitates the acceptance of additional open-heart surgery at a future date. Fortunately, pregnancy does not appear to shorten this interval ([North and colleagues, 1999](#); [Salazar and co-workers, 1999](#)).

MANAGEMENT. Full anticoagulation throughout pregnancy is recommended with either warfarin or heparin after the woman is counseled regarding respective risks. Most authors recommend full heparinization as described in [Chapter 46 \(p. 1238\)](#) to prolong the partial thromboplastin time by 1.5 to 2.5 times baseline values. Just before delivery, heparin is stopped. If delivery supervenes while the anticoagulant is still effective, and extensive bleeding is encountered, protamine sulfate is given. Anticoagulant therapy with warfarin or heparin may be restarted 6 hours following vaginal delivery, usually with no problems. Following cesarean delivery, however, full anticoagulation should be withheld for at least 24 hours. [Clark and colleagues \(2000\)](#) reviewed the use of coumarin derivatives in breast-feeding women and concluded that warfarin can be safely given as it has minimal transfer to milk.

CONTRACEPTION. Because of their possible thrombogenic action, oral contraceptives containing estrogen and a progestin are relatively contraindicated in women with prosthetic valves ([Chap. 58, p. 1528](#)). Such women are generally fully anticoagulated, and thus any increased risk is speculative. Sterilization should be considered because of serious problems during pregnancy.

VALVE REPLACEMENT DURING PREGNANCY

Although usually postponed, valve replacement during pregnancy occasionally may be lifesaving. A number of reviews and small series all confirm that surgery on the heart or great vessels is associated with major maternal and fetal morbidity and mortality. [Westaby and associates \(1992\)](#) reviewed 115 cardiac surgeries using cardiopulmonary bypass from 1959 through 1990. They reported two maternal deaths and 17 percent fetal deaths. [Weiss and colleagues \(1998a\)](#) reviewed published cases from 1984 through 1996. In a total of 70 women, 59 of whom had cardiopulmonary bypass, maternal mortality was 6 percent and perinatal mortality was 30 percent. Valvar surgery was associated with a 9 percent maternal death rate.

[Strickland and colleagues \(1991\)](#) reported the Mayo Clinic experience in 10 women undergoing cardiopulmonary bypass with pump times ranging from 18 to 154 minutes. The fetal response to bypass was usually bradycardia, and they recommended that high-flow, normothermic perfusion be used if possible. [Khandelwal and associates \(1996\)](#) meticulously recorded fetal and uterine blood flow velocity patterns during a 74-minute bypass procedure at 19 weeks for aortic valve replacement. Despite high peak flow rates and sustained mean arterial pressures, uterine and umbilical artery resistances rose greatly, and fetal hydrocephalus and ascites were apparent within 2 days. [Tripp and co-workers \(1999\)](#) described use of pulsatile perfusion during aortic valve replacement at 14 weeks.

MITRAL VALVOTOMY. This operation is less common because the incidence of rheumatic mitral stenosis has declined. [Schenker and Polishuk \(1968\)](#) reported a total of 325 pregnancies in 182 women who previously had undergone mitral valvotomy. Despite this, heart failure developed in 42 percent of these women at some point during their first pregnancy following surgery. This percentage increased with successive pregnancies, and women suffering heart failure in one pregnancy inevitably had recurrence in subsequent pregnancies. Coexisting atrial fibrillation was especially ominous and commonly was associated with heart failure, thromboembolic disease, and death.

MITRAL VALVOTOMY DURING PREGNANCY. In the past, tight mitral stenosis that required intervention during pregnancy usually was treated surgically by closed mitral valvotomy ([Pavankumar and associates, 1988](#)). Following surgery, functional classification was usually downgraded from class III or IV to class I. There were no maternal deaths, and the fetal death rate was 7 percent. [Birincioglu and co-workers \(1999\)](#) described six women in whom mitral valve replacement was done in conjunction with cesarean delivery.

Within the past 20 years, percutaneous transcatheter balloon dilatation of the mitral valve has largely replaced surgical valvuloplasty during pregnancy ([Caulin-Glaser and Setaro, 1999](#); [Gupta and associates, 1998](#)).

HEART TRANSPLANTATION

By 1994, the registry of the International Society for Heart and Lung Transplantation had compiled data from more than 30,000 heart and heart-lung transplant operations ([Hosenpud and associates, 1994](#)). The 3-year survival rate is 75 percent and it was inevitable that some of these women would become pregnant. [Lowenstein and associates \(1988\)](#) reported the first successful pregnancy in a transplant recipient. [Key and associates \(1989\)](#) as well as [Kim and colleagues \(1996\)](#) provided detailed data to show that the transplanted heart responded normally to pregnancy-induced changes.

Complications are common during pregnancy. [Branch and collaborators \(1998\)](#) analyzed 47 pregnancies in 35 women entered into the National Transplantation Pregnancy Registry. Almost half delivered before 37 weeks, and 40 percent had maternal complications. At follow-up, 20 percent of these women had died. [Troche and co-workers \(1998\)](#) reported 10 pregnancies from the France Transplant Association. Hypertension complicated nine, half were delivered by cesarean, and half the fetuses had growth restriction. [Dashe and associates \(1998\)](#) reviewed 32 pregnancies reported in heart or heart-lung transplant recipients. Almost half had hypertension, 25 percent had preeclampsia, and 38 percent were delivered preterm. A third underwent cesarean delivery. About 20 percent experienced rejection episodes in pregnancy, and in 40 percent cyclosporine doses were increased. Although there were no direct maternal deaths, three women had died within 6 months to 3 years after delivery.

VALVAR HEART DISEASE

Rheumatic fever is uncommon in the United States because of less crowded living conditions, availability of penicillin, and evolution of nonrheumatogenic streptococcal strains. Still, it remains the chief cause of serious mitral valvar disease in women. During epidemics of streptococcal pharyngitis, as many as 3 percent of untreated young adults may develop rheumatic fever.

MITRAL STENOSIS

Rheumatic endocarditis causes three fourths of cases of mitral stenosis. The contracted valve impedes blood flow from the left atrium to the ventricle. With tight mitral stenosis, the left atrium is dilated, as shown in [Figure 44-2](#). As shown in [Table 44-5](#), left-atrial pressure is chronically elevated and may result in significant passive pulmonary hypertension and a fixed cardiac output ([Carabello and Crawford, 1997](#)). The increased preload of normal pregnancy, as well as other factors that require increased cardiac output, may cause ventricular failure with pulmonary edema in these women with relatively fixed cardiac output. Indeed, 25 percent of women with mitral stenosis have cardiac failure for the first time during pregnancy ([Caulin-Glaser and Setaro, 1999](#)). In some cases, this is confused with idiopathic peripartum cardiomyopathy ([Cunningham and colleagues, 1986](#)).

The normal mitral-valve surface area is 4.0 cm². When stenosis narrows this to less than 2.5 cm², symptoms usually develop ([Desai and colleagues, 2000](#)). The most prominent complaint is dyspnea due to pulmonary venous hypertension and pulmonary edema. Other common symptoms are fatigue, palpitations, cough, and hemoptysis.

In patients with significant mitral stenosis, tachycardia of any etiology shortens ventricular diastolic filling time and increases the mitral gradient, which raises left atrial and pulmonary venous and capillary pressures and may result in pulmonary edema ([Ramin and Gilstrap, 1999](#)). Thus, sinus tachycardia is often treated prophylactically with β -blocking agents. Atrial tachyarrhythmias, including fibrillation, are common in mitral stenosis and are treated aggressively with cardioversion if necessary. Atrial fibrillation also predisposes to mural thrombus formation and aortic embolization, which may lead to a thrombotic cerebrovascular accident.

MANAGEMENT. Limited physical activity is generally recommended. If symptoms of pulmonary congestion develop, activity is restricted even more, dietary sodium is restricted, and diuretic therapy started. A β -blocker drug is often given to slow heart rate response to activity and anxiety. [Al Kasab and associates \(1990\)](#) treated 25 pregnant women with mitral stenosis with either propranolol or atenolol. Their mean heart rate was decreased from 86 to 78 beats/min, and 92 percent had significant symptomatic improvement as measured by reassignment to a lower New York Heart Association classification. If new-onset atrial fibrillation develops, intravenous verapamil, 5 to 10 mg, is given, or electrocardioversion is performed. For chronic fibrillation, digoxin or a β - or calcium-channel blocker is given to slow ventricular response. Anticoagulation with heparin is also indicated.

Labor and delivery are particularly stressful for women with tight mitral stenosis. Pain, work, and anxiety cause tachycardia, with increasing chances of rate-related heart failure. Epidural analgesia for labor, with strict attention to avoid intravenous fluid overload, is ideal. As shown in [Figure 44-3](#), pulmonary capillary wedge pressures usually increase even more immediately postpartum. [Clark and colleagues \(1985\)](#) hypothesize that this is likely due to loss of the low-resistance placental circulation as well as "autotransfusion" from the lower extremities and pelvic veins and the now empty uterus. Abrupt increases in preload may lead to increased pulmonary capillary wedge pressure and pulmonary edema. Thus, care must be taken to avoid fluid overload ([Ramin and Gilstrap, 1999](#)).

Vaginal delivery is preferable, and some authors recommend elective induction so that labor and delivery can be monitored and attended by the most knowledgeable team. In cases of severe stenosis with chronic heart failure, insertion of a pulmonary artery catheter may help guide management decisions. Intrapartum endocarditis prophylaxis is required.

MITRAL INSUFFICIENCY

Mitral regurgitation develops when there is improper coaptation of mitral-valve leaflets during systole, and this is eventually followed by left-ventricular dilatation and eccentric hypertrophy ([Table 44-5](#)). Chronic mitral regurgitation may be due to a number of causes, including rheumatic fever, mitral-valve prolapse, or left-ventricular dilatation of any etiology—for example, dilated cardiomyopathy. Mitral-valve vegetation, known as *Libman-Sacks endocarditis*, is relatively common in women with antiphospholipid antibodies which may co-exist with systemic lupus erythematosus ([Roldan and colleagues, 1996](#); see [Chap. 52, p. 1391](#)). Less common causes include a calcified mitral annulus, possibly some appetite suppressants, and in older women, ischemic heart disease. Acute mitral insufficiency is caused by rupture of a chordae tendineae, infarction of papillary muscle, or by leaflet perforation from infective endocarditis.

In nonpregnant patients, symptoms from mitral-valve incompetence are rare, and valve replacement is seldom indicated, except for infective endocarditis. Likewise, mitral regurgitation is well tolerated during pregnancy, probably due to decreased systemic vascular resistance, which actually results in less regurgitation. Heart failure only rarely develops during pregnancy, and occasionally tachyarrhythmias need to be treated. Prophylaxis against bacterial endocarditis is given intrapartum.

AORTIC STENOSIS

Stenosis of the aortic valve is a disease of aging, and in a woman less than 30 years old, it is most likely due to a congenital lesion. This is the result of the decline in incidence of rheumatic diseases. The most common stenotic lesion is a bicuspid valve. Stenosis reduces the normal 2- to 3-cm² aortic orifice and creates resistance to ejection. A systolic pressure gradient develops between the left ventricle and the systemic arterial outflow tract. Concentric left-ventricular hypertrophy follows, and if severe, end-diastolic pressures become elevated, ejection fraction declines, and cardiac output is reduced ([Table 44-5](#)). Characteristic clinical manifestations develop late and include chest pain, syncope, heart failure, and sudden death from arrhythmias. Life expectancy after exertional chest pain develops averages only 5 years, and valve replacement is indicated for symptomatic patients.

Clinically significant aortic stenosis is uncommonly encountered during pregnancy. Mild to moderate degrees of stenosis are well tolerated, but severe disease is life threatening. The principal underlying hemodynamic problem is the fixed cardiac output associated with severe stenosis. During pregnancy, a number of factors may be encountered that commonly decrease preload further and thus aggravate the fixed cardiac output. Some examples include blood loss, regional analgesia, and vena caval occlusion. Importantly, all of these factors decrease cardiac, cerebral, and uterine perfusion. Because of these considerations, severe aortic stenosis may be extremely dangerous during pregnancy. Reports after 1975 describe a collective mortality of 7 percent ([Lao and colleagues, 1993b](#)). Patients with valve gradients exceeding 100 mm Hg appear to be at greatest risk.

MANAGEMENT IN PREGNANCY. For the asymptomatic pregnant woman, no treatment except close observation is required. Management of the symptomatic woman includes strict limitation of activity and prompt treatment of infections. If symptoms persist despite bed rest, valve replacement or valvotomy using cardiopulmonary bypass must be considered. In general, balloon valvotomy for aortic valve disease is avoided because of a serious complication rate of over 10 percent. Some of these complications include stroke, aortic rupture, aortic valve insufficiency, and death ([Carabello and Crawford, 1997](#)). In rare cases, however, it

may be preferable to perform valve replacement during pregnancy ([Angel and colleagues, 1988](#); [Lao and associates, 1993a](#)).

For women with critical aortic stenosis, intensive monitoring during labor is important. Pulmonary artery catheterization may be helpful because of the narrow margin separating fluid overload from hypovolemia. Patients with aortic stenosis are dependent upon adequate end-diastolic ventricular filling pressures to maintain cardiac output and systemic perfusion. Abrupt decreases in end-diastolic volume may result in hypotension, syncope, myocardial infarction, and sudden death. Thus the key to the management of these women is the avoidance of decreased ventricular preload and maintenance of cardiac output. During labor and delivery, such women should be managed on the "wet" side, maintaining a margin of safety in intravascular volume in anticipation of unexpected hemorrhage. In women with a competent mitral valve, pulmonary edema is rare, even with moderate volume overload.

During labor, narcotic epidural analgesia seems ideal, thus avoiding potentially hazardous hypotension, which may be encountered with standard conduction analgesia techniques. [Easterling and colleagues \(1988\)](#) used standard epidural analgesia for five women with severe stenosis and demonstrated immediate and profound effects of decreased filling pressures. Thus, as emphasized by [Thornhill and Camann \(1994\)](#), slow administration of dilute local anesthetics into the epidural space allows for a safe block. [Lao and associates \(1993b\)](#) used this routinely in 20 such women. Forceps or vacuum delivery are used for standard obstetrical indications in hemodynamically stable women. Bacterial endocarditis prophylaxis is given at delivery.

AORTIC INSUFFICIENCY

Aortic regurgitation is the diastolic flow of blood from the aorta into the left ventricle. Common causes of aortic valvar incompetence are rheumatic fever, connective tissue abnormalities, and congenitally acquired lesions. With Marfan syndrome, the aortic root may dilate, resulting in aortic insufficiency (see p. 1201). Acute insufficiency may develop with bacterial endocarditis or aortic dissection. Aortic as well as mitral-valve insufficiency have been linked to the appetite suppressants fenfluramine and dexfenfluramine ([Gardin, 2000](#); [Jick, 1998](#); Khan, 1998, and all of their associates). These lesions (usually mild) are duration related and aortic regurgitation develops in 9 to 14 percent of exposed patients compared with 4 percent of nonexposed controls ([Jick, 2000](#)).

With chronic disease, left-ventricular hypertrophy and dilatation develop ([Table 44-5](#)). This is followed by slow-onset fatigue, dyspnea, and edema, although rapid deterioration usually follows. Aortic insufficiency is generally well tolerated during pregnancy. Like mitral-valve incompetence, diminished vascular resistance is thought to improve the lesion ([Mendelson and Lang, 1995](#)). Symptoms necessitate therapy for heart failure, including bed rest, sodium restriction, and diuretics. Epidural analgesia is used for labor as well as vaginal or cesarean delivery. Bacterial endocarditis prophylaxis is given at delivery.

CONGENITAL HEART DISEASE

The incidence of congenital heart disease in the United States is approximately 8 per 1000 live-born infants. About a third of these have critical disease that requires cardiac catheterization or surgery, or they die within the first year. Others will require surgery in childhood, and 85 percent survive to adulthood ([Moodie, 1994](#)). Estimates of incidence and distribution of specific lesions will depend on the age group surveyed—for example newborns versus autopsy studies. According to [Nugent and associates \(1990\)](#), the more common lesions at birth are ventricular septal defect (28 percent), pulmonary stenosis (10 percent), patent ductus (8 percent), atrial septal defect (7 percent), aortic stenosis (4 percent), and aortic coarctation (4 percent). Most adults—80 to 85 percent—with significant disease have had some type of surgical intervention in childhood ([Perloff, 1997](#)).

[Mendelson and Lang \(1995\)](#) divide congenital heart lesions that complicate pregnancy into three groups:

1. Volume overload or left-to-right shunts, examples of which include atrial or ventricular septal defects.
2. Pressure overload, such as aortic and pulmonary stenosis, aortic coarctation, and hypertrophic subaortic stenosis.
3. Cyanotic lesions or right-to-left shunts that include Fallot tetralogy and Eisenmenger syndrome.

SEPTAL DEFECTS

After bicuspid aortic valve, **atrial septal defects** are the most commonly encountered congenital cardiac lesion in adults. They comprise a third of cases in adults ([Brickner and colleagues, 2000](#)). Many of these cases are asymptomatic until the third or fourth decade. The secundum-type defect accounts for 70 percent of all cases, and associated mitral-valve myxomatous abnormalities with prolapse are common. Most clinicians recommend repair if discovered in adulthood. Pregnancy is well tolerated unless pulmonary hypertension has developed, but this is rare because pulmonary artery pressures are low with an atrial septal defect ([Zuber and associates, 1999](#)). If congestive heart failure or an arrhythmia develops, treatment is given. Bacterial endocarditis prophylaxis is controversial, unless the defect was repaired with a patch. The risk is higher with associated mitral-valve pathology. The risk of atrial septal defect for the fetus is 5 to 10 percent.

Ventricular septal defects spontaneously close in 90 percent of patients during childhood. In adults the lesion follows bicuspid aortic valve, atrial septal defect, and pulmonic stenosis in frequency. Almost 75 percent of defects are paramembranous, and physiological derangements are related to their size. In general, if the defect is less than 1.25 cm², pulmonary hypertension and heart failure do not develop. When the effective size of the defect is greater than the aortic valve orifice, symptoms rapidly develop, and most children undergo surgical repair before pulmonary hypertension develops. In contrast, adults with unrepaired large defects develop left-ventricular failure and pulmonary hypertension, as well as a high incidence of bacterial endocarditis ([Brickner and colleagues, 2000](#)).

Pregnancy is well tolerated with small to moderate left-to-right shunts. When pulmonary arterial pressures reach systemic levels, however, there is reversal or bidirectional flow or **Eisenmenger syndrome**. When this develops, maternal mortality is 30 to 50 percent. [Jackson and colleagues \(1993\)](#) described two women who had severe pulmonary hypertension despite early repair of septal defects in childhood. One pregnancy was aborted and the second woman died 5 days following preterm delivery. Thus, pregnancy is contraindicated, and therapeutic abortion is advised if contraception fails. Bacterial endocarditis is common with unrepaired defects, and antibiotic prophylaxis is recommended. Unless repair is associated with residual septal defect, the risk of endocarditis is low. About 5 to 10 percent of offspring will have a ventricular septal defect.

PERSISTENT DUCTUS ARTERIOSUS

Like other shunts, the physiological consequences of this lesion are related to its size. Most significant lesions are repaired in childhood. In those not undergoing repair, mortality is high beginning in the fifth decade ([Brickner and co-workers, 2000](#)). Thus, some women with an unrepaired persistent ductus will have developed pulmonary hypertension. Heart failure may develop in these women, and if systemic blood pressure falls, reversal of blood flow from the pulmonary artery into the aorta causes cyanosis. Sudden drops in blood pressure at delivery, as with conduction analgesia or hemorrhage, may lead to fatal collapse. Therefore, hypotension should be avoided whenever possible and treated vigorously if it develops. Prophylaxis for bacterial endocarditis should be given at delivery. The incidence of inheritance is about 5 percent.

CYANOTIC HEART DISEASE

When congenital heart lesions are associated with right-to-left shunting of blood past the pulmonary capillary bed, then cyanosis develops. The classical and most commonly encountered lesion in pregnancy is the **Fallot tetralogy**. This is characterized by a large ventricular septal defect, right ventricular hypertrophy, and an overriding aorta. The magnitude of the shunt varies inversely with systemic vascular resistance. Hence, during pregnancy, when peripheral resistance decreases, the shunt increases and cyanosis worsens. Women who have undergone repair, and in whom cyanosis did not reappear, do well in pregnancy.

Some women with **Ebstein anomaly** of the tricuspid valve may reach reproductive age. Right-ventricular failure from volume overload and appearance or worsening of cyanosis are common during pregnancy. If there is no cyanosis, these women usually tolerate pregnancy well.

EFFECT ON PREGNACY. Women with cyanotic heart disease do poorly during pregnancy. With uncorrected Fallot tetralogy, for example, maternal mortality approaches 10 percent. Any disease complicated by severe maternal hypoxemia is likely to lead to miscarriage, preterm delivery, or fetal death. There is a relationship between chronic hypoxemia and the polycythemia it causes with the outcome of pregnancy. When hypoxemia is intense enough to stimulate a rise in hematocrit above 65 percent, pregnancy wastage is virtually 100 percent.

[Sawhney and colleagues \(1998\)](#) reported stillborn infants in 14 percent and fetal growth restriction in 36 percent of 24 pregnancies in women with cyanotic heart disease. [Shime and associates \(1987\)](#) reported that 13 of 23 women with cyanotic heart disease developed functional deterioration during pregnancy, and seven had

cardiac failure. Three of these 23 infants (13 percent) died, and low birthweight was common. While [Zuber and co-workers \(1999\)](#) reported good outcomes in 19 women with Fallot tetralogy, they emphasized that prepregnancy functional class and systolic ventricular function were good in all of them.

PREGNANCY AFTER SURGICAL REPAIR. With satisfactory surgical correction prior to pregnancy, maternal risks are decreased dramatically, and fetal environment is improved. [Singh and associates \(1982\)](#) described 40 pregnancies in 27 women with surgically corrected tetralogy. They concluded that in women with no major residual defects after surgery, that pregnancy is usually well tolerated. [Lao \(1994\)](#), [Megerian \(1994\)](#), [Lynch-Salamon \(1993\)](#), and their colleagues described a total of 14 pregnancies in 10 women following successful *Mustard repair* for **transposition of the great vessels**. Two women developed cardiac failure during pregnancy and two others developed worrisome arrhythmias. [Connolly and co-workers \(1999\)](#) reported 60 pregnancies in 22 women who had transposition corrected in childhood. Maternal complications were uncommon and only two women developed heart failure, there was one case of endocarditis, and a woman with a single coronary artery had a myocardial infarction. All 50 live-born infants survived.

Labor and Delivery. Vaginal delivery is preferred unless there is an obstetrical indication for cesarean delivery. **Pulmonary artery catheter monitoring has limitations because of the sometimes bizarre anatomical abnormalities.** Care must be taken to avoid sudden blood pressure decreases. For labor pain, epidural opiates may suffice. There is controversy regarding epidural analgesia versus general anesthesia for cesarean delivery ([Thornhill and Camann, 1994](#)).

EISENMENGER SYNDROME

This syndrome is secondary pulmonary hypertension that develops with any cardiac lesion in which pulmonary vascular resistance becomes greater than systemic vascular resistance and in which there is some right-to-left shunting. The most common underlying defects are atrial or ventricular septal defects and persistent ductus arteriosus. Patients usually are asymptomatic, but eventually pulmonary hypertension is severe enough to cause right-to-left shunting.

The prognosis for pregnancy depends on the severity of pulmonary hypertension. In a review of 44 cases through 1978, [Gleicher and associates \(1979\)](#) reported maternal and perinatal mortality rates to be about 50 percent. There has been little improvement since then ([Table 44-6](#)). [Yentis and colleagues \(1998\)](#) reported a 40 percent maternal death rate from the United Kingdom from 1991 through 1995. [Weiss and co-workers \(1998b\)](#) cited 36 percent maternal deaths in a review of 73 pregnancies. Of 26 deaths, only three were antepartum and 23 occurred during delivery or within a month postpartum. These women tolerate hypotension poorly, and the cause of death usually is right-ventricular failure with cardiogenic shock. Management is discussed later in this chapter.

OTHER CARDIOVASCULAR CONDITIONS

PULMONARY HYPERTENSION

High pulmonary blood pressure is generally secondary to cardiac or pulmonary disease, and common causes are persistent and prolonged left-to-right shunting with development of Eisenmenger syndrome as previously discussed. Other causes are chronic lung disease, hemoglobinopathies, cocaine use, human immunodeficiency virus (HIV) infection, and appetite suppressants ([Rubin, 1997](#)). According to [Edenborough and colleagues \(2000\)](#), pulmonary hypertension and cor pulmonale complicating cystic fibrosis has an especially poor pregnancy prognosis ([Chap. 46, p. 1243](#)).

Primary pulmonary hypertension, characterized by medial hypertrophy and plexiform lesions, is usually idiopathic, but some previously unexplained cases may be due to antiphospholipid antibodies ([Chap. 52, p. 1391](#)). It has also been seen in young women who took certain appetite suppressants ([Gaine and Rubin, 1998](#)). The prognosis is bad and the mean survival from diagnosis is about 2 years. Long-term therapy with epoprostenol (prostacyclin) given intravenously by continuous infusion significantly lowers pulmonary vascular resistance ([McLaughlin and colleagues, 1998](#)). [Easterling and associates \(1999\)](#) recommend that response to nifedipine and prostacyclin be documented for at least a year before pregnancy is advised.

EFFECTS ON PREGNANCY. Maternal mortality is appreciable, whether pulmonary hypertension is primary or secondary. [Torres and associates \(1994\)](#) documented diminished pulmonary vascular resistance during pregnancy in a woman with primary disease. [Kiss and colleagues \(1995\)](#) reviewed literature since 1956 and reported a maternal mortality rate of 7 of 11 (65 percent) women with primary pulmonary hypertension. [Weiss and associates \(1998b\)](#) reviewed 27 cases reported from 1978 through 1996 and found a 30 percent mortality rate. As discussed, women with Eisenmenger syndrome also have formidable mortality ([Table 44-6](#)).

While pregnancy is contraindicated with severe disease, milder degrees of secondary pulmonary hypertension probably go unnoticed. For example, with the more common use of pulmonary artery catheterization in women with heart disease, we have identified women with mild to moderate pulmonary hypertension who tolerated pregnancy, labor, and delivery quite well. [Bogges and colleagues \(1995\)](#) described nine women with interstitial and restrictive lung disease who ostensibly had varying degrees of pulmonary hypertension. Three women had severe disease, and all nine tolerated pregnancy reasonably well.

Treatment of symptomatic pregnant women includes limitation of activity and avoidance of the supine position in late pregnancy. Diuretics, supplemental oxygen, and vasodilator drugs are standard therapy for symptoms. [Goodwin \(1999\)](#) and [Robinson \(1999\)](#) and their colleagues have described both chronic and acute therapy with inhaled nitric oxide in two pregnant women. [Easterling and associates \(1999\)](#) successfully used nifedipine and prostacyclin during pregnancy, and [Badalian and co-workers \(2000\)](#) described continued epoprostenol (prostacyclin) infusion throughout a twin pregnancy.

Management of labor and delivery is particularly problematic. **These women are at greatest risk when there is diminished venous return and right ventricular filling which is associated with most maternal deaths.** Regional analgesia is problematic because of possible hypotension. Careful attention is given to blood loss at delivery and avoidance of standard (non-narcotic) epidural analgesia. [Pollack and colleagues \(1990\)](#), as well as others, have reported successful labor analgesia without significant cardiovascular effects from morphine administered intrathecally. [Thornhill and Camann \(1994\)](#) recommend intrathecal morphine, which can be supplanted by careful administration of epidural local anesthetics. They also argue against the use of pulmonary artery catheterization for a number of technical and safety issues, not the least of which is that data are usually not clinically useful. [Weiss and co-workers \(2000\)](#) described a woman with severe primary pulmonary hypertension who was successfully delivered by cesarean using epidural analgesia and while inhaling 20 mg of aerosolized iloprost.

MITRAL-VALVE PROLAPSE

This diagnosis implies the presence of a pathological connective-tissue disorder—often termed *myxomatous degeneration*—which may involve the valve leaflets themselves, the annulus, or the chordae tendinae. Until recently, this condition was thought to have a prevalence as high as 15 percent in otherwise normal young women. Community-based studies, however, indicate the incidence to be only 2 to 3 percent ([Freed and colleagues, 1999](#)). For referred cases, it is commonly associated with a wide variety of other cardiac disorders, including atrial septal defect, Marfan syndrome, Epstein anomaly, and hypertrophic cardiomyopathy. The etiology of isolated myxomatous degeneration is unknown.

Most women with mitral-valve prolapse are asymptomatic and are diagnosed by routine physical examination or as an incidental finding at echocardiography. The small percentage of women with symptoms have anxiety, palpitations, dyspnea, atypical chest pain, and syncope. [Nishimura and colleagues \(1985\)](#) identified only those patients with redundant mitral-valve leaflets to be at increased risk of sudden death, infective endocarditis, or cerebral embolism. Still, of 213 young women with documented ischemic strokes, only 1.9 percent had mitral-valve prolapse compared with 2.7 percent of controls ([Gilon and co-workers, 1999](#)).

DIAGNOSIS. Mitral-valve prolapse implies the presence of a pathological condition and should be diagnosed with great caution and precision. Reliance upon strict diagnostic criteria is essential before assigning a pathological diagnosis or administration of endocarditis prophylaxis ([Nishimura and McGoon, 1999](#)).

EFFECTS ON PREGNANCY. Pregnant women with mitral-valve prolapse rarely have cardiac complications. In fact, pregnancy-induced hypervolemia may improve alignment of the mitral-valve ([Rayburn and colleagues, 1987](#)). For women who are symptomatic, β -blocking drugs are given to decrease sympathetic tone, relieve chest pain and palpitations, and reduce the risk of life-threatening arrhythmias. In general, mitral-valve prolapse has not been deleterious to pregnancy. We manage these women as if not pregnant and prescribe β -blocker drugs for symptoms. Mitral-valve prolapse with regurgitation is considered to be a significant risk factor for development of bacterial endocarditis. Women should be given antibiotic prophylaxis if there is regurgitation, valvular damage, or any of the risk factors discussed. Patients without evidence of pathological myxomatous change may in general expect excellent pregnancy outcome ([Chia and associates, 1994](#)).

PERIPARTUM CARDIOMYOPATHY

This is a diagnosis of exclusion and is similar to idiopathic dilated cardiomyopathy that occurs in nonpregnant adults. A relationship of pregnancy with dilated cardiomyopathy was cited by Virchow and Porak in 1870. While the term peripartum cardiomyopathy has been used widely to describe women with peripartum heart failure with no readily apparent etiology, it is doubtful that there is a pregnancy-induced cardiomyopathy. The National Heart, Lung, and Blood Institute convened a

review panel which concluded that the disease is an acute condition rather than a preexisting one preceding pregnancy ([Pearson and colleagues, 2000](#)).

Because other causes must be excluded, careful evaluation of new-onset ventricular dysfunction is essential. According to [Fatkin and collaborators \(1999\)](#), a third of cases of idiopathic dilated cardiomyopathy are inherited. [Felker and colleagues \(2000\)](#) performed endomyocardial biopsy in 1230 nonpregnant patients who had unexplained cardiomyopathy. In exactly half of these, a cause for cardiomyopathy was found and the most common was myocarditis. [Feldman and McNamara \(2000\)](#) recently reviewed this association. Dilated cardiomyopathy is also found in HIV¹ infection ([Barbaro and associates, 1998](#)). We carefully evaluated 28 women at Parkland Hospital with peripartum heart failure of obscure etiology who were initially thought to have idiopathic cardiomyopathy. In 21 of these, heart failure was ultimately attributed to hypertensive heart disease, clinically silent mitral stenosis, obesity, or viral myocarditis ([Cunningham and associates, 1986](#)). In the study by [Felker and co-workers \(2000\)](#), 26 of 51 women with peripartum cardiomyopathy had histological incidence of myocarditis on endomyocardial biopsy.

Chronic hypertension with superimposed preeclampsia is a common cause of heart failure during pregnancy ([Chap. 45, p. 1212](#)). In some cases, mild antecedent hypertension is undiagnosed, and when superimposed preeclampsia develops, it may cause otherwise inexplicable peripartum heart failure. Obesity is a common co-factor with chronic hypertension, and it can cause or contribute to underlying ventricular hypertrophy ([Fig. 44-4](#)). In the Framingham Heart Study, obesity alone was correlated with increased left-ventricular mass ([Lauer and colleagues, 1991](#)).

Regardless of the underlying condition that causes cardiac dysfunction, women who develop peripartum heart failure often have obstetrical complications that either contribute to or precipitate heart failure. For example, preeclampsia is common and may precipitate afterload failure. Acute anemia from blood loss magnifies the physiological effects of compromised ventricular function. Similarly, infection and accompanying fever increase cardiac output and oxygen utilization.

IDIOPATHIC CARDIOMYOPATHY IN PREGNANCY. After a thorough search excludes an underlying cause for heart failure, idiopathic cardiomyopathy may be considered ([Brown and Bertolet, 1998](#); [Hibbard and associates, 1999](#)). We identified this in about 1 in 15,000 deliveries and this incidence is not different from that of idiopathic cardiomyopathy in young nonpregnant women ([Cunningham and colleagues, 1986](#)). [Lampert \(1993\)](#) and [Mabie \(1993\)](#) and their associates have implicated prolonged β -mimetic tocolysis with terbutaline as provoking cardiomyopathy. As previously discussed, clinically undetected **myocarditis** is found in up to half of these women if biopsy is done. [O'Connell and colleagues \(1986\)](#) found that a third of pregnant women with idiopathic cardiomyopathy had biopsy evidence of myocarditis compared with only 10 percent of nonpregnant patients.

Women with cardiomyopathy present with signs and symptoms of congestive heart failure. Dyspnea is universal, and other symptoms include orthopnea, cough, palpitations, and chest pain ([Sheffield and Cunningham, 1999](#)). The hallmark finding usually is impressive cardiomegaly ([Fig. 44-5](#)). Echocardiographic and Doppler studies confirm increased end-diastolic dimensions, an ejection fraction less than 45 percent, and/or fractional shortening of less than 30 percent ([Hibbard and co-workers, 1999](#)).

Therapy consists of treatment for heart failure ([Brown and Bertolet, 1998](#)). Sodium intake is limited and diuretics are given to reduce preload. Afterload reduction with hydralazine or another vasodilator is accomplished; however, angiotensin-converting enzyme inhibitors should be avoided if the woman is undelivered ([Chap. 38, p. 1014](#)). Digoxin is given for its inotropic effects unless complex arrhythmias are identified. Because there is a high incidence of associated pulmonary embolism, "low-dose" heparin is often recommended. [Carlson and co-workers \(2000\)](#) described a woman who presented postpartum with a lower-extremity arterial thromboembolism.

PROGNOSIS. The distinction between peripartum heart failure from an identifiable cause versus idiopathic cardiomyopathy is important. This distinction is somewhat artificial because, if biopsy is done, recall that at least half of women with peripartum cardiomyopathy will be found to have histological myocarditis. As shown in [Figure 44-6](#), the 5- and 10-year survival rates are substantially lower with idiopathic disease. [Ford and co-workers \(2000\)](#) found better prognoses in women with idiopathic disease not complicated by underlying disease. According to [Lampert and associates \(1997\)](#), half of all women with peripartum cardiomyopathy regain left-ventricular function within 6 months, and they have a good prognosis. Conversely, the other half have high morbidity and mortality rates. Even women who regain normal ventricular function may have evidence for underlying pathology when dobutamine challenge testing is done ([Lampert and colleagues, 1993](#)).

It is important to determine the severity of underlying heart disease in women with new-onset peripartum heart failure. [Witlin and associates \(1997\)](#) studied 28 such women without an antecedent history of heart disease and found that two thirds had chronic hypertension. Their outcomes were dismal: five died, three underwent heart transplantation, and 18 had continued cardiac impairment. From their review, [Heider and co-workers \(1999\)](#) also concluded that the long-term prognosis is poor.

SUBSEQUENT PREGNANCY. Women with persistent ventricular dysfunction do not tolerate subsequent pregnancy very well. Even those with recovered ventricular function may have deterioration when pregnant again. Already discussed are the findings of [Lampert and associates \(1993, 1997\)](#) who demonstrated ventricular dysfunction to occur with dobutamine infusion in women with recovered normal resting function. [Albanesi and da Silva \(1999\)](#) described a propensity for ventricular dysfunction in 3 of 12 women in subsequent pregnancy.

INFECTIVE ENDOCARDITIS

This infection involves cardiac endothelium and produces vegetations that usually deposit on a valve. Infective endocarditis can involve a native or a prosthetic valve, or it may be associated with intravenous drug abuse. Children and adults who survive corrective surgery for congenital heart disease are at greatest risk ([Morris and co-workers, 1998](#)). About 75 percent of adults have a known preexisting heart lesion. The relative risks of endocarditis with some lesions are listed in [Table 44-7](#).

Subacute bacterial endocarditis usually is due to a low-virulence bacterial infection superimposed on an underlying lesion. These are usually native valve infections. Organisms that cause indolent bacterial endocarditis are most commonly viridans group streptococci, or *Enterococcus* species. Group B streptococcal endocarditis can be subacute or acute. [Gallagher and Watanakunakorn \(1986\)](#) observed that almost 10 percent of the latter cases reported since 1962 were in pregnant women.

Acute endocarditis is usually caused by coagulase-positive staphylococci. *S. aureus* is the predominant organism in a third of native valve infections, and it causes half of those in intravenous drug abusers ([Kaye, 1998](#)). In those not associated with drug use, the left side is involved in 80 percent of cases, and mortality is nearly 50 percent ([Roder and colleagues, 1999](#)). *S. epidermidis* commonly causes prosthetic valve infections. *Streptococcus pneumoniae* and *Neisseria gonorrhoeae* may cause acute, fulminating disease. [Bataskov and colleagues \(1991\)](#) described fatal gonococcal endocarditis complicating pregnancy. [Deger and Ludmir \(1992\)](#) reported antepartum endocarditis caused by *N. sicca*, and we have had a maternal death due to endocarditis from *N. mucosa* ([Cox and associates, 1988](#)). Although group B streptococcal infections are common in pregnant women and newborns, very few cases of endocarditis have been described ([Kangavari and co-workers, 2000](#)).

Symptoms of endocarditis are variable and often develop insidiously. Fever is virtually universal, and a murmur is heard in over 85 percent of cases ([Kaye, 1998](#)). Anorexia, fatigue, and other constitutional symptoms are common, and the illness is frequently described as "flu-like." Other findings are anemia, proteinuria, and manifestations of embolic lesions, including petechiae, focal neurological manifestations, chest or abdominal pain, and ischemia in an extremity. In some cases, heart failure develops. In the usual case, symptoms usually persist for several weeks before the diagnosis is made. Thus, a high index of suspicion is necessary to consider endocarditis. Diagnosis is confirmed by excluding other causes of febrile illnesses and recovering positive blood cultures for typical organisms. Echocardiography and two-dimensional sector scanning are useful, but lesions only 3 to 4 mm in size or those on the tricuspid valve may be missed. **A negative echocardiographic study does not exclude endocarditis.**

Treatment is primarily medical with appropriate timing of surgical intervention if this becomes necessary. Knowledge of the infecting organism is imperative for sensible antimicrobial selection. Most viridans streptococci are sensitive to penicillin G given intravenously along with gentamicin for 2 weeks ([Kaye, 1998](#)). Complicated infections are treated longer, and women allergic to penicillin are either desensitized or given intravenous ceftriaxone or vancomycin for 4 weeks. Staphylococci, enterococci, and other organisms are treated according to microbial sensitivity for 4 to 6 weeks. Prosthetic valve infections are treated for 6 to 8 weeks. Persistent native valve infection may require replacement, and this is even more commonly indicated with an infected prosthetic valve.

ENDOCARDITIS IN PREGNANCY. Infective endocarditis is uncommon during pregnancy and the puerperium. Over a 7-year period, the incidence of endocarditis at Parkland Hospital was about 1 in 16,000 deliveries ([Cox and associates, 1988](#)). Two of seven women died. Treatment is the same as that described earlier. From their review, [Seaworth and Durack \(1986\)](#) and [Cox and Leveno \(1989\)](#) cited maternal mortality of about 25 to 35 percent.

ANTIMICROBIAL PROPHYLAXIS. The efficacy of antimicrobial prophylaxis to prevent bacterial endocarditis is questionable. Only 13 percent of cases arising in patients with high-risk cardiac lesions do so after a procedure ([van der Meer and associates, 1992](#)). The American Heart Association recommends prophylaxis based on risk stratification, and its 1997 recommended regimens are shown in [Table 44-8](#).

OBSTETRICAL PROCEDURES. The 1997 guidelines include a long list of invasive procedures for which prophylaxis is recommended. Importantly, most dental procedures are included. Cesarean delivery constitutes an indication, but prophylaxis is optional with vaginal delivery. The incidence of transient bacteremia at delivery is about 5 to 10 percent ([Boggess and colleagues, 1996](#)). Although there is meager evidence that a significant number of cases of bacterial endocarditis have been prevented with antimicrobial prophylaxis given for uncomplicated delivery, its risk and costs are not great ([McFaul and associates, 1988](#); [Seaworth and Durack, 1986](#)). Individualization seems appropriate. For example, with premature or prolonged membrane rupture, manual placental removal, or fourth-degree perineal lacerations in women with high- or moderate-risk lesions, prophylaxis is reasonable.

In the current guidelines shown in [Table 44-8](#), prophylaxis for high-risk patients includes an initial dose of antimicrobial(s) to be completed within 30 minutes before the procedure is begun. Another dose is given 6 hours later. Obviously, accurate prediction of delivery time is problematic to timely administration of the first dose.

ARRHYTHMIAS

Cardiac arrhythmias are commonly encountered during pregnancy, labor and delivery, and the puerperium. It is debated whether arrhythmias are more common during pregnancy, but in our experiences, their detection is probably increased because of more frequent visits during prenatal care. Perhaps the normal but mild hypokalemia of pregnancy induces arrhythmias ([Chap. 8, p. 177](#)). Most arrhythmias in young women are not associated with organic heart disease, and most often their treatment is not different from that for nonpregnant patients.

Bradyarrhythmias, including complete heart block, are compatible with a successful pregnancy outcome. Some women with complete heart block will have syncope during labor and delivery and occasionally temporary cardiac pacing is necessary. Women with permanent artificial pacemakers usually tolerate pregnancy well ([Jaffe and associates, 1987](#)). With fixed-rate devices, cardiac output apparently is increased by augmented stroke volume.

Tachyarrhythmias are relatively common. Whenever these arrhythmias are encountered, underlying cardiac disease should be considered. *Wolff-Parkinson-White syndrome* may first appear during pregnancy, but some women with previously diagnosed arrhythmias have an increased incidence of tachycardia during pregnancy ([Widerhorn and co-workers, 1992](#)). **Paroxysmal supraventricular tachycardia** is encountered most frequently. [Siu and associates \(1997\)](#) followed 25 women who had supraventricular tachycardia diagnosed before pregnancy. Half of these women had Wolff-Parkinson-White syndrome. Six of 13 women without Wolff-Parkinson-White Syndrome and 3 of 12 with the condition had supraventricular tachycardia during pregnancy. If vagal maneuvers do not stimulate conversion, treatment consists of digoxin, adenosine, or calcium-channel blocking drugs. Experience is accruing that adenosine is effective for cardioversion in hemodynamically stable pregnant women ([Chakhtoura and co-workers, 1998](#)). Although these drugs cross the placenta, they do not appear to harm the fetus. [Dunn and Brost \(2000\)](#), however, reported fetal bradycardia in response to adenosine given intravenously for maternal supraventricular tachycardia. Electrical cardioversion also is not contraindicated in pregnancy.

Ventricular tachycardia is uncommon in healthy young women without underlying heart disease. [Brotsky and associates \(1992\)](#) described seven pregnant women with new-onset ventricular tachycardia and reviewed 23 previously published reports. Most of these women were not found to have structural heart disease, and in 60 percent, arrhythmias were stimulated by physical exercise or psychological stress. Of those remaining, two had myocardial infarction, two had a prolonged QT interval, and anesthesia provoked tachycardia in another. In 6 of 26, no precipitating event was found. The investigators concluded that pregnancy events probably precipitated tachycardia and recommended β -blocker therapy for control.

Atrial flutter or fibrillation are more likely associated with underlying disease, such as thyrotoxicosis. Major complications include stroke ([Ezekowitz and Levine, 1999](#)). Thus, heparin is recommended by some authors if fibrillation is chronic, was identified before pregnancy, and persists during pregnancy. If atrial fibrillation is associated with mitral stenosis, pulmonary edema may develop in late pregnancy if the ventricular rate is increased. Digitalis is given to diminish ventricular response, and quinidine may prevent its recurrence.

DISEASES OF THE AORTA

Marfan syndrome and coarctation of the aorta are two aortic diseases that place the pregnant woman at increased risk for **aortic dissection**. Other risk factors are bicuspid aortic valve and Turner or Noonan syndrome. [Pepin and colleagues \(2000\)](#) reported a high rate of aortic dissection or rupture in patients with *Ehlers-Danlos syndrome* ([Chap. 52, p. 1399](#)). Although the mechanism(s) involved are unclear, the initiating event in aortic dissection is an aortic intimal tear, and following medial hemorrhage, rupture may occur. It is taught that half of all aortic dissections in women under age 40 develop during late pregnancy ([Simpson and D'Alton, 1997](#)). [Oskoui and Lindsay \(1994\)](#), however, disputed this. They reviewed 196 consecutive aortic dissections and found nine in women less than 40, and none were pregnant. [Easterling and colleagues \(1991\)](#) found that aortic diameter increased significantly in normal women over the course of pregnancy. This increase was even greater for women who developed preeclampsia.

In most cases, women with aortic dissection present with severe chest pain described as ripping, tearing, or stabbing in nature. Diminution or loss of peripheral pulses in conjunction with a recently acquired murmur of aortic insufficiency are important physical findings. The differential diagnosis of aortic dissection includes myocardial infarction, pulmonary embolism, pneumothorax, and aortic valve rupture. [Lang and Borow \(1991\)](#) rightfully add obstetrical catastrophes to the list, especially placental abruption and uterine rupture.

Over 90 percent of patients have an abnormal chest x-ray. Although aortic angiography is the most definitive method for confirming the diagnosis, noninvasive imaging with sonography, computed tomography, and magnetic resonance imaging are being used more frequently. The urgency of the clinical situation frequently will dictate which procedure is best. Initial medical treatment is given to lower blood pressure. Proximal dissections most often need to be resected, along with aortic valve replacement if indicated. Distal dissections are more complex, and many may be treated medically.

MARFAN SYNDROME. This syndrome is usually inherited as an autosomal dominant trait with a high degree of penetrance. It is caused by an abnormal *fibrillin* produced by a mutation in the FBN1 gene located on chromosome 15q21. Fibrillin is a constituent of elastin, and thus this is a systemic connective-tissue disorder which is characterized by generalized weakness that can result in dangerous cardiovascular complications. Because all tissues are involved, other defects are frequent and include joint laxity and scoliosis. Progressive aortic dilatation causes aortic valve insufficiency, and there may be infective endocarditis, and mitral-valve prolapse with insufficiency. Aortic dilatation and dissecting aneurysm are the most serious abnormalities. Early death is due either to valvar insufficiency and heart failure or to a dissecting aneurysm. Long-term benefits from β -blocker therapy have been described for nonpregnant adults ([Shores and colleagues, 1994](#)).

EFFECT OF PREGNANCY. Deaths due to dissecting aortic aneurysm during pregnancy are frequent in women with Marfan syndrome. The previous grave concerns of the effects of pregnancy seem to have been overestimated. For example, from their review of published cases, [Elkayam and associates \(1995\)](#) found that 20 of 32 women had aortic dissection or rupture and 16 of these died. In a prospective longitudinal evaluation of 21 women during 45 pregnancies from the Johns Hopkins Hospital, only two had dissection and one died postpartum from graft infection ([Rossiter and colleagues, 1995](#)). They concluded that aortic dilatation more than 40 mm in diameter or mitral-valve dysfunction are high-risk factors for life-threatening cardiovascular complications during pregnancy. Conversely, women with minimal or no dilatation, and those with normal cardiac function by echocardiography, are counseled regarding the small but serious potential risk of aortic dissection.

[Elkayam and colleagues \(1995\)](#) also concluded that pregnancy was safer in women with Marfan syndrome who had no cardiovascular manifestations or aortic arch dilatation. They recommended β -blocker prophylactic therapy during pregnancy. The aortic root usually measures about 20 mm, and if dilatation reaches 40 mm, then dissection is more likely ([Simpson and D'Alton, 1997](#)). If it reaches 50 to 60 mm, then elective surgery should be considered before pregnancy ([Gott and collaborators, 1999](#); [Pretre and Von Segesser, 1997](#)). Aortic root replacement during pregnancy has been associated with hypoxic-ischemic cerebral damage in a 29-week fetus ([Mul and co-workers, 1998](#)). While Marfan syndrome itself is not an indication, they recommended cesarean delivery if there is aortic involvement. Otherwise, obstetrical indications for delivery are followed. BR>

The condition is autosomally dominant and thus half of offspring are affected. Prenatal diagnosis is usually possible using linkage analysis ([Chap. 36](#)).

AORTIC COARCTATION. This is a relatively rare lesion often accompanied by lesions of other large arteries. For example, a bicuspid aortic valve is seen with echocardiography in a fourth of affected patients, and another 10 percent have cerebral artery aneurysms. Other associated lesions are persistent ductus arteriosus, septal defects, and Turner syndrome. The collateral circulation arising above the level of the coarctation expands, often to a striking extent, to cause localized erosion of rib margins by hypertrophied intercostal arteries. Typical findings on physical examination are hypertension in the upper extremities but normal or reduced blood pressures in the lower extremities. [Dizon-Townson and colleagues \(1995\)](#) described diagnosis during pregnancy using magnetic resonance imaging.

EFFECTS ON PREGNANCY. The major complications of coarctation are congestive heart failure after long-standing severe hypertension, bacterial endocarditis of the **bicuspid aortic valve**, and aortic rupture. Maternal mortality rates average about 3 percent ([McAnulty and co-workers, 1990](#)). Because hypertension may worsen

in pregnancy, antihypertensive therapy using β -blocking drugs is usually required. Aortic rupture is more likely to occur late in pregnancy or early in the puerperium. Rupture may be associated with changes in the media that are histologically similar to those of Erdheim idiopathic medial cystic necrosis. Cerebral hemorrhage from **circle of Willis aneurysms** may also develop.

Congestive heart failure demands vigorous efforts to improve cardiac function and may warrant pregnancy interruption. Some authors have recommended that resection of the coarctation be undertaken during pregnancy to protect against the possibility of a dissecting aneurysm and aortic rupture. This has significant risks, especially for the fetus, because all the collaterals must be clamped for variable periods of time.

Some authors recommend cesarean delivery to prevent transient arterial blood pressure elevations that commonly accompany labor. It is feared that such blood pressure increases might lead to rupture of either the aorta or coexisting cerebral aneurysms. Available evidence, however, suggests that cesarean delivery should be limited to obstetrical indications. Bacterial endocarditis prophylaxis is given at delivery. About 2 percent of infants born to an affected patient will have the lesion.

ISCHEMIC HEART DISEASE

Coronary artery disease, which may lead to **myocardial infarction**, is a rare complication of pregnancy. While [Mendelson and Lang \(1995\)](#) cite the collective incidence of myocardial infarction complicating pregnancy to be 1 in 10,000, it probably is much lower than this. Frequently, women with coronary artery disease have classical risk factors such as cigarette smoking, familial hyperlipidemia, obesity, or hypertension. [Bagg and colleagues \(1999\)](#) reviewed 22 diabetic pregnant women with ischemic heart disease or class H diabetes ([Chap. 51, p. 1361](#)). They as well as [Reece and associates \(1986\)](#) and [Pombar and colleagues \(1995\)](#) documented unusually high mortality in pregnant diabetics who suffered myocardial infarction. [Sutaria and collaborators \(2000\)](#) and [Mousa and associates \(2000\)](#) each documented coronary artery occlusion in two pregnant smokers with hypercholesterolemia following a routine 500-mg ergometrine intramuscular injection. [Schulte-Sasse \(2000\)](#) described myocardial ischemia with prostaglandin E₁ vaginal suppositories. [Thorpe and colleagues \(1994\)](#) described a 22-year-old woman with antiphospholipid antibodies who suffered a myocardial infarction 10 days postpartum.

Diagnosis during pregnancy is not different than in the nonpregnant patient. Measurement of serum levels of the cardiac-specific contractile protein, *troponin I*, is accurate for diagnosis. [Shivvers and colleagues \(1999\)](#) showed that troponin was undetectable across normal pregnancy.

PREGNANCY WITH PRIOR MYOCARDIAL DISEASE. The advisability of pregnancy after a myocardial infarction is unclear. Ischemic heart disease is characteristically progressive, and because it is usually associated with hypertension or diabetes, pregnancy seems inadvisable. Certainly, pregnancy increases cardiac workload; therefore, symptoms as well as adequacy of ventricular function prior to conception will determine outcome.

[Vinatier and associates \(1994\)](#) reviewed the 30 reported cases of pregnancy in women who had sustained an *infarction remote from pregnancy*. Although none of these women died, four had congestive heart failure and four had worsening angina during pregnancy. [Pombar and co-workers \(1995\)](#) reviewed outcomes of women with diabetes-associated ischemic heart disease and infarction. Three had undergone coronary artery bypass grafting before pregnancy. Of 17 women, eight died during pregnancy. All of these investigators concluded that ventricular performance should be assessed prior to conception using ventriculography, radionuclide studies, echocardiography, and coronary angiography. If there is no significant ventricular dysfunction, pregnancy will likely be tolerated. For the woman who becomes pregnant before these studies are performed, echocardiography should be done. Exercise tolerance testing may be indicated, and radionuclide ventriculography results in very little radiation exposure for the fetus ([Chap. 42, p. 1153](#)).

MYOCARDIAL INFARCTION DURING PREGNANCY. Treatment is similar to that of nonpregnant patients. [Hankins and co-workers \(1985\)](#) reviewed pregnancy outcomes in 68 cases and reported an overall maternal mortality rate of 30 to 35 percent. [Hands and colleagues \(1990\)](#) found an overall mortality of 30 percent. Of 50 women who sustained infarction in the third trimester, 40 percent died, compared with only 20 percent of the other 35 women who had an infarction earlier in pregnancy. Women who sustain an infarction less than 2 weeks prior to labor are at especially high risk of death ([Esplin and Clark, 1999](#)).

Acute management is similar to that in nonpregnant patients. Nitroglycerin and morphine are given with close blood pressure monitoring ([Esplin and Clark, 1999](#)). Lidocaine is given to suppress malignant arrhythmias. Calcium-channel or β -blockers are given if indicated. *Tissue plasminogen activator* has been used in pregnant women remote from delivery ([Schumacher and associates, 1997](#)). If the infarct has healed sufficiently, cesarean delivery is reserved for obstetrical indications, and most authors recommend epidural analgesia to reduce pain during labor ([Esplin and Clark, 1999](#)). Epidural analgesia or general anesthesia may be used for cesarean delivery. [Thornhill and Camann \(1994\)](#) recommend pulmonary artery catheter monitoring with an infarction within 6 months or when there is ventricular dysfunction. Others, including us, recommend such monitoring only if there is cardiac dysfunction.

In some women, invasive or surgical procedures may be indicated because of unrelenting disease. [Hands and associates \(1990\)](#) reported successful use of percutaneous transluminal coronary angioplasty in a 36-week pregnant woman. [Sanchez-Ramos and co-workers \(1994\)](#) and [Craig and Ilton \(1999\)](#) described percutaneous balloon angioplasty and transluminal intracoronary stenting. [Garry and colleagues \(1996\)](#) used an intra-aortic balloon pump in a woman who sustained an infarction at 25 weeks. They then performed bypass grafting at 32 weeks.

HYPERTROPHIC CARDIOMYOPATHY

Although concentric left-ventricular hypertrophy commonly develops after long-standing hypertension, there is a familial as well as a sporadic form not related to hypertension termed **idiopathic hypertrophic subaortic stenosis**. It is commonly associated with pheochromocytoma, Friedreich ataxia, Turner syndrome, and neurofibromatosis. In the half of cases that are inherited, about 50 percent are autosomally dominant disorders ([Baughman, 1992](#)). The abnormality is in the myocardial muscle, and it is characterized by idiopathic left-ventricular myocardial hypertrophy that may provide a pressure gradient to left-ventricular outflow ([Lang and Borow, 1991](#)). Diagnosis is confirmed by Doppler echocardiography.

The majority of affected women are asymptomatic, but dyspnea, anginal or atypical chest pain, syncope, and arrhythmias may develop. Complex arrhythmias may progress to sudden death, which is the most common form of death. Asymptomatic patients with runs of ventricular tachycardia are especially prone to sudden death. Symptoms are usually worsened by exercise.

MANAGEMENT IN PREGNANCY. Although limited reports suggest that pregnancy is well tolerated, congestive heart failure may develop. [Benitez \(1996\)](#) reviewed 109 pregnancies in 52 women with hypertrophic cardiomyopathy. Worsening of symptoms, including heart failure, angina, or arrhythmias developed in 40 percent, and two women died. Strenuous exercise is prohibited during pregnancy. Abrupt positional changes are avoided to prevent reflex vasodilation and decreased preload. Likewise, drugs that evoke diuresis or diminish vascular resistance are not used. If symptoms develop, especially angina, β -adrenergic or calcium-channel blocking drugs are given. The route of delivery is determined by obstetrical indications. Spinal analgesia is contraindicated, and even carefully administered epidural analgesia is controversial ([Thornhill and Camann, 1994](#)). Endocarditis prophylaxis is given at delivery. Infants rarely demonstrate inherited lesions at the time of birth.

TABLE 44-8. American Heart Association Guidelines for Bacterial Endocarditis Prophylaxis for Genitourinary and Gastrointestinal Procedures

High-risk patients^a—ampicillin plus gentamicin:

Intravenous or intramuscular ampicillin, 2 g, plus gentamicin, 1.5 mg/kg (not to exceed 120 mg), within 30 min before the procedure, then ampicillin 1 g, intramuscularly or intravenously, or amoxicillin, 1 g orally, 6 hours after the initial dose.

Penicillin-allergic patients—vancomycin and gentamicin:

Intravenous vancomycin, 1 g over 1-2 h, plus intravenous or intramuscular gentamicin, 1.5 mg/kg (not to exceed 120 mg); infusion to be completed within 30 min before the procedure.

Moderate-risk patients^{a, b}—amoxicillin or ampicillin:

Oral amoxicillin, 2 g orally, 1 h before the procedure, or ampicillin, 2 g either intravenously or intramuscularly within 30 min of beginning the procedure.

^a High- and moderate-risk lesions are listed in Table 44-7.

^b Recommended regimen for dental procedures.

45. Chronic Hypertension

Hypertension that antedates pregnancy is one of the most common medical complications encountered during pregnancy. Its variable incidence and severity, along with the well-known proclivity for pregnancy to induce or aggravate hypertension, has caused much confusion concerning the management of pregnant hypertensive women. For example, the majority of women with underlying chronic hypertension demonstrate improved blood pressure control during pregnancy and have largely uneventful pregnancies. Some, however, experience dangerous worsening of hypertension that is frequently accompanied by proteinuria, pathological edema, and convulsions. These latter women—except that chronic hypertension antedated pregnancy—are indistinguishable from an otherwise normotensive young nullipara who develops severe preeclampsia-eclampsia.

DEFINITIONS

There is a wide range of blood pressures in normal adults. The range in those with abnormally high pressures is also wide. Categorization therefore primarily relates to acute or long-term adverse effects associated with the sustained level of those blood pressures. Associations with normal or various levels of abnormal blood pressure are based on morbidity and mortality primarily in adult men. A useful categorization from the latest [Joint National Committee \(1997\)](#) on the Detection, Evaluation, and Treatment of High Blood Pressure is shown in [Table 45-1](#). Within these categories, morbidity or mortality is further influenced by age, gender, race, and personal behaviors including smoking, excessive alcohol intake, obesity, and physical activity.

In adults, proven benefits accrue with treatment of chronic hypertension at sustained diastolic blood pressures of 90 mm Hg or greater (Korotkoff phase V) and/or systolic pressures of 160 mm Hg or more. Benefits are apparent even in otherwise healthy adults and treatment at even lower levels may benefit patients who are elderly, who have appreciable underlying atherosclerotic disease and/or postmyocardial infarction; or who have evidence of renal or cardiac dysfunction; or who have had a cerebrovascular thrombosis or hemorrhage.

DIAGNOSIS

A diagnosis of chronic hypertension complicating pregnancy is made whenever hypertension precedes pregnancy, or hypertension occurs prior to 20 weeks ([Chap. 24, p. 569](#)). Infrequently, women without chronic hypertension have repeated pregnancies in which hypertension appears only late in pregnancy. This is classified as *transient hypertension*, and likely is evidence of latent hypertensive vascular disease. The results of long-term follow-up studies of [Chesley and co-workers \(1976\)](#), as well as those of [Sibai and colleagues \(1986b, 1991, 1992\)](#), are supportive of this view.

In most women with hypertensive vascular disease, increased blood pressure is the only demonstrable finding. Some, however, have complications that increase the risk not only of pregnancy but also of life expectancy. These include hypertensive or ischemic cardiac disease, renal insufficiency, prior cerebrovascular event, or retinal hemorrhages and exudates. Hypertensive vascular disease in pregnancy is encountered more frequently in older women. Obesity is another important predisposing factor, and as discussed in [Chapter 48 \(p. 1298\)](#), chronic hypertension may be increased as much as tenfold in obese compared with nonobese women. Moreover, obese women with chronic hypertension are more likely to develop superimposed preeclampsia ([Rey and Couturier, 1994](#)). As perhaps expected in older and usually obese women, diabetes mellitus is also prevalent. Finally, heredity, which includes racial factors, plays an important role in the development of chronic hypertension. Disease is common in African Americans and Mexican Americans, and frequently many members of the same family are hypertensive ([Centers for Disease Control and Prevention, 1995](#)).

In most women with chronic hypertension, the blood pressure falls by the second trimester, but the decrement is usually temporary ([Ayala and associates, 1997](#); [Cunningham and Lowe, 1991](#); [Sibai and colleagues, 1990a](#)). In most cases, the blood pressure rises during the third trimester to levels somewhat above those in early pregnancy ([Fig. 45-1](#)). Adverse outcomes in these women are dependent largely upon whether superimposed preeclampsia develops.

TREATMENT IN NONPREGNANT ADULTS

Even at the mildest end of the spectrum of abnormal blood pressures categorized in [Table 45-1](#), therapy to reduce pressure is beneficial. [Ferrer and associates \(2000\)](#) have analyzed evidence from randomized trials of nonpregnant women aged 30 to 54 years. They computed that about 250 such women with mild to moderate hypertension would need to be treated for 5 years to prevent one cardiovascular event such as stroke or myocardial infarction. More than 20 large trials involving over 50,000 participants have established that antihypertensive treatment in adults with mild to moderate hypertension decreases mortality, stroke, and major cardiac events ([Collins and MacMahon, 1994](#); [Gueyffier and collaborators, 1997](#)). Thus, regardless of pregnancy status, many such women would likely have been placed on antihypertensive medications as well as institution of behavioral lifestyle modifications prior to pregnancy. Nonpharmacological interventions include weight loss, prescribed physical activity, dietary adjustment, and cessation of smoking, excessive alcohol, and caffeine usage.

In women diagnosed with presumed chronic hypertension prior to midpregnancy, the benefits and safety of instituting antihypertensive therapy are less clear because of largely hypothetical concerns regarding their effect on fetal growth. Clearly, antihypertensive therapy in nonpregnant adult women with sustained diastolic pressures of 90 mm Hg or greater would not be considered harmful.

PRECONCEPTIONAL AND EARLY PREGNANCY EVALUATION

Evaluation of women with chronic hypertension is of great importance for either counseling or management during pregnancy. Ideally, they should be counseled prior to undertaking pregnancy ([Chap. 9, p. 212](#)). The duration of chronic hypertension, level of blood pressure control, and antihypertensive therapy is ascertained. Their general health, daily activities, diet, and adverse personal behaviors should be determined. Adverse events such as cerebrovascular accident, myocardial infarction, cardiac failure, or renal dysfunction are especially pertinent. These women are at marked increase risk for a recurrence or worsening of these outcomes during pregnancy. Women who require multiple antihypertensives for control of hypertension, or those who are poorly controlled, are also at increased risk for adverse pregnancy outcomes.

Evaluation also includes assessment of renal, hepatic, and cardiac function. Cardiac assessment should be targeted toward ascertainment of any dysrhythmias and/or evidence of left ventricular hypertrophy indicating either long-standing or poorly controlled hypertension, or both. Women with appreciable left-ventricular hypertrophy are at increased risk for cardiac dysfunction and congestive heart failure during pregnancy. In women with any prior adverse outcome, or in long-term hypertension, echocardiography is indicated.

Renal function is assessed by serum creatinine and quantification of proteinuria. If either is abnormal, these women are at further increased risk for adverse effects on pregnancy. The [Working Group Report on Hypertension in Pregnancy \(2000\)](#) of the National Heart, Lung, and Blood Institute concluded that the risks of fetal loss and accelerated deterioration of renal disease are increased if serum creatinine is above 1.4 mg/dL at conception. It can be difficult, however, to separate the effects of the pregnancy from inevitable progression of renal disease ([Cunningham and associates, 1990](#); [Jones and Hayslett, 1996](#)). As a general principle, while not precisely linear, renal insufficiency is inversely proportional to increased risk of hypertensive complications on pregnancy outcome. Pregnancy is relatively contraindicated in women who, despite therapy, maintain persistent diastolic pressures of 110 mm Hg or greater, require multiple antihypertensives, or whose serum creatinine is greater than 2 mg/dL. Stronger contraindications include women who have had prior cerebrovascular thrombosis or hemorrhage, myocardial infarction, or cardiac failure.

Assessment of functional physical capabilities in regard to symptoms at rest and with mild or moderate activity should be determined. In women with prior cardiac dysfunction, baseline pulmonary function testing and longitudinal vital capacity testing throughout pregnancy may provide early identification of decreasing cardiac function and early pulmonary congestion. Ophthalmological evaluation is of importance for women with longstanding chronic hypertension.

EFFECTS OF CHRONIC HYPERTENSION ON PREGNANCY

MATERNAL EFFECTS

Most women taking monotherapy and whose hypertension is well controlled prior to pregnancy will do well. However, even these women have an increased risk of abruptio placentae, superimposed preeclampsia, and increased hospitalization. In addition, [Jain \(1997\)](#) reported a maternal mortality of 230 per 100,000 live births in women with hypertension compared with about 10 per 100,000 for normotensive women. The more severe the baseline maternal disease, and especially with documented end-organ damage, the more likely these complications.

Pregnancy-aggravated hypertension typically becomes manifest by a sudden rise in blood pressure that frequently is eventually complicated by substantial proteinuria. Extreme hypertension—systolic pressure greater than 200 mm Hg and diastolic pressure of 130 mm Hg or more—may rapidly result in oliguria and renal dysfunction. With the development of superimposed severe preeclampsia or eclampsia, the outlook for both infant and mother is serious unless the pregnancy is terminated. A number of common adverse pregnancy outcomes that are increased in women with chronic hypertension are considered next.

ABRUPTIO PLACENTAE. Premature placental separation is discussed in detail in [Chapter 25 \(p. 621\)](#). The incidence of abruptio placentae in a number of investigations is about 1 in 150 ([Ananth and associates, 1999](#)). This incidence is appreciably increased in women with hypertension. [Sibai and colleagues \(1998\)](#) reported placental abruption in 1.5 percent of 776 women with hypertension preceding pregnancy. [Caritis and associates \(1998\)](#) reported that 1 to 2 percent of 2539 women at high risk for preeclampsia enrolled in a low-dose aspirin trial had placental abruption. [Hauth and co-workers \(1995\)](#) performed meta-analysis of low-dose aspirin trials in women at high and low risk for preeclampsia, and reported that abruptio placentae occurred in about 1.4 percent. Thus, the risk of abruptio placentae in women with chronic hypertension is two- to threefold greater than for normotensive women. [Ananth and colleagues \(1999\)](#) observed that smoking increased these risks even further.

SUPERIMPOSED PREECLAMPSIA. The incidence of superimposed preeclampsia in women with chronic hypertension is variable because there is no precise definition. [August and Lindheimer \(1999\)](#) reported that superimposed preeclampsia developed in from 4 to 40 percent of these women. The incidence is higher in women with severe hypertension in early pregnancy ([Sibai, 1991](#)). Clearly, the occurrence of superimposed preeclampsia is directly related to the severity of baseline hypertension, as well as the need for treatment to achieve control. In the randomized Maternal Fetal Medicine Network study, [Caritis and co-workers \(1998\)](#) employed predefined criteria for preeclampsia in 774 women with chronic hypertension. They identified superimposed preeclampsia in 25 percent of these women. In another analysis of these same women, [Sibai and co-workers \(1998\)](#) reported that the incidence of superimposed preeclampsia was similar whether or not there was proteinuria at baseline. The incidence significantly increased, however, in those who had hypertension for at least 4 years or who had preeclampsia during a prior pregnancy.

Studies of low-dose aspirin therapy to reduce the incidence of superimposed preeclampsia in women with chronic hypertension have shown little benefit. In an early study, [Beaufils and colleagues \(1985\)](#) reported that therapy with low-dose aspirin and the antiplatelet agent dipyridamole was beneficial in reducing the incidence of superimposed preeclampsia and fetal growth restriction. In a European multicenter trial (EPREDA), [Uzan and co-workers \(1991\)](#) found that these same drugs were associated with significantly increased birthweight and a decreased incidence of fetal growth restriction in high-risk women. In the Network study reported by [Caritis and associates \(1998\)](#), the incidence of superimposed preeclampsia or fetal growth restriction were similar in women assigned to low-dose aspirin or placebo. In this same trial, maternal serum thromboxane B₂ reduction was not predictive of improved pregnancy outcomes with low-dose aspirin ([Hauth and colleagues, 1998](#)). As shown in [Figure 45-2](#), a summary of randomized trials of low-dose aspirin in women with chronic hypertension suggests that the only benefit is fewer preterm deliveries.

MATERNAL ECONOMIC AND LIFESTYLE DEMANDS. There is little quantitative data to relate these issues to outcomes in pregnant women with chronic hypertension. As a group, these women require more time with their physicians to include office visits, fetal-maternal assessment in the third trimester, and increased hospitalization. Home rest affects economic stability as well as family dynamics. They require more time off from work, which is especially burdensome if they are self-employed or must care for children or other family members. These realities are discussed during preconceptional or early pregnancy counseling ([Chap. 9, p. 212](#)).

FETAL/NEWBORN EFFECTS

A number of adverse perinatal outcomes are substantively increased in pregnancy complicated by chronic hypertension.

FETAL GROWTH RESTRICTION. This incidence is in direct relation to the severity of hypertension. Its precise incidence and severity varies dependent upon other maternal factors, the choice of growth chart used in making this diagnosis, and certainly of confirmed gestational age. Maternal factors include age; the severity and control of hypertension, including need for additional antihypertensive medications; and presence of end-organ damage such as renal or cardiac dysfunction. Because of these factors, there is no data regarding safety or efficacy of treatment of women with mild chronic hypertension predating pregnancy. While such treatment is not harmful for the mother, the potential benefits or adverse fetal-neonatal effects have not been determined.

In the Network trial described above, [Sibai and colleagues \(1998\)](#) reported that only 10.7 percent of 763 women with chronic hypertension had small-for-gestational age newborns. Women with chronic hypertension and proteinuria early in pregnancy had 23 percent of infants who weighed less than the 10th percentile compared with 10 percent in women without baseline proteinuria. [Von Dadelszen and co-workers \(2000\)](#) employed meta-analysis to investigate the relation between fetal growth and oral antihypertensives to treat mild to moderate pregnancy hypertension. They concluded that a treatment-induced mean arterial pressure decrease was associated with significantly increased small-for-gestational age infants. This review is greatly confounded by inclusion of women with gestational and/or pregnancy-induced hypertension treated later in pregnancy as compared with women whose chronic hypertension was treated throughout pregnancy.

OTHER ADVERSE PERINATAL OUTCOMES. Preterm birth is increased in women with chronic hypertension ([McCowan and colleagues, 1996](#); [Meis and co-workers, 1998](#)). From The Network, [Sibai and colleagues \(1998\)](#) reported that 33 percent of 763 women with chronic hypertension delivered before 37 weeks, and 18 percent before 35 weeks. They cited a perinatal death rate of 46 per 1000, which is markedly increased over healthy nulliparas. [Rey and Couturier \(1994\)](#) found a similar incidence of perinatal loss.

MANAGEMENT DURING PREGNANCY

The goal in women whose pregnancy is complicated by chronic hypertension is to minimize or prevent any of the adverse maternal or perinatal outcomes previously discussed. In general, management is targeted toward prevention of moderate or severe hypertension as well as prevention of severe pregnancy-aggravated hypertension. To some extent, these goals can be achieved pharmacologically with special attention to assure medication compliance. Personal health behavioral modifications include dietary counseling and reduction of behaviors such as smoking, alcohol, cocaine, or other substance abuse. It is accepted that women with severe hypertension must always be treated for maternal indications regardless of pregnancy status. This includes pregnant women with prior adverse outcomes, including cerebrovascular events, myocardial infarction, and cardiac or renal dysfunction. We agree with the philosophy of beginning antihypertensive treatment in an otherwise healthy woman with persistent diastolic pressures of 100 mm Hg or greater ([August and Lindheimer, 1999](#)). With end-organ dysfunction, treatment of pregnant women with diastolic pressures of 90 mm Hg or higher should be considered. Other than simply lowering blood pressure, there are no data indicating salutary effects in pregnancy outcomes. Specifically, the incidence of superimposed preeclampsia is not lowered. Moreover, there is no evidence that perinatal outcomes are improved by such treatment. As emphasized by the [Working Group Report \(2000\)](#), there is a need for further trials of treatment or observation in women with chronic hypertension and their possible benefits on pregnancy outcomes.

ANTIHYPERTENSIVE DRUGS

The following summary of antihypertensive drugs is categorized by their primary mode of action ([Table 45-2](#)) and as abstracted from several sources, including the *2000 Physician's Desk Reference*. In adults with chronic hypertension, initial pharmacological therapy is generally one of four agents: a diuretic, a low-dose of an angiotensin-converting enzyme inhibitor, a β -blocking agent, or a long-acting calcium-channel antagonist.

DIURETICS. Commonly used drugs include thiazide diuretics and loop-acting diuretics such as furosemide ([Brater, 1998](#)). In the short term, diuretics lower blood pressure by sodium and water diuresis and intravascular volume depletion. With time, there is "sodium escape" and intravascular volume depletion is corrected. Some aspect of lowered peripheral vascular resistance may contribute to the effectiveness of these agents. Diuretics have been shown to reduce long-term morbidity and mortality in adult men with chronic hypertension ([Williams, 1998](#)). Largely for theoretical concerns, diuretics are usually not instituted as first-line therapy during pregnancy, particularly after 20 weeks ([Working Group Report, 2000](#)).

ADRENERGIC BLOCKING AGENTS. These agents can act *centrally* by reducing nervous system sympathetic outflow and effect generalized decreased vascular tone. Central-acting agents include clonidine and α -methyl dopa. *Beta-adrenergic receptor blockers* are also included in this category, and they also cause a generalized decrease in sympathetic tone. Examples are propranolol, metoprolol, and atenolol. The *α/β -adrenergic blocker*, labetalol is a commonly used agent in this category. Peripheral blockers are thought to have more potential for postural hypotension than the centrally acting agents. Based on clinical experience, the most commonly used drugs in pregnancy to treat hypertension are methyl dopa or a β - or α/β -receptor blocker.

VASODILATORS. Hydralazine directly relaxes arterial smooth muscle and is used parenterally for treatment of acute severe intrapartum or immediate postpartum

hypertension ([Chap. 24, p. 592](#)). Use of oral hydralazine as a sole oral agent for chronic hypertension is not recommended because of its relatively weak antihypertensive effects and because of resultant tachycardia. It may be effective for long-term use as an adjunct to other antihypertensives.

CALCIUM-CHANNEL ANTAGONISTS. These agents are divided into three subclasses based on modification of calcium entry into cells and interference with binding sites on voltage-dependent calcium channels. Common agents in these categories include the dihydropyridine nifedipine and the phenylalkyl amine derivative, verapamil. These agents have negative inotropic effects and thus can worsen cardiac dysfunction and congestive cardiac failure. [Pahor and associates \(2000\)](#) concluded that these agents were inferior to other first-line drugs in nonpregnant hypertensives. There is little published experience with these agents during pregnancy ([Smith and colleagues, 2000](#)).

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS. These agents inhibit the conversion of angiotensin-I to the potent vasoconstrictor angiotensin-II. They are associated with serious fetal effects and are not used during pregnancy ([Chap. 38, p. 1014](#)). Angiotensin-receptor antagonists have effects similar to angiotensin-converting enzyme inhibitors, albeit instead of blocking the production of angiotensin-II, they inhibit binding to its receptor.

DRUG TREATMENT DURING PREGNANCY

As discussed, continued antihypertensive treatment for pregnant women with chronic hypertension is debated. While beneficial to the mother to reduce her blood pressure, theoretically the lower pressure would decrease uteroplacental perfusion and possibly jeopardize her fetus. There is little experience, but some observational studies are shown in [Table 45-3](#).

[Sibai and colleagues \(1983\)](#) reported their experience with chronic hypertension in 211 consecutive women with mild hypertension. Treatment was either not given or antihypertensive drugs were discontinued at the first prenatal visit. Only 13 percent of these 211 women required antihypertensive therapy later in pregnancy for diastolic pressures exceeding 110 mm Hg, and the perinatal mortality was 28 per 1000. Antihypertensive treatment was prescribed for 82 women whose diastolic pressure exceeded 90 mm Hg, while 82 women whose diastolic pressures remained less than 90 mm Hg were given no treatment. The perinatal mortality in each group was similar, but fetal growth restriction was increased fourfold in the treated group, presumably because of worse hypertension.

To summarize the studies presented in [Table 45-3](#), all investigators found that superimposed preeclampsia or pregnancy-aggravated hypertension was associated with a worse prognosis. Importantly, treatment did not decrease the incidence of this complication. Most pregnancy outcomes were good without treatment. Perinatal mortality rates were low unless superimposed preeclampsia developed.

Some randomized trials of antihypertensive drug therapy in pregnant women with mild chronic hypertension are shown in [Table 45-4](#). Only three trials were conducted during the 1990s, and only two were of appreciable size. Thus, data are not sufficient to provide a definitive answer regarding whether to treat women with mild or even moderate hypertension in pregnancy. One important observation of the two large and more contemporaneous studies was that no adverse outcomes were found in the treatment group. Thus, it is not unreasonable to treat women with uncomplicated mild or moderate sustained chronic hypertension who would otherwise be prescribed antihypertensive therapy when they were not pregnant.

The theoretical concern of fetal growth restriction due to reduced placental perfusion by lowering maternal blood pressure is confounded in that worsening blood pressure itself is associated with abnormal fetal growth. [Breart and colleagues \(1982\)](#) found that women with chronic hypertension whose diastolic pressure was less than 90 mm Hg had a 3 percent risk of fetal growth restriction, those with 90 mm Hg had a 6 percent risk, and those with 110 mm Hg or more had a 16 percent risk. Growth restriction from maternal treatment was not supported by the two large randomized trials shown in [Table 45-4](#).

Results of the carefully done study of chronic hypertension in pregnant women reported by the Memphis group are summarized in [Table 45-5](#). In this trial, [Sibai and colleagues \(1990a\)](#) randomized 263 women with mild to moderate chronic hypertension at 6 to 13 weeks to no treatment, or to receive either labetalol or a-methyldopa. The aim of therapy was to maintain the blood pressure less than 140/90 mm Hg. Women treated throughout pregnancy had significantly lower blood pressures than women randomized to no treatment, and the incidence of adverse outcomes was not altered by treatment. As perhaps expected, more women not initially given treatment eventually required antihypertensive therapy for serious hypertension, defined as blood pressure greater than 160/110 mm Hg.

A more recent randomized trial of women with mild to moderate hypertension in pregnancy was reported by the [Gruppo di Studio Ipertensione in Gravidanza \(1998\)](#). In this multicenter study, 283 women were randomized to treatment with slow-release nifedipine, 10 mg twice daily until delivery, or to no treatment. Women given no treatment were given nifedipine if diastolic pressure exceeded 110 mm Hg. These investigators also found no apparent benefit but also no harm in the nifedipine versus expectant management groups. Preterm delivery was high in both groups—45 percent in treated and 37 percent nontreated. There was no difference between the two groups in mean birthweight or growth-restricted infants.

SEVERE CHRONIC HYPERTENSION. As discussed, the prognosis for pregnancy outcomes with chronic hypertension is related to the severity of the disease before pregnancy. Many women with severe hypertension also have underlying renal disease ([Cunningham and colleagues, 1990](#)). [Sibai and co-workers \(1986a\)](#) described 44 pregnancies in women whose blood pressure at 6 to 11 weeks was 170/110 mm Hg or higher ([Table 45-3](#)). They were given treatment with a-methyldopa and oral hydralazine to maintain blood pressures less than 160/110 mm Hg, and they were hospitalized for treatment with parenteral hydralazine if blood pressures exceeded 180/120 mm Hg. Half developed superimposed preeclampsia, and all adverse perinatal outcomes were in this group. Specifically, all infants in the women with superimposed preeclampsia were preterm, nearly 80 percent were growth restricted, and the perinatal mortality rate was 48 percent. By contrast, in the women with severe hypertension who did not develop superimposed preeclampsia, only 5 percent of fetuses were growth restricted and all survived.

ANTIHYPERTENSIVE DRUG SELECTION

Despite the relatively good results obtained with a-methyldopa, and the comparable results obtained without antihypertensive drugs, adrenergic-blocking drugs have been used extensively in England, Scotland, and Australia ([Redman, 1982](#); [Rubin and colleagues, 1983](#); [Walker and associates, 1983](#)). The results of treatment with labetalol are consistent with the view that the drug offers no advantages over a-methyldopa ([Sibai and colleagues, 1990a](#)). [Rey \(1992\)](#) observed that a-methyldopa significantly reduced uterine pulsatility indexes in chronically hypertensive women and in women with mild preeclampsia. Indexes were decreased in most, but not all, fetuses. [Rubin and colleagues \(1983\)](#) reported salutary results from a prospective study in which they compared placebo with the β -blocker atenolol given to 120 women with hypertension first apparent early in the third trimester. Because nearly 60 percent of their subjects were nulliparous, it was difficult to separate women with chronic hypertension from those with preeclampsia. The placebo group had worse perinatal outcomes, but there were more nulliparas assigned (67 versus 50 percent), and thus presumably more women had preeclampsia at the onset of the study. The same group ([Butters and colleagues, 1990](#)) reported that atenolol treatment of chronically hypertensive women resulted in a higher incidence of growth-restricted neonates compared with untreated controls.

More recently, [Lydakis and colleagues \(1999\)](#) studied 223 women attending an antenatal hypertension clinic and who had 312 pregnancies. They concluded that atenolol treatment was associated with lower birthweight and ponderal indices as well as a trend toward more preterm births when compared with other antihypertensive monotherapy or to no treatment. Finally, ominous fetal heart rate patterns during labor were reported in 20 percent of women receiving β -blocker therapy for hypertension ([Montan and Ingemarsson, 1989](#)). The incidence of ominous patterns was increased even more in growth-restricted fetuses and in half of women given epidural analgesia.

[Smith and colleagues \(2000\)](#) reviewed the use of nifedipine to treat hypertension or for tocolysis in pregnancy. They summarized data reported from 1975 to 1997. They concluded that nifedipine is an effective drug to treat severe hypertension in pregnancy or for preterm labor. The studies of chronic nifedipine use in pregnancy, however, are too small to make recommendations about its routine use for women with chronic hypertension.

[Vermillion and associates \(1999\)](#) reported a randomized clinical trial of oral nifedipine compared with intravenous labetalol to treat 50 women with a hypertensive emergency of pregnancy. They reported that blood pressure control was significantly quicker with nifedipine but that both drugs were effective. [Scardo and colleagues \(1999\)](#) performed noninvasive hemodynamic evaluation in women within this same trial and found that women given nifedipine had a significantly increased cardiac index compared with women given labetalol. This accompanied a significantly decreased systemic vascular resistance in women given nifedipine.

[Mulrow and colleagues \(2000\)](#) performed a review for the Agency for Healthcare Research and Quality and summarized the risks and benefits of antihypertensive agents given to pregnant women ([Table 45-6](#)).

THERAPY RECOMMENDATIONS. The National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy (2000) stresses the limited data from which to draw conclusions concerning whether to treat mild chronic hypertension in pregnant women. The group did, however, recommend therapy to prevent hypertensive vascular damage when maternal diastolic blood pressure reached 100 mm Hg. They also concluded that early treatment of hypertension

would probably reduce the need for subsequent hospitalization during pregnancy. In the study by [Sibai and associates \(1990a\)](#), subsequent treatment was needed for dangerous hypertension in 11 percent of women not given initial treatment, compared with only 6 percent in women given either a-methyldopa or labetalol beginning earlier in pregnancy. Methyldopa has been more extensively studied during pregnancy ([Montan and colleagues, 1992, 1993](#)). Indeed, [Cockburn and co-workers \(1982\)](#) reported no adverse effects in children up to 7^{1/2} years old whose mothers were treated with methyldopa for hypertension during pregnancy. [Haddad and Sibai \(1999\)](#) concluded that methyldopa is the initial agent of choice for treatment of pregnant women with mild to moderate chronic hypertension.

FETAL ASSESSMENT

Women with well-controlled chronic hypertension with no prior complicating factors can generally be expected to have a good pregnancy outcome. Because even otherwise healthy women with mild hypertension have an increased risk of abruptio placentae, superimposed preeclampsia, preterm delivery, and fetal growth restriction, serial antepartum assessment of fetal well-being is recommended ([American College of Obstetricians and Gynecologists, 1999](#)). The gestational age at which to initiate such testing varies with the severity of the disease and the overall clinical course. This is discussed in detail in [Chapter 40](#). According to the Agency for Healthcare Research and Quality ([Ferrer and colleagues, 2000](#)), there are no data to address either the benefits or harm of various monitoring strategies for pregnant women with chronic hypertension.

PREGNANCY-AGGRAVATED HYPERTENSION OR SUPERIMPOSED PREECLAMPSIA

From the aforementioned studies, an incidence of superimposed preeclampsia of 25 percent would be commonly accepted for women with chronic hypertension ([Caritis and co-workers, 1998](#)). The diagnosis of superimposed preeclampsia may be difficult to make in these women. It is most difficult to be assured of the diagnosis in women with hypertension and underlying renal disease with proteinuria ([Cunningham and associates, 1990](#)).

In women with uncomplicated chronic hypertension, criteria that support the diagnosis of superimposed preeclampsia include the development of proteinuria; neurological symptoms, including severe headaches and visual disturbances; generalized pathological edema; oliguria; and certainly, convulsions or pulmonary edema. Laboratory abnormalities that support the diagnosis include increasing serum creatinine, thrombocytopenia, or appreciable serum hepatic transaminase elevations.

Some women with chronic hypertension have a worsening during pregnancy with no other findings of superimposed preeclampsia. This is most common near the end of the second trimester. In the absence of other supporting criteria for superimposed preeclampsia, including normal fetal growth and amniotic fluid volume, these women likely represent the higher end of the normal blood pressure curve shown in [Figure 45-1](#). It is reasonable in such patients to either begin or increase the dose of antihypertensive therapy.

DELIVERY

The decision to effect delivery of women with chronic hypertension is viewed in the context of the clinical course, including severity of the underlying condition. In women with uncomplicated well-controlled chronic hypertension with an otherwise normal pregnancy course and with normal fetal growth and amniotic fluid volume, it is the practice at our institutions to await labor at term. In women with complications or in whom fetal testing becomes abnormal, or both, induction is considered. Thus, even markedly preterm pregnancies with superimposed severe preeclampsia or appreciable fetal growth restriction or abruptio placentae will prompt delivery. Special consideration for delivery of women with multifetal gestation and chronic hypertension is also warranted, and delivery is usually initiated prior to term. Women with a multifetal gestation and preeclampsia have greater incidence of adverse outcomes, including placental abruption and poor neonatal outcomes, than do those with singleton pregnancy and preeclampsia ([Sibai and colleagues, 2000](#)).

In general, vaginal delivery is usually attempted. This includes women with severe aggravated hypertension or superimposed preeclampsia. Most women, including those with preterm severe superimposed preeclampsia, can be induced successfully and have vaginal delivery ([Alexander and colleagues, 1999](#); [Atkinson and associates, 1995](#)). Epidural analgesia for labor pain is appropriate in these women with chronic hypertension and superimposed preeclampsia. [Lucas and colleagues \(2001\)](#) randomized 738 women with pregnancy-induced hypertension to either epidural analgesia or to patient-controlled intravenous meperidine. Although more women assigned to epidural analgesia required ephedrine to correct hypertension (11 versus 0 percent) neonatal and maternal outcomes were similar. In a retrospective analysis of 327 women with severe hypertensive disease, [Hogg and associates \(1999\)](#) reported that epidural analgesia was safe in women with high-risk pregnancies complicated by superimposed severe preeclampsia. [Hogg and co-workers \(2000\)](#) reported preliminary data from a randomized trial of 105 women with severe preeclampsia. They found similar maternal and fetal outcomes in women assigned to epidural analgesia or to a patient-controlled intravenous analgesia ([Table 45-7](#)). Finally, [Wallace and co-workers \(1995\)](#) randomized 80 women with severe preeclampsia who were to undergo cesarean delivery. They were given either general anesthesia or epidural or spinal-epidural analgesia. Although a fourth of women in the latter two groups developed hypotension, neonatal outcomes were all good ([Chap. 15, p. 379](#)).

POSTPARTUM CONSIDERATIONS

In many respects, postpartum observation and prevention and management of adverse complications are similar in women with severe chronic hypertension and those with severe preeclampsia-eclampsia. The development of cerebral edema, heart failure or pulmonary edema, or renal dysfunction is especially high within 24 to 36 hours following delivery ([Benedetti and colleagues, 1980, 1985](#); [Cunningham and associates, 1986](#); [Sibai and co-workers, 1990b](#)). Following delivery, maternal peripheral resistance may increase as early as 6 hours postpartum. Thus, left-ventricular workload is acutely increased and further aggravated at the same time that appreciable amounts of interstitial fluid are mobilized for excretion. Prompt treatment of severe hypertension, with or without diuretic therapy, is of great importance.

Many women with chronic hypertension and superimposed severe preeclampsia have contracted blood volumes compared with normal pregnant women ([Pritchard and colleagues, 1984](#); [Silver and associates, 1998](#)). These women have marked vasoconstriction and, in general, have increased blood loss which may cause oliguria postpartum. It may be difficult and hazardous to attempt to maintain intravascular volume and renal perfusion solely with intravenous crystalloid or colloid solutions. In such women, blood transfusion may be necessary to maintain intravascular volume to ensure tissue perfusion.

TABLE 45-1. Classification of Blood Pressure for Adults Ages 18 Years and Older

Category	Systolic Pressure^a (mm Hg)	Diastolic Pressure^a (mm Hg)
Normal ^b	< 130	< 85
High normal	130-139	85-89
Hypertension ^c		
Stage 1 (mild)	140-159	90-99
Stage 2 (moderate)	160-179	100-109
Stage 3 (severe)	180-209	110-119
Stage 4 (very severe)	= 210	= 120

^a When systolic and diastolic pressures fall into different categories, the higher category is used to classify blood pressure status.

^b Optimal blood pressure with respect to cardiovascular risk is < 120/80 mmHg. Used only for adults aged 18 years and older not taking antihypertensive drugs and not acutely ill.

^c Based on the average of two or more readings taken at each of two or more visits after an initial screening.

From the Joint National Committee (1997).

TABLE 45-3. Observational Studies of the Effects of Treatment of Chronic Hypertension During Pregnancy

Study and Treatment	No.	Superimposed Preeclampsia (%)	Perinatal Mortality (per 1000)
Chesley (1978)			
Chronic hypertension ^a (1972-1974), no antihypertensives	593	6	32
Superimposed preeclampsia ^b (1960-1974), hydralazine + a-methyldopa	196	—	214
Redman (1980) ^c			
Chronic hypertension	184	25	16
Superimposed preeclampsia	69	—	145
Sibai and associates (1983)			
Chronic hypertension, no antihypertensives	193	10	5
Superimposed preeclampsia, a-methyldopa and/or hydralazine	22	—	227
Mabie and associates (1986)			
Chronic hypertension, diastolic pressure < 90 mm Hg, no treatment	137	29	29
Chronic hypertension, diastolic pressure 90-100 mm Hg, a-methyldopa	26	46	0
Sibai and associates (1986a)			
Severe chronic hypertension, 170/100 mm Hg or greater, a-methyldopa + hydralazine	44	52	250
Rey and Couturier (1994)			
Chronic hypertension, treat if diastolic pressure > 100 mm Hg	337	21	45

^a Three maternal deaths due to stroke, pulmonary embolus, and aspiration pneumonia.

^b Two deaths due to stroke and postoperative infection.

^c Data from Ounsted and associates (1983), reporting on long-term follow-up of children from the original and continuing study of treatment of chronic hypertension in pregnancy by Redman (1980).

TABLE 45-6. Benefits and Risks of Antihypertensive Agents Given to Pregnant Women

Agent or Class	Benefits	Adverse Effects	Clinical Experience in Pregnancy
Methyldopa	<i>Fetal:</i> Insufficient evidence to rule out large effect on perinatal morbidity or mortality. <i>Maternal:</i> Insufficient evidence to rule out large effect on maternal morbidity.	<i>Fetal:</i> Evidence of no major adverse events. <i>Maternal:</i> Evidence of no major adverse events.	Large
β -blockers	<i>Fetal:</i> Insufficient evidence to rule out large effect of perinatal morbidity or mortality.	<i>Fetal:</i> Limited evidence of possible fetal growth restriction with atenolol used early in pregnancy.	Large
α/β -blockers	<i>Maternal:</i> Insufficient evidence to rule out large effect on maternal morbidity.	<i>Maternal:</i> Evidence of no major adverse events.	Small
Diuretics	<i>Fetal:</i> Insufficient evidence to rule out large effect on perinatal morbidity or mortality. <i>Maternal:</i> Insufficient evidence to rule out large effect on maternal morbidity.	<i>Fetal:</i> Evidence of no major adverse events. <i>Maternal:</i> Evidence of no major adverse events.	Large
Calcium-channel blockers	<i>Fetal:</i> Insufficient evidence to rule out large effect on perinatal morbidity or mortality. <i>Maternal:</i> Insufficient evidence to rule out large effect on maternal morbidity.	<i>Fetal:</i> Very limited evidence of no major adverse events. <i>Maternal:</i> Very limited evidence of no major adverse events.	Small
Hydralazine	<i>Fetal:</i> Insufficient evidence to rule out large effect on perinatal morbidity or mortality. <i>Maternal:</i> Insufficient evidence to rule out large effect on maternal morbidity.	<i>Fetal:</i> Evidence of no major adverse events. <i>Maternal:</i> Evidence of no major adverse events.	Moderate (for chronic hypertension).
ACE inhibitors and ARBs	<i>Fetal:</i> No evidence. <i>Maternal:</i> No evidence.	<i>Fetal:</i> Risk of fetal renal failure if used in second or third trimester. <i>Maternal:</i> No evidence.	Small None

ACE = angiotensin-converting enzyme; ARB = angiotensin-receptor blocker.

46. Pulmonary Disorders

During pregnancy, there are a number of important adaptations of the respiratory system and changes in pulmonary function. Physiologically these changes are necessary so that the increased oxygen demands of the hyperdynamic circulation and the fetus can be satisfied. There is no evidence that pulmonary function is impaired because of pregnancy, but inferential data suggest that advanced pregnancy may intensify the pathophysiological effects of many acute and chronic lung diseases. An example for acute disease is the disparate number of adult deaths in pregnant women that were observed during the influenza pandemics of 1918 to 1919 and 1957 to 1958. An example for chronic disease is the poor tolerance to pregnancy of women with severe chronic lung disease and especially cor pulmonale.

From 1 to 4 percent of pregnancies are complicated by asthma. During winter months, both viral as well as bacterial pneumonitis are frequent in young adults. Tuberculosis is more frequent now than it has been in many years and, more worrisome, mycobacterial infections are becoming resistant to contemporaneous tuberculostatic medications. Finally, a number of chronic pulmonary disorders—albeit uncommon—may precede pregnancy and present special management problems.

PULMONARY PHYSIOLOGY

The important and sometimes marked changes in the respiratory system induced by pregnancy are discussed in detail in [Chapter 8 \(p. 185\)](#). Because of their importance to the clinical approach of lung disease complicating pregnancy, some of these are now reiterated. There are four lung volumes and four lung capacities that are used commonly to describe pulmonary physiology. Except for residual volume and lung capacities derived therefrom, these can be measured using direct spirometric techniques. The physiological changes induced by pregnancy have been summarized by [de Swiet \(1991\)](#):

1. **Vital capacity** may be increased by 100 to 200 mL.
2. **Inspiratory capacity** increases by about 300 mL by late pregnancy.
3. **Expiratory reserve volume** decreases from a total of 1300 mL to about 1100 mL.
4. **Residual volume** decreases from a total of 1500 mL to about 1200 mL.
5. **Functional residual capacity**, the sum of expiratory reserve and residual volumes, is reduced considerably, by about 500 mL.
6. **Tidal volume** increases considerably from about 500 to 700 mL.
7. **Minute ventilation** increases 40 percent, from 7.5 L to a total of 10.5 L/min; this is primarily due to increased tidal volume because the respiratory rate is unchanged.

The sum of these changes is substantively increased ventilation due to deeper but not more frequent breathing. Presumably these changes are induced to help supply increased basal oxygen consumption, which increases incrementally by 20 to 40 mL/min in the second half of pregnancy. As a result, arterial PO₂ falls very slightly, PCO₂ averages 28 mm Hg, plasma pH is slightly alkalotic at 7.45, and bicarbonate decreases to about 20 mEq/L.

DYSPNEA DURING PREGNANCY. Pregnant women are frequently aware of the need to breathe. The common complaint of "shortness of breath" is not associated with exercise, and frequently is worse when the woman is sitting down. [Milne and associates \(1978\)](#) reported that about half of women notice dyspnea at rest by midpregnancy, and three fourths complained of this by 31 weeks. Although its exact mechanisms are unclear, dyspnea has been attributed to alveolar hyperventilation and a response to substantively decreased CO₂, as well as a consequence of normal anatomical changes in the thorax.

PNEUMONIA

According to the National Center for Health Statistics ([Hoyert and colleagues, 1998](#)), in the United States in 1997, pneumonia and influenza were the tenth leading cause of death in persons aged 25 to 44 years. Mortality from community-acquired pneumonia may be as high as 5 percent in the elderly and chronically ill; however, in young and healthy women the rate is much less.

Pneumonia is inflammation affecting the lung parenchyma distal to the larger airways and involving the respiratory bronchioles and alveolar units. Bronchopneumonia refers to patchy and diffuse areas of involvement, and at least implies a less severe form of pneumonitis because there is no consolidation seen radiographically. Pneumonitis causing an appreciable loss of ventilatory capacity is tolerated less well by women during pregnancy. This generalization seems to hold true regardless of the etiology of the pneumonia. Moreover, hypoxemia and acidosis are poorly tolerated by the fetus, and they frequently lead to preterm labor after midpregnancy. Because many cases of pneumonia follow common viral upper respiratory illnesses, worsening or persistence of symptoms should prompt consideration for the diagnosis of pulmonary parenchymal infection. **Any pregnant woman suspected of having pneumonia should undergo anteroposterior and lateral chest radiography.**

BACTERIAL PNEUMONIA

Bacteria usually reach the lung by inhalation or by aspiration of nasopharyngeal secretions. Some bacterial organisms that cause community-acquired pneumonia, such as *Streptococcus pneumoniae*, are part of the normal resident flora. Viruses usually are not present in normal flora. There are a number of factors that can upset the symbiotic relationship between colonizing bacteria and the mucosal and phagocytic defenses of the nasopharynx and bronchial tree. For example, there may be acquisition of a new virulent and invasive strain, or infection may follow a viral infection. Importantly, cigarette smoking and chronic bronchitis favor colonization with *S pneumoniae*, *Haemophilus influenzae*, and *Legionella*. Other risk factors include smoking, asthma, binge drinking, and human immunodeficiency virus (HIV) infection ([Munn and colleagues, 1999](#); [Yost and associates, 2000](#)).

INCIDENCE AND CAUSES. According to [Bartlett and Mundy \(1995\)](#), the attack rate for all adults is 12 per 1000. It is much lower for young healthy women, and over the 5-year period from 1993 to 1997, the incidence of pneumonia complicating nearly 75,000 pregnancies at Parkland Hospital was about 1 in 600 ([Yost and associates, 2000](#)).

At least two thirds of adult pneumonias are bacterial, and *S pneumoniae* causes many of these. [Brown and Lerner \(1998\)](#) reviewed six studies totalling 1500 patients with community-acquired pneumonia. About a third were caused by *S pneumoniae* and in another third the etiological agent was not identified. Other common causes were *Mycoplasma pneumoniae*, *H influenzae*, and viruses, especially influenza A. *Chlamydia pneumoniae* likely is a significant cause of pneumonia during pregnancy as it is responsible for 5 to 10 percent of pneumonia in hospitalized adults ([Bartlett and Mundy, 1995](#)). *Legionella pneumophila* occasionally causes outbreaks or sporadic cases in young adults, and it has been reported with pregnancy ([Eisenberg and colleagues, 1997](#); [Evenson, 1998](#)). In one case, it was associated with septic shock ([Tewari and co-workers, 1997](#)). [Gherman and associates \(1995\)](#) described a 32-week pregnant woman in whom *Chlamydia psittaci* caused both pneumonia and fetal-placental infection.

DIAGNOSIS. Typical symptoms of pneumonia include productive cough, fever, chest pain, and dyspnea. Mild upper respiratory symptoms and malaise usually precede these symptoms. There usually is mild leukocytosis. Chest x-ray is essential for diagnosis, although its appearance does not accurately predict the etiology ([Fig. 46-1](#)).

As discussed, the responsible pathogen is identified in perhaps only half of cases. Although some recommend examination of Gram-stained sputum to search for pneumococci or possibly staphylococci, the [American Thoracic Society \(1993\)](#) stresses that its sensitivity and specificity vary widely. Likewise, although routine sputum cultures often demonstrate pathogenic organisms, they too have poor predictability. [Bartlett and Mundy \(1995\)](#) reported that half of sputum samples show likely pathogens. Invasive techniques such as transtracheal aspiration are seldom indicated. Serological testing and cold agglutinin measurements are not routinely recommended. Finally, there are no currently available tests for bacterial antigens that are useful in evaluation of most of these patients.

MANAGEMENT. According to the [American Thoracic Society \(1993\)](#), the decision for hospitalization is perhaps the single most important decision for management of community-acquired pneumonia. Although it is the policy at Parkland Hospital to hospitalize all pregnant women with radiographically confirmed pneumonia, this is

probably not necessary with appropriate home health care. At the least, risk factors—especially if multiple—that are shown in [Table 46-1](#) should prompt consideration for hospitalization. Initial hospitalization can serve to allow close observation for the first day or so to be sure that infection is responsive to therapy. Pneumonia is a common cause of acute respiratory distress syndrome ([Ware and Matthay, 2000](#)). In some pregnant women, respiratory failure requires assisted ventilation ([Chap. 43, p. 1164](#)).

Because of factors cited, antimicrobial treatment must be empirical. Given that the majority of adult pneumonias are caused by pneumococci, mycoplasmas, or chlamydia, erythromycin therapy is the logical choice in the uncomplicated case ([American Thoracic Society, 1993](#)). The usual dose is 500 to 1000 mg every 6 hours, and this can be given intravenously, at least initially. [Yost and colleagues \(2000\)](#) reported that erythromycin monotherapy was effective in all but one of 99 pregnant women hospitalized with uncomplicated pneumonia. The newer erythromycin analogs are acceptable.

For women with the complications listed in [Table 46-1](#), or in those in whom staphylococcal or *Haemophilus* pneumonia is suspected, then cefotaxime, ceftizoxime, or cefuroxime is given instead. A β -lactam antimicrobial with a β -lactamase inhibitor is also suitable. Erythromycin added to either of these latter two regimens is recommended by some clinicians, and this is our practice at Parkland Hospital ([Yost and associates, 2000](#)). Of concern is the emergence of pneumococcal resistance. The [Centers for Disease Control and Prevention \(1999a\)](#) performed sentinel surveillance and found that 25 percent of strains were resistant to penicillin in 1997 compared with 14 percent for 1993-1994. Multidrug resistance is about 10 percent ([Whitney and co-workers, 2000](#)). Recently, the [Food and Drug Administration \(2000\)](#) has approved *levofloxacin* for treatment of adults with penicillin-resistant pneumococcal pneumonia. The drug is a fluoroquinolone and is classified as category C ([Briggs and colleagues, 1998](#)).

Clinical improvement is usually evident by 48 to 72 hours. Fever typically lasts 2 to 4 days. If fever persists, follow-up radiography should be considered. It is common for radiographic findings to worsen initially, and there may be progression of infiltrates or development of a pleural effusion. About 20 percent of cases of pneumococcal pneumonia have associated effusion; however, with mild clinical disease that is improving, such findings are inconsequential. Conversely, radiographic deterioration in the setting of severe community-acquired pneumonia is a poor prognostic feature and highly predictive of mortality.

PREVENTION. Pneumococcal vaccine has been shown to be 60 to 70 percent protective against the 23 vaccine-related serotypes. Its use may help decrease emergence of drug-resistant pneumococci. The vaccine is not given to otherwise healthy pregnant women. It is recommended by the [Advisory Committee on Immunization Practices \(1997\)](#) for immunocompromised adults including those with HIV¹ infection. It is also given to those who have underlying diabetes, or cardiac, pulmonary, or renal disease. Another example is the pregnant woman with asplenia, for example, sickle-cell disease, who is especially susceptible to these infections.

EFFECT OF PNEUMONIA ON PREGNANCY. There is no doubt that maternal mortality from pneumonia was considerable during the preantibiotic era. In 1939, Finland and Dublin reported a 32 percent maternal mortality rate in 212 women. Since then, an overall downward trend in maternal and fetal morbidity and mortality has been emphasized. In five recent studies shown in [Table 46-2](#), the overall maternal (1.6 percent) and perinatal (2.2 percent) mortality rates are still formidable. Preterm birth rates are increased over baseline. Importantly, 7 percent of these 323 women required intubation. These outcomes underscore the severity of pneumonia and also serve to emphasize the need for prompt diagnosis, close observation, and effective treatment.

VIRAL PNEUMONIA

INFLUENZA PNEUMONIA. Influenza is an acute respiratory infection caused by viruses of the *Orthomyxoviridae* family. Influenza A and B form one genus of these RNA viruses, and they are identified by nucleoprotein antigenic reactions. Some of their serological characteristics are reviewed in [Chapter 56 \(p. 1463\)](#). Outbreaks occur virtually every year, with global pandemics every 10 to 15 years. The virus is spread by aerosolized droplets and quickly infects ciliated columnar epithelium, alveolar cells, mucus gland cells, and macrophages. If uncomplicated, the usual clinical course is 2 to 5 days.

Influenza A is more serious than type B, and it is epidemic in the winter months. The onset of epidemics vary annually as do their duration and peak periods ([Centers for Disease Control and Prevention, 2000b](#)). In most healthy adults, infection is self-limited, but pneumonia is the most common complication. Clinically, it is difficult to distinguish from bacterial pneumonia, especially infection caused by pneumococci. Primary pneumonitis is the most severe form, and it is characterized by sparse sputum production and radiographic interstitial infiltrates ([Fig. 46-2](#)). Secondary bacterial pneumonia is more common and usually is caused by streptococci or staphylococci. Secondary infection usually manifests after 2 to 3 days of clinical improvement.

PREVENTION. For all of the previously discussed reasons, beginning in 1998, the [Centers for Disease Control and Prevention \(2000c\)](#) has recommended vaccination for all pregnant women after the first trimester. **Regardless of the stage of pregnancy, women who are at high risk because of underlying disease such as diabetes or heart disease should be vaccinated against influenza.** There is no evidence that influenza vaccine is teratogenic ([Chap. 10, p. 240](#)). Also, as [Munoz and Englund \(2000\)](#) indicated, some childhood protection against influenza will accrue.

TREATMENT. Generally, supportive treatment with antipyretics and bed rest is recommended for uncomplicated influenza ([Apuzzio, 1999](#)). The first class of drugs that has been available since 1976 for influenza treatment block ion-channel activity of viral M2 protein. **Amantadine or rimantadine**, 200 mg daily, are effective in reducing severity of infection if begun within 48 hours of symptoms. These may also be given prophylactically to high-risk nonimmunized exposed women and will prevent 50 to 90 percent of clinical infections ([Couch, 2000](#)). Both drugs are category C and while teratogenic in high doses given to animals, it is unclear if they are teratogenic to humans ([Briggs and colleagues, 1998](#)). Thus, after the first trimester, consideration should be given to their use depending on the clinical situation.

A new class of antiviral drugs—**neuraminidase inhibitors**—are highly effective to treat early influenza in adults ([Centers for Disease Control and Prevention, 1999d, 2000c](#); [Gubareva and associates, 2000](#)). **Oseltamivir** for oral use and **zanamivir** by inhalation were approved in 1999. Neither drug is approved for use in children or pregnant women. When given to nonpregnant patients for long-term prophylaxis, oseltamivir was 80 to 85 percent effective in preventing symptomatic influenza ([Hayden and colleagues, 1999](#)). Inhaled zanamivir has been found effective for early treatment and prevention of complications in high-risk nonpregnant patients ([MIST Study Group, 1998](#)).

EFFECTS ON PREGNANCY. In the influenza pandemic of 1918-1919, pneumonia was a grave complication of pregnancy ([Cox and Subbarao, 1999](#)). In a study of 1350 cases, [Harris \(1919\)](#) reported a maternal mortality rate of 27 percent, which increased to 50 percent when pneumonia developed. The 1957-1958 pandemic was also severe, and half of childbearing-age women who died of influenza in Minnesota were pregnant ([Freeman and Barno, 1959](#)). Fortunately, during the last decade mortality rates have been substantially reduced. Despite this, [Neuzil and colleagues \(1998\)](#) reported that hospitalization for influenza was increased fivefold in third-trimester women compared with nonpregnant controls.

[Irving and colleagues \(2000\)](#) found no evidence of transplacental infection in 138 cord samples from pregnancies with second- or third-trimester influenza. Also, there is no firm evidence that the virus causes congenital malformations ([Apuzzio, 1999](#)). [Saxen and associates \(1990\)](#) identified no association between first-trimester influenza in 248 mothers of anencephalic fetuses. Conversely, in a case-control study, [Lynberg and associates \(1994\)](#) found a threefold risk of neural-tube defects if there was maternal influenza early in pregnancy. These may be related to associated hyperthermia ([Kashyap and Gruslin, 2000](#)).

Schizophrenia is more common in individuals born in late winter and early spring. Although some have provided epidemiological evidence that midpregnancy fetal exposure to influenza A increases the risks for schizophrenia, [McGrath and Castle \(1995\)](#), as well as [Kashyap and Gruslin \(2000\)](#), concluded from their reviews that the association is weak ([Chap. 53, p. 1420](#)).

VARICELLA PNEUMONIA

Varicella-zoster virus is a member of the DNA herpesvirus family, and almost 95 percent of adults are immune ([Glantz and Mushlin, 1998](#)). Primary infection causes **chickenpox**, which has an attack rate of 90 percent in seronegative individuals. In the healthy patient, the typical maculopapular and vesicular rash is accompanied by constitutional symptoms and fever for 3 to 5 days. BR>

Although secondary skin infection with streptococci or staphylococci is the most common complication of chickenpox, varicella pneumonia is the most serious. It develops in about 10 percent of adults ([Nathwani and colleagues, 1998](#)). It usually appears 3 to 5 days into the course of the illness and is characterized by tachypnea, a dry cough, dyspnea, fever, and pleuritic chest pain. Chest x-ray discloses characteristic nodular infiltrates and interstitial pneumonitis ([Fig. 46-3](#)). In fatal cases, the lungs show scattered areas of necrosis and hemorrhage. Although resolution of pneumonitis parallels that of the skin lesions, fever and compromised pulmonary function may persist for weeks.

PREGNANCY. There is no convincing evidence that pregnant women are more likely to develop pneumonitis ([Nathwani and associates, 1998](#)). Although, retrospective studies cited disparate mortality in pregnancy, more recent descriptive studies indicate a mortality rate similar to nonpregnant persons. Still, this is about 10 percent, which makes the disease quite formidable. [Paryani and Arvin \(1986\)](#) reported that 4 of 43 pregnant women with chickenpox developed pneumonia, and

one of the two who required ventilatory support died.

Serious infection with sepsis or pneumonia is associated with preterm delivery. If infection develops before 20 weeks, the fetus can be infected and permanent sequela may result ([Chap. 56, p. 1464](#)).

MANAGEMENT. Although its efficacy has yet to be proved, most authors recommend treatment for varicella pneumonitis with intravenous acyclovir, 10 mg/kg every 8 hours. In one retrospective study, nonpregnant patients with pneumonia who were given acyclovir within 36 hours of admission had improved oxygenation by the sixth day compared with untreated controls ([Haake and co-workers, 1990](#)). [Smego and Asperilla \(1991\)](#) reviewed acyclovir treatment for varicella pneumonia and found an average 15 percent maternal mortality rate.

PROPHYLAXIS. Administration of **varicella-zoster immunoglobulin (VZIG)** will either prevent or attenuate varicella infection in exposed susceptible individuals if given within 96 hours. The dose is 125 units per 10 kg given intramuscularly with a maximum dose of 625 units or 5 vials. Immunoglobulin is recommended by the Centers for [Disease Control \(1984\)](#) for immunocompromised susceptible adults who are exposed. Because of the severity of varicella during pregnancy, some clinicians recommend immunoglobulin administration for otherwise healthy but seronegative pregnant women ([Chapman, 1998](#); [Chapman and Duff, 1993](#)). Up to 80 to 90 percent of adults are immune from prior symptomatic or asymptomatic infection; thus antibody testing with enzyme-linked immunosorbent assay (ELISA) or fluorescent antibody to membrane antigen (FAMA) should be done, if possible, prior to immune globulin therapy ([Rouse and associates, 1996](#)). Demonstration of antibodies by complement fixation indicates relatively recent infection. A rising complement-fixation titer is evidence for current or very recent disease.

PREVENTION. An attenuated varicella live-virus vaccine (Varivax) was licensed in 1995 by the Food and Drug Administration. It is recommended as one 0.5-mL dose for children 12 months to 12 years of age. For susceptible adults, two doses, 4 to 8 weeks apart, are recommended. [Glantz and Mushlin \(1998\)](#) concluded that routine prenatal serological testing of women with a negative varicella history is not cost-effective.

The vaccine is contraindicated in pregnancy. The vaccine virus can infect the fetus, with the highest risk between 13 and 20 weeks ([Stallings, 2000](#)). [Huang and colleagues \(1999\)](#) described a woman at term who ostensibly developed acute varicella after exposure to her two children who had been vaccinated 8 days previously. The manufacturer, Merck & Co., Inc. (West Point, Pennsylvania, 800-986-8999), has established a registry to follow outcomes when women are vaccinated within 3 months before pregnancy or at any time during pregnancy ([Centers for Disease Control and Prevention, 1996](#)).

FUNGAL AND PARASITIC PNEUMONIA

Fungal and parasitic pulmonary infections are usually of greatest consequence in the immunocompromised host, especially the woman with acquired immunodeficiency syndrome (AIDS).

PNEUMOCYSTIS PNEUMONIA. The most common infectious complication in women with [AIDS²](#) is interstitial pneumonia caused by the parasite *Pneumocystis carinii*. Prior to the 1980s, this infection had last been prevalent during epidemics in World War II, when it was associated with opportunistic infection in malnourished individuals. In immunocompromised patients, this is a life-threatening infection, and since the AIDS epidemic began in the 1980s, it is a common complication ([Chap. 57, p. 1493](#)). Symptoms include dry cough, tachypnea, and dyspnea, and the characteristic radiographic finding is a diffuse infiltrate. Although the organism can be identified by sputum culture, bronchoscopy with lavage or biopsy may be necessary. Maternal mortality may be quite high, but this may represent bias for reporting severe cases ([Saade, 1997](#)).

[Stratton and colleagues \(1992\)](#) described 35 pregnant women with pneumocystis pneumonia enrolled in the [AIDS³](#) Clinical Trials Centers. Treatment is with trimethoprim-sulfamethoxazole or pentamidine. Both drugs are category C. In some cases, tracheal intubation and mechanical ventilation may be required ([Albino and Shapiro, 1994](#); [Saade, 1997](#)).

For some immunodeficiency virus-positive patients, the [Centers for Disease Control \(1999c\)](#) recommends prophylaxis against pneumocystis infection with once-daily double-strength oral trimethoprim-sulfamethoxazole. These include women with CD4+ T-lymphocyte counts less than 200/uL, those with a history of oropharyngeal candidiasis, or those in whom CD4+ cells constitute less than 20 percent of lymphocytes.

FUNGAL PNEUMONIA. Any of a number of fungi can cause pneumonia during pregnancy. These are usually seen in women with [HIV¹](#) infection or those who are otherwise immunocompromised. Infections include histoplasmosis, coccidioidomycosis, cryptococcosis, and blastomycosis ([Chap. 56, p. 1479](#)). Their spores are found in soil, and although infection is common, it usually is mild and self-limited. Infection is characterized by cough and fever; only rarely is there dissemination.

Histoplasmosis and blastomycosis are not believed to be more common or more severe during pregnancy. Conversely, many have considered that **coccidioidomycosis** more commonly undergoes dissemination during pregnancy when compared with nonpregnant women ([Stevens, 1995](#)). This may be related to a stimulatory effect of the organism by estradiol-17 β ([Powell and associates, 1983](#)). [Wack and colleagues \(1988\)](#) analyzed 10 cases among more than 47,000 pregnant women and concluded that the disease was rare. [Arsura and associates \(1998\)](#) reported 61 pregnant women with symptomatic infection. Half had associated *erythema nodosum*, which indicated a better overall prognosis. Most cases of **cryptococcal infection** reported during pregnancy are meningitis. [Ely and co-workers \(1998\)](#) described four otherwise healthy pregnant women who had cryptococcal pneumonia. Diagnosis is difficult because clinical presentation is similar to other community-acquired pneumonias.

Treatment of pregnant women with disseminated fungal infections has been successful using intravenous *amphotericin B* (category B) or *ketoconazole* (category C) ([McGregor and associates, 1986](#); [Wack and colleagues, 1988](#)). Other anti-fungals effective against these infections include *flucytosine* and *fluconazole*, both category C ([Briggs and colleagues, 1998](#)).

ASTHMA

Asthma affects about 3 to 4 percent of the general population. The mortality rate from asthma ranges from 1 to 3 percent, and it causes nearly 5000 deaths annually in the United States. There are also long-term chronic sequelae that include reduced ventilatory function ([Lange and colleagues, 1998](#)). [The National Asthma Education Program \(1993\)](#) estimates that 1 to 4 percent of pregnancies are complicated by asthma. Status asthmaticus complicates about 0.2 percent of pregnancies ([Mabie and associates, 1992](#)).

PATHOPHYSIOLOGY

Asthma is a chronic inflammatory airway disorder with a major hereditary component. According to [Lemanske and Busse \(1997\)](#), increased airway responsiveness and inflammation have been linked to chromosomes 11q13 (high-affinity IgE receptor), 5q (cytokine gene cluster), and 14q (T-cell antigen receptor). There must also be an environmental stimulant in susceptible individuals. The hallmarks of asthma are reversible airway obstruction from bronchial smooth muscle contraction, mucus hypersecretion, and mucosal edema. There is airway inflammation and responsiveness to a number of stimuli, including irritants, viral infections, aspirin, cold air, and exercise. Mast cells and eosinophils are stimulated by stem-cell factor, cytokines, and kinases ([Holgate, 1997](#)). Mast-cell activation mediates bronchoconstriction by release of histamines, prostaglandin D₂, and leukotrienes. **Because F-series prostaglandins and ergonovine exacerbate asthma, these commonly used obstetrical drugs should be avoided if possible.**

CLINICAL COURSE

Clinically, asthma represents a broad spectrum of illness ranging from mild wheezing to severe bronchoconstriction capable of causing respiratory failure, severe hypoxemia, and death. The functional result of acute bronchospasm is airway obstruction and decreased air flow. The work of breathing progressively increases and patients present with chest tightness, wheezing, or breathlessness. Subsequent alterations in oxygenation primarily reflect ventilation-perfusion mismatching as the distribution of airway narrowing is uneven.

The clinical stages of asthma are summarized in [Table 46-3](#). With mild disease, hypoxia initially is well compensated by hyperventilation, as reflected by a normal arterial oxygen tension and decreased carbon dioxide tension with resultant respiratory alkalosis. As airway narrowing worsens, ventilation-perfusion defects increase and arterial hypoxemia ensues. With severe obstruction, ventilation becomes impaired sufficiently because of respiratory muscle fatigue to result in early CO₂ retention. Because of hyperventilation, this may only be seen initially as an arterial CO₂ tension returning to the normal range. Finally, with critical obstruction, respiratory failure follows, characterized by hypercapnia and acidemia.

Although these changes are generally reversible and well tolerated in the healthy nonpregnant individual, early stages of asthma may be dangerous to the pregnant woman and her fetus. The smaller functional residual capacity and the increased effective shunt render her more susceptible to develop hypoxia and hypoxemia.

EFFECTS OF PREGNANCY ON ASTHMA

There is no evidence that pregnancy has a predictable effect on underlying asthma. [Schatz and colleagues \(1988\)](#) prospectively studied both symptoms and spirometry measurements throughout pregnancy and the puerperium in 366 asthmatic women. They reported that about a third each of these women improved, remained unchanged, or clearly worsened. In another prospective study of 198 pregnancies by [Stenius-Aarniala and associates \(1988\)](#), almost 40 percent of women required more intensive therapy for their asthma at some time during the pregnancy. **Thus, about one third of asthmatic women can expect worsening of disease at some time during pregnancy.**

Women beginning pregnancy with severe asthma are more likely to experience worsening disease than are those with mild disease. In about 60 percent of women, asthma behaves similarly with successive pregnancies. Although [Schatz and colleagues \(1988\)](#) reported a 10 percent asthma exacerbation during labor and delivery, [Wendel and associates \(1996\)](#) found this to be only 1 percent. Importantly, [Mabie and associates \(1992\)](#) reported an 18-fold increased risk of exacerbation following cesarean delivery compared with vaginal delivery.

EFFECTS OF ASTHMA ON PREGNANCY

Asthma, especially when severe, can affect pregnancy outcome substantively. Shown in [Table 46-4](#) are maternal and perinatal outcomes in 3858 pregnancies complicated by asthma. In most studies, increased incidences of preeclampsia, preterm labor, low-birthweight infants, and perinatal mortality are noted. Although unproven, it seems logical that better perinatal outcomes would result from well-controlled asthma ([Schatz, 1999](#)). Maternal deaths may occur from **status asthmaticus**. Life-threatening complications include pneumothorax, pneumomediastinum, acute cor pulmonale, cardiac arrhythmias, and muscle fatigue with respiratory arrest. Mortality rates are substantively increased when asthma requires mechanical ventilation.

FETAL EFFECTS

Both animal and human studies are suggestive that maternal alkalosis may cause fetal hypoxemia well before maternal oxygenation is compromised ([Rolston and associates, 1974](#)). Fetal compromise is hypothesized to result from a combination of factors to include decreased uterine blood flow, decreased maternal venous return, and an alkaline-induced leftward shift of the oxyhemoglobin dissociation curve. Once the mother can no longer maintain normal oxygen tension and hypoxemia develops, the fetus responds with decreased umbilical blood flow, increased systemic and pulmonary vascular resistance, and finally decreased cardiac output. Realization that the fetus may be seriously compromised before maternal disease is severe underscores the need for aggressive management of all pregnant women with acute asthma. Monitoring the fetal response, in effect, becomes an indicator of maternal compromise.

CLINICAL EVALUATION

The subjective impression by the patient of the severity of asthma frequently does not correlate with objective measures of airway function or ventilation. Clinical examination also is inaccurate to predict severity, but useful signs include labored breathing, tachycardia, pulsus paradoxus, prolonged expiration, and use of accessory respiratory muscles. Signs of a potentially fatal attack include central cyanosis and altered level of consciousness.

Arterial blood gas analysis provides objective assessment of maternal oxygenation, ventilation, and acid-base status. With this information, the severity of an acute attack can be assessed ([Table 46-3](#)). In a prospective evaluation, however, [Wendel and associates \(1996\)](#) did not find routine blood gas analysis to help direct care in most pregnant women. In addition, care must be taken to interpret the results in relation to normal values for pregnancy. For example, a P_{CO_2} greater than 35 mm Hg with a pH less than 7.35 is consistent with hyperventilation and CO_2 retention in a pregnant woman.

Pulmonary function testing has become routine in the management of chronic and acute asthma. Sequential measurements of the forced expiratory volume in one second (FEV_1) from maximum expiration is the single best measure to reflect severity of disease. The peak expiratory flow rate (PEFR) correlates well with the FEV_1 , and it can be measured reliably with inexpensive portable peak flow meters. [Brancazio and associates \(1997\)](#) showed that the $PEFR^4$ did not change over pregnancy in normal women. These two measurements are the most useful tests to monitor airway obstruction. An FEV_1 less than 1 L or less than 20 percent of predicted correlates with severe disease as manifest by hypoxia, poor response to therapy, and a high relapse rate ([Noble and colleagues, 1988](#)).

MANAGEMENT OF CHRONIC ASTHMA

According to the [National Asthma Education Program \(1993\)](#), effective management of asthma during pregnancy includes:

1. Objective assessment of pulmonary function and fetal well-being.
2. Avoidance or control of environmental precipitating factors.
3. Pharmacological therapy.
4. Patient education.

In general, women with moderate to severe asthma are instructed to measure and record PEFrs twice daily. Predicted values range from 380 to 550 L/min, and each woman has her own baseline value. Recommendations for therapy adjustments can be made using these measurements.

Outpatient treatment depends on the severity of disease. Shown in [Tables 46-5](#) and [46-6](#) are drugs and suggested doses for home management of asthma in the pregnant woman. For mild asthma, **β -agonists** given by inhalation as needed are usually sufficient ([Drazen and colleagues, 1996](#)). **Inhaled corticosteroids** are the preferred treatment for persistent asthma ([Lipworth, 1999](#); [National Institutes of Health, 1997](#)). Inhalations are administered every 3 to 4 hours as needed. The goal is to reduce the use of β -agonists for symptomatic relief. A case-control study from Canada with a cohort of over 15,600 nonpregnant asthmatics showed that inhaled corticosteroids reduced hospitalizations by 80 percent ([Blais and associates, 1998](#)). [Wendel and colleagues \(1996\)](#) reported a 55 percent reduction in readmissions for severe asthma exacerbations in pregnant women maintained on inhaled corticosteroids along with β -agonist therapy.

Cromolyn sodium (category B) and **nedocromil** inhibit mast-cell degranulation. They are ineffective for acute asthma and are taken chronically for prevention.

Theophylline is a methylxanthine, and its various salts are bronchodilators and possibly anti-inflammatory. Some of its derivatives are considered useful for oral maintenance therapy of outpatients who do not respond optimally to inhaled corticosteroids and β -agonists. Sustained-release theophylline preparations may also be helpful for use before bedtime in women with nocturnal symptoms.

Leukotriene modifiers are new drugs that inhibit leukotriene synthesis. Some examples include *zileuton*, *zafirinkast*, and *montelukast* ([Medical Letter, 1999](#)). Their pharmacology and mechanisms of action were reviewed recently by [Drazen and colleagues \(1999\)](#). They are given either orally or by inhalation for prevention and are not effective with acute disease. Their role in asthma treatment is currently unclear, and there is very little experience with their use in pregnancy.

MANAGEMENT OF ACUTE ASTHMA

Treatment of acute asthma during pregnancy is similar to that for the nonpregnant asthmatic. An exception is a significantly lowered threshold for hospitalization for the pregnant woman. Most will benefit from intravenous hydration to help clear pulmonary secretions. Supplemental oxygen is given by mask after a blood gas sample is obtained. The therapeutic aim is to maintain the PO_2 greater than 60 mm Hg, and preferably normal, along with 95 percent oxygen saturation. Baseline pulmonary function testing includes FEV_1 or $PEFR^4$. Continuous pulse oximetry and electronic fetal monitoring may provide useful information.

First-line pharmacological therapy of acute asthma includes use of a **β -adrenergic agonist**, either epinephrine, isoproterenol, terbutaline, albuterol, isoetharine, or metaproterenol ([National Heart, Lung and Blood Institute, 1991](#); [Nelson, 1995](#)). The more commonly used short-acting agents, their dosages, and routes of

administration are listed in [Table 46-6](#). These drugs bind to specific cell-surface receptors and activate adenylyl cyclase, which increases intracellular cyclic AMP to modulate bronchial smooth muscle relaxation. They are given subcutaneously, by inhalation, or orally and are also used for maintenance therapy of outpatients. The long-acting preparations are used preferentially for maintenance.

It is now recommended that **corticosteroids** be given early to all patients in the course of severe acute asthma ([National Heart, Lung and Blood Institute, 1991](#)). Most recommended doses are probably higher than necessary. Still, in the United States, intravenous methylprednisolone, 40 to 60 mg, is usually given every 6 hours. Equipotent doses of hydrocortisone by infusion or prednisone orally can be given instead. **Because their onset of action is several hours, it is emphasized that steroids, whether given intravenously or by aerosol, are given along with β -agonists for treatment of acute asthma.**

Further management depends on the response to therapy. If initial therapy with β -agonists is associated with return of the [PEFR⁴](#) to above 70 percent of baseline, then discharge is considered. Some women may benefit from 23-hour observation. Alternatively, for the woman with obvious respiratory distress or if the PEFR is less than 70 percent predicted after three doses of β -agonist, admission is advisable. She is given intensive therapy to include inhaled β -agonists, intravenous corticosteroids, and close observation for worsening respiratory distress or fatigue in breathing ([Wendel and colleagues, 1996](#)).

STATUS ASTHMATICUS AND RESPIRATORY FAILURE. Severe asthma of any type not responding after 30 to 60 minutes of intensive therapy is termed status asthmaticus. For nonpregnant patients with status asthmaticus, [Braman and Kaemmerlen \(1990\)](#) have shown that management in an intensive care unit will result in a good outcome in almost all cases. During pregnancy, consideration should be given to early intubation when the maternal respiratory status continues to decline despite aggressive treatment (see [Table 46-3](#)). Fatigue, carbon dioxide retention, or hypoxemia are indications for intubation and mechanical ventilation.

MANAGEMENT OF LABOR AND DELIVERY

Regularly scheduled medications are continued through labor and delivery. Stress-dose corticosteroids are administered to any woman given systemic steroid therapy within the preceding 4 weeks. The usual drug is 100 mg of hydrocortisone given intravenously every 8 hours. The peak expiratory flow rate should be determined on admission. If asthma symptoms develop, then serial measurements are made after treatments.

In choosing an analgesic for labor, a non-histamine-releasing narcotic, such as fentanyl, may be preferable to meperidine or morphine. Epidural analgesia for labor is ideal. For surgical delivery, conduction analgesia is preferred because tracheal intubation can trigger severe bronchospasm. In the event of refractory postpartum hemorrhage, prostaglandin E₂ and other uterotonics should be used instead of prostaglandin F_{2a}, which has been associated with significant bronchospasm in asthmatic patients. Moreover, oxygen desaturation following 15-methyl PGF_{2a} given for postpartum hemorrhage has been reported in women without reactive airway disease ([Hankins and colleagues, 1988](#)).

THROMBOEMBOLIC DISEASE

Pregnancy and the puerperium traditionally are considered as one of the highest risks for otherwise healthy women to develop venous thrombosis and pulmonary embolism. Certainly, these remain a major cause of maternal death in the United States. From the Centers for Disease Control and Prevention, [Koonin and colleagues \(1997\)](#) reported that thrombotic pulmonary embolism caused 20 percent of 1459 pregnancy-related deaths in the United States from 1987 through 1990. [Jacob and co-workers \(1998\)](#) reported a similar incidence for Utah from 1982 through 1994. It was also the leading cause of direct maternal deaths in the United Kingdom from 1994 through 1996 ([de Swiet, 2000](#)).

INCIDENCE

The apparent decrease in the frequency of thromboembolism complicating pregnancy likely is related to more sophisticated diagnostic tests used to confirm the clinical diagnosis ([American College of Obstetricians and Gynecologists, 1997](#)). Also, the frequency of venous thromboembolic disease during the puerperium decreased remarkably when early ambulation became practiced widely. Stasis is probably the strongest single predisposing event to deep vein thrombosis and, therefore, should be minimized. Shown in [Table 46-7](#) are reported incidences of thromboembolism—both deep venous thrombosis and pulmonary embolism—in almost 1 million pregnancies. From these reports, the incidence of all thromboembolism is 1 per 1000 pregnancies. About half are identified antepartum and the other half in the puerperium. In about 15 percent, pulmonary embolism either accompanies deep venous thrombosis or occurs de novo. Risk factors cited in some of these studies included cesarean delivery, which had a fivefold risk. Smoking also increased the risk, and postpartum thrombosis occurrence amplified with preeclampsia. [Bernstein and Weiss \(2000\)](#) described a risk scoring system to predict thromboembolism in pregnancy or postpartum.

More recently, attention has been directed to a number of isolated deficiencies of proteins involved either in coagulation inhibition or in the fibrinolytic system. These deficiencies—collectively referred to as *thrombophilias*—can lead to hypercoagulability and recurrent venous thromboembolism ([Gherman and Goodwin, 2000](#); [Lockwood, 1999](#)). They are discussed in more detail in [Chapter 52 \(p. 1390\)](#). Principal thrombophilias arise from mutations that cause quantitative or qualitative deficiencies of antithrombin III, proteins S and C, factors V and IX, prothrombin, and homozygosity for an abnormal methylenetetrahydrofolate reductase (MTHFR) gene. Additionally, double heterozygosity for factor V Leiden and G20210A prothrombin mutations—and presumably others—appears to increase the risk for recurrent thromboembolism ([De Stefano and associates, 1999](#)).

According to [Greer \(1999\)](#), the most common inherited thrombophilia known at this time is due to the **factor V Leiden** mutation that causes **resistance to activated protein C**—a natural anticoagulant. In a case-control study of 119 women who had thromboembolism during pregnancy, [Gerhardt and colleagues \(2000\)](#) found that 44 percent (7.7 percent controls) had factor V Leiden mutation with a subsequent ninefold risk for thrombosis. This risk was even higher if another mutation co-existed. [McCull and co-workers \(1999\)](#) found a fivefold increased incidence of prothrombin or factor V Leiden mutations in pregnancy complicated by thromboembolism.

The risk for antepartum thromboembolism with these inherited defects is not precisely known. In a small study, [Hough and colleagues \(1996\)](#) attributed a 15 percent risk to pregnancy-related thrombosis with the factor V Leiden mutation. The risk of thrombosis with protein C deficiency is estimated to be 3 to 10 percent, and for protein S deficiency it may be up to 6 percent. These risks are increased postpartum and are estimated to be 7 to 19 percent and 7 to 22 percent for proteins C and S deficiencies respectively ([Greer, 1999](#)).

SUPERFICIAL VEIN THROMBOSIS

Thrombosis limited strictly to the superficial veins of the saphenous system is treated with analgesia, elastic support, and rest. If it does not soon subside, or if deep venous involvement is suspected, appropriate diagnostic measures are taken; and heparin is given if deep vein involvement is confirmed. Superficial thrombophlebitis is typically seen in association with superficial varicosities or as a sequela to intravenous catheterization.

DEEP VEIN THROMBOSIS

Most cases in pregnancy are confined to the deep veins of the lower extremity. In the study from Memphis, two thirds involved the extremity only ([Witlin and colleagues, 1999](#)). In the study from Los Angeles, three fourths involved the extremities ([Gherman and associates, 1999](#)). In the Parkland experience, 16 of 20 women had deep venous thrombosis without embolism.

CLINICAL PRESENTATION. The signs and symptoms of deep venous thrombosis involving the lower extremity vary greatly, depending in large measure upon the degree of occlusion and the intensity of the inflammatory response. [Ginsberg and colleagues \(1992\)](#) reported that 58 of 60 antepartum women had thromboses in the left leg, and it was bilateral in the other two. [Gherman and associates \(1999\)](#) described an 80 percent occurrence in the left leg. Classical puerperal thrombophlebitis involving the lower extremity, sometime called **phlegmasia alba dolens** or **milk leg**, is abrupt in onset, with severe pain and edema of the leg and thigh. The thrombus typically involves much of the deep venous system from the foot to the iliofemoral region. Occasionally, reflex arterial spasm causes a pale, cool extremity with diminished pulsations. More likely, there may be appreciable volume of clot yet little reaction in the form of pain, heat, or swelling. Importantly, calf pain, either spontaneous or in response to squeezing, or to stretching the Achilles tendon (Homans sign), may be caused by a strained muscle or a contusion. The latter may be common during the early puerperium as the consequence of inappropriate contact between the calf and the delivery table leg holders.

DIAGNOSIS. Although **venography** or **phlebography** remains the standard for confirmation of deep venous thrombosis, noninvasive methods have largely replaced this test to confirm the clinical diagnosis. Venography is time-consuming, expensive, cumbersome, and has serious complications. Likewise, **impedance plethysmography**, which was used for some time as a noninvasive screening method, is seldom used today.

Real-time ultrasonography, used along with duplex and color Doppler ultrasound, is currently the procedure of choice to detect proximal deep vein thrombosis ([American College of Obstetricians and Gynecologists, 2000](#)). [Lensing and colleagues \(1989\)](#) evaluated 220 consecutive nonpregnant patients with clinically suspected deep venous thrombosis. They compared contrast venography with real-time ultrasonography and evaluated the **common femoral** and **popliteal veins** for full compressibility (no thrombosis) and noncompressibility (thrombosis). Both of these vessels were fully compressible in 142 of 143 patients with normal venograms (specificity, 99 percent). All 66 patients with proximal-vein thrombosis had noncompressible femoral or popliteal veins, or both (sensitivity, 100 percent).

According to [Goldhaber \(1998\)](#), a third of patients with negative findings on compression sonography will have an associated pulmonary embolism. This can happen either because the thrombosis has embolized, or because it arose from deep pelvic veins inaccessible to ultrasound evaluation. **In pregnant women, thrombosis associated with pulmonary embolism frequently originates in the iliac veins.**

Magnetic resonance imaging is reserved for specific cases in which the ultrasound findings are equivocal, or with negative ultrasound findings but strong clinical suspicion. This technique allows for excellent delineation of anatomical detail above the inguinal ligament, and phase images can be used to diagnose the presence or absence of pelvic vein flow ([Fig. 46-4](#)). An additional advantage is the ability to image in coronal and sagittal planes. [Erdman and co-workers \(1990\)](#) reported that magnetic resonance imaging was 100 percent sensitive and 90 percent specific for detection of venographically proven deep venous thrombosis in nonpregnant patients. Furthermore, in 44 percent of patients without deep venous thrombosis, they were able to demonstrate nonthrombotic conditions to explain the clinical findings that originally had suggested venous thrombosis. Some examples include cellulitis, edema, hematomas, or superficial phlebitis.

Computed tomographic scanning also may be used to assess the lower extremities. It is widely available but requires contrast agents and ionizing radiation. As discussed in [Chapter 42 \(p. 1151\)](#), radiation exposure to the fetus is negligible unless the pelvic veins are imaged.

PULMONARY EMBOLISM

Although it causes about 10 percent of maternal deaths, pulmonary embolism is relatively uncommon during pregnancy and the puerperium. From reports in the past 10 years of nearly 1 million pregnancies, the incidence averages about 1 in 6400 ([Table 46-7](#)). These reports indicate an almost equal prevalence for antepartum and postpartum embolism, but those developing postpartum have a higher mortality. In many cases, but certainly not all, clinical evidence for deep venous thrombosis of the legs precedes pulmonary embolization. In others, especially those that arise from deep pelvic veins, the woman usually is asymptomatic until symptoms of embolization develop ([Figs. 46-4](#) and [46-5](#)).

CLINICAL PRESENTATION. Findings from the International Cooperative Pulmonary Embolism Registry (ICOPER) were recently described by [Goldhaber and colleagues \(1999\)](#). Over a 2-year period, almost 2500 nonpregnant patients with a proven pulmonary embolism were enrolled. The most common symptoms were dyspnea (82 percent), chest pain (49 percent), cough (20 percent), syncope (14 percent), and hemoptysis (7 percent). According to the [American College of Obstetricians and Gynecologists \(1997\)](#), predominant clinical findings included tachypnea (89 percent), dyspnea (81 percent), pleuritic pain (72 percent), apprehension (59 percent), cough (54 percent), tachycardia (43 percent), and hemoptysis (34 percent). In some cases there is an accentuated pulmonic closure sound, rales, or friction rub. Right axis deviation may or may not be evident on the electrocardiogram. Even with massive pulmonary embolism, signs, symptoms, and laboratory data to support the diagnosis of pulmonary embolism may be deceptively nonspecific.

DIAGNOSIS. In most centers, **ventilation-perfusion scintigraphy** is used because it is the least invasive technique that can accurately diagnose pulmonary embolism. These scans utilize a small dose of a radioactive agent, usually technetium (^{99m}Tc) macroaggregated albumin, which is administered intravenously. There is negligible fetal radiation exposure ([Chap. 42, p. 1153](#)). The scan may not provide a definite diagnosis because many other conditions—for example, pneumonia or local bronchospasm—can cause perfusion defects. Ventilation scans with inhaled xenon 133 or ^{99m}Tc were added to perfusion scans in the hope that ventilation would be abnormal, but perfusion normal, in areas of pneumonia or hypoventilation. Thus, while ventilation scanning increased the probability of an accurate diagnosis of pulmonary embolism in patients with **large perfusion defects** and **ventilation mismatches**, such as that shown in [Figure 46-5](#), normal ventilation-perfusion does not rule out pulmonary embolism.

Because of these uncertainties, the National Heart, Lung and Blood Institute commissioned the Prospective Investigation of Pulmonary Embolism Diagnosis ([PIOPED, 1990](#)). This study was designed to determine the sensitivities and specificities of ventilation-perfusion scans to diagnose pulmonary embolism. This investigation included 933 patients of whom 931 underwent scintigraphy and 755 pulmonary angiography; 33 percent of the 755 patients studied angiographically had pulmonary embolism. While almost all patients with an embolism had abnormal scans of high, intermediate, or low probability, so did most without embolism (sensitivity, 98 percent; specificity, 10 percent). Of 116 patients with high-probability scans, 88 percent had an embolism seen on angiography, but only a minority of those with a pulmonary embolism had a high-probability scan (sensitivity, 41 percent; specificity, 97 percent). Of 322 with intermediate-probability scans, 33 percent had an embolism on angiography, and for those with low-probability scan, the figure was 12 percent. **Importantly, 4 percent of patients with a near-normal to normal scan had pulmonary embolism detected by angiography.**

The [PIOPED](#)⁵ investigators concluded that a high-probability scan usually indicates pulmonary embolism, but that only a small number of patients with emboli have a high-probability scan. A low-probability scan combined with a strong clinical impression that embolism is unlikely makes the possibility of pulmonary embolism remote. Similarly, near-normal or normal scans make the diagnosis very unlikely. Finally, an intermediate-probability scan is of no help in establishing the diagnosis. Thus, the scan combined with clinical assessment permits a noninvasive diagnosis or exclusion of pulmonary embolism for only a minority of patients.

Because of these inaccuracies, most investigators recommend an integrated diagnostic approach for women with intermediate or low-probability scan results. For example, [Goldhaber \(1998\)](#) recommends continuation of workup if there is a high D-dimer serum level because normal levels have excellent negative predictive value. In patients with an elevated D-dimer level, he recommends noninvasive studies of the deep leg veins or pulmonary angiography. **Spiral computed tomography** has been used to noninvasively diagnose pulmonary embolism. It shows promise in identifying large vessel emboli but is less accurate for multiple small emboli. Finally, as discussed earlier and shown in [Figure 46-4](#), magnetic resonance imaging can be used to visualize thromboses arising in pelvic veins ([Erdman and colleagues, 1990](#)).

MANAGEMENT OF THROMBOEMBOLISM

DEEP VEIN THROMBOSIS. Treatment of deep venous thrombosis consists of anticoagulation, bed rest, and analgesia. For all women, during either pregnancy or postpartum, initial anticoagulation is with either unfractionated heparin or with low-molecular-weight heparin. For women still pregnant, heparin therapy is continued, and for those postpartum, warfarin therapy is given.

Most often, pain soon is relieved by these measures. After symptoms have completely abated, graded ambulation should be started with the legs fitted with elastic stockings, and anticoagulation continued. Recovery to this stage usually takes about 7 to 10 days.

HEPARIN. Intravenous heparin is given initially. The dosage schedule recommended by the [American College of Obstetricians and Gynecologists \(2000\)](#) includes a loading dose of 80 U/kg (minimum 5000 U). This is followed by a continuous infusion of heparin, 15 to 25 U/kg/hr. After 4 hours, the activated partial thromboplastin time (aPTT) is determined and adjusted as shown in [Table 46-8](#). Once a steady state is achieved, then the aPTT is measured daily.

Deep venous thrombosis may also be treated with subcutaneous adjusted-dose heparin to maintain the aPTT at 1.5 times the control value as determined at 6 hours after the last injection ([Hull and colleagues, 1992](#)). Alternately, treatment with one of the low-molecular-weight heparin compounds is suitable ([American College of Obstetricians and Gynecologists, 1998](#)).

The ideal duration of therapy for pregnant women is uncertain. The [American College of Obstetricians and Gynecologists \(1997\)](#) recommends therapeutic subcutaneous heparinization for 3 to 4 months, followed by prophylactic or "mini-dose" heparin throughout pregnancy and for 6 to 12 weeks postpartum. [Kearon and colleagues \(1999\)](#) recently reported findings from a study of 162 nonpregnant patients with thromboses and a variety of underlying illnesses. Anticoagulation carried out for 6 months prevented 95 percent of recurrences from 3 to 6 months. Specifically, patients continuing therapeutic heparin had a recurrence rate 1.3 percent per patient year compared with 27 percent in the group in which heparin was stopped at 3 months.

WARFARIN. Postpartum venous thrombosis is treated initially with heparin as described. Heparin is continued until oral anticoagulation with warfarin can be accomplished. If intravenous heparin and oral warfarin are initiated simultaneously, then heparin can be discontinued safely after 5 days. These women are anticoagulated with warfarin for at least 3 months. As previously discussed, data from [Kearon and colleagues \(1999\)](#) indicate that 6 months is preferable. **Warfarin is contraindicated in antepartum patients.**

LOW-MOLECULAR-WEIGHT HEPARIN. Clinical experience with low-molecular-weight heparin has accrued over the past decade ([Ginsberg and Hirsh, 1998](#)). This is a family of derivatives of commercial heparin that average about 4000 to 5000 daltons compared with about 12,000 to 16,000 daltons for conventional heparin. One such preparation, *logipram*, was shown to be safe and effective for treatment of proximal vein thrombosis in nonpregnant patients ([Hull and co-workers, 1992](#)). [Simmons and colleagues \(1997\)](#) showed equivalent efficiency and major complications in 612 nonpregnant patients with a pulmonary embolism randomized to either subcutaneous *tinzaprin* or intravenous heparin. The [Columbus Investigators \(1997\)](#) compared *reviparin* with unfractionated heparin to treat 1021 patients with venous thromboembolism, a third of whom had pulmonary embolism. The study drug was as safe and effective as standard heparin.

Thus, a number of preparations, all of which are pharmacologically unique, have been shown to be effective in preventing and treating deep vein thrombosis, but with fewer bleeding complications. Other advantages are once- or twice-daily administration, and most authors recommend that these subcutaneously administered drugs do not have to be monitored ([American College of Obstetricians and Gynecologists, 1998](#); [Lensing and associates, 1999](#)). Their use in pregnant women has been limited and was reviewed recently by [Bates \(1999\)](#) and [Chan \(1999\)](#).

MANAGEMENT OF PULMONARY EMBOLISM. Treatment for pulmonary embolism is similar to that for deep venous thrombosis, but with less well-documented results. In general, heparin is given initially in a fashion similar to that for deep venous thrombosis. The [American College of Obstetricians and Gynecologists \(2000\)](#) recommends an intravenous loading dose of 80 U/kg with management otherwise as given for deep venous thrombosis.

Other methods are acceptable, and most authors recommend starting with a dose of 1000 U/hour after an initial bolus dose of 5000 to 10,000 U given intravenously. The dose is maintained to produce a twofold prolongation of the activated partial thromboplastin time. Other methods include either intermittent intravenous injections of 5000 U heparin every 4 hours or 7500 U every 6 hours. Finally, heparin may be given subcutaneously in doses of 10,000 U every 8 hours or 20,000 U every 12 hours. The common theme in these regimens is that the total daily heparin dose is between 25,000 and 40,000 U.

In nonpregnant patients, the most common cause of death is recurrent pulmonary embolism ([Goldhaber, 1998](#)). To prevent this, most authors recommend therapeutic anticoagulation for 4 to 6 months. For women who develop thromboembolism postpartum, or for those who were given heparin antepartum and are now delivered, warfarin therapy is usually given.

VENA CAVAL FILTERS. Routine placement of a vena caval filter has no added advantage to heparin given alone to prevent pulmonary embolism in patients with deep vein thrombosis ([Decousus and associates, 1998](#)). In the very infrequent circumstances where heparin therapy fails to prevent recurrent pulmonary embolism from the pelvis or legs, or when embolism develops from these sites despite heparin given for their treatment, then a vena caval filter is indicated. The device is inserted through either the jugular or femoral vein. [Greenfield and Michna \(1988\)](#) recommend suprarenal placement during pregnancy. [Hux and colleagues \(1986\)](#) described the use of the Greenfield filter in five pregnant women and another who was 3 days postpartum. [Thomas and associates \(1997\)](#) described successful use of the Greenfield filter in eight pregnant women with complications of venous thromboembolism.

Retrievable filters may be used as short-term protection against embolism. These may be removed before they become endothelialized by 10 days, or they can be left permanently. [Neill and colleagues \(1997\)](#) described use of a **Gunther Tulip filter** placed at 37 weeks in a woman with recurrent embolization despite adequate anticoagulation. She underwent cesarean delivery at 38 weeks, and the filter removed 5 days postpartum.

COMPLICATIONS OF ANTICOAGULATION. The most serious complication with any of these regimens is hemorrhage, which is more likely if there has been recent surgery or lacerations, such as with delivery. Troublesome bleeding also is more likely if the heparin dosage is excessive. Unfortunately, many management schemes using laboratory testing to identify whether heparin dosage is sufficient to inhibit further thrombosis, yet not cause serious hemorrhage, have been discouraging.

Other complications include heparin-induced thrombocytopenia and osteoporosis (Toglia and Weg, 1996). Thrombocytopenia usually manifests within 2 to 3 weeks of initial therapy. Its incidence is 3 to 6 percent of patients given porcine heparin. Osteoporosis develops with long-term administration and is associated with heparin doses of 15,000 to 20,000 U/day for more than 6 months and is more prevalent in cigarette smokers ([American College of Obstetricians and Gynecologists, 1997, 2000](#)). Heparin-induced osteopenia is considered further in [Chapter 50 \(p. 1349\)](#).

ANTICOAGULATION AND ABORTION. The treatment of deep venous thrombosis with heparin does not preclude termination of pregnancy by careful curettage ([Chap. 33, p. 871](#)). After the products of conception are removed without trauma to the reproductive tract, heparin can be restarted in several hours in therapeutic doses without undue risk.

ANTICOAGULATION AND DELIVERY. Neither unfractionated nor low-molecular-weight heparins cross the placenta. The effects on blood loss at delivery will depend upon a number of variables, including:

1. Dose, route, and time of administration.
2. Magnitude of incisions and lacerations.
3. Intensity of postpartum myometrial contraction and retraction.
4. Presence of other coagulation defects.

Measured blood loss is not greatly increased with vaginal delivery if the midline episiotomy is modest in depth, there are no lacerations of the genital tract, and the uterus promptly becomes firmly contracted. Such ideal circumstances do not always prevail during and after vaginal delivery. For example, [Mueller and Leberz \(1969\)](#) described 10 women with antepartum thrombophlebitis treated with heparin. Three who continued to receive heparin during labor and delivery bled remarkably and developed large hematomas.

In general, therapeutic heparin therapy should be stopped during the time of labor and delivery. If the uterus is well contracted and there has been negligible trauma to the lower genital tract, it can be restarted within several hours. Otherwise, a delay of 1 or 2 days may be prudent. Protamine sulfate administered slowly intravenously will generally reverse the effect of heparin promptly and effectively. Protamine sulfate should not be given in excess of the amount needed to neutralize the heparin, because it has an anticoagulant effect.

The woman who has very recently suffered a pulmonary embolism and who must be delivered by cesarean presents a serious problem. Reversal of anticoagulation may be followed by another embolus, and surgery while she is fully anticoagulated frequently results in life-threatening hemorrhage or troublesome hematomas. In this situation, consideration should be given before surgery for placement of a vena caval filter.

Serious bleeding is likely when heparin in usual therapeutic doses is administered to a woman who has undergone cesarean delivery within the previous 48 to 72 hours. Again, preexisting defects in the hemostatic mechanism, such as thrombocytopenia, or impaired platelet function as induced by aspirin, enhance the likelihood of hemorrhage with heparin.

THROMBOEMBOLISM ANTEDATING PREGNANCY

Optimal management of women with firm evidence of a prior thromboembolism is unclear. The [National Institutes of Health Consensus Conference \(1986\)](#) concluded that the woman with either deep venous thrombosis or pulmonary embolism in a *prior* pregnancy should be given prophylactic subcutaneous heparin in doses of 5000 U, either two or three times daily throughout pregnancy. Similar recommendations were made in 1992 by the American College of Chest Physicians. The [American College of Obstetricians and Gynecologists \(2000\)](#) recommends 5000 to 10,000 units every 12 hours throughout pregnancy.

The study by [Tengborn and colleagues \(1989\)](#) suggests that such prophylaxis is not effective. They reported outcomes in 87 pregnant Swedish women who had prior thromboembolic disease. Despite heparin prophylaxis, usually 5000 U twice daily, 3 of 20 (15 percent) women developed antepartum recurrence, compared with 8 of 67 (12 percent) not given heparin.

The use of low-molecular-weight heparin has been reported to be efficacious for prophylaxis in high-risk pregnant women. [Nelson-Piercy and co-workers \(1997\)](#) gave enoxaparin, 40 mg subcutaneously once daily, during 69 pregnancies during which no thromboemboli were identified antepartum. One woman receiving only 20 mg subcutaneously daily developed a pulmonary embolus postpartum. Another concern was that a third of these women developed osteopenia. [Hunt and associates \(1997\)](#) gave Fragmin subcutaneously and monitored anti-Xa activity. None of 34 treated women had thromboembolism, but one had osteoporotic vertebral collapse

postpartum. More recently, [Brill-Edwards and associates \(2000\)](#) withheld antepartum heparin prophylaxis in 125 such women. Only 3 (2.4 percent) had recurrence and they concluded that prophylaxis was unnecessary.

Our practice at Parkland Hospital for many years for women with a history of prior thromboembolism has been to administer subcutaneous heparin, 5000 to 7500 units two to three times daily. With this regimen, the recurrence of documented deep venous thrombosis embolization has been rare. More recently, we have successfully used 40 mg enoxaparin subcutaneously daily.

TUBERCULOSIS

Although still a major worldwide concern, tuberculosis has become less common in the United States in recent decades. In 1998, the rate was 6.8 per 100,000 persons ([Centers for Disease Control and Prevention, 1999b](#)). The number of cases of tuberculosis in women of childbearing age increased 40 percent in the United States between 1985 and 1992 ([Cantwell and colleagues, 1994](#)).

Importantly, tuberculosis in foreign-born persons has increased by 50 percent and in 1998 comprised 40 percent of the estimated 18,000 cases in the United States ([Centers for Disease Control and Prevention, 1999b](#)). Indeed, the disease in this country is one of the elderly, the urban poor, minority groups, and patients with acquired immunodeficiency syndrome ([McKenna and colleagues, 1995](#)).

Cure rates with directly observed 6-month short-course therapy approaches 90 percent for new infections ([China Tuberculosis Control Collaboration, 1996](#)). Of special concern is the recent emergence of drug-resistant tuberculosis. In the United States, 12 percent of 13,500 strains isolated from 1994 to 1997 were resistant to at least one drug ([Pablos-Mendez and colleagues, 1998](#)). The Global Tuberculosis Program of the World Health Organization showed in 1997 that there was variable drug resistance in 35 countries. Importantly, multidrug-resistant strains, defined as combined resistance to isoniazid and rifampin, averaged 1.4 percent but were as high as 14 percent in some countries. More recently, the World Health Organization published expanded data from 58 countries and cited similar findings ([Brown, 2000](#)). Moreover, 6-month chemotherapy with first-line drugs is inadequate in many cases caused by resistant strains ([Espinal and associates, 2000](#)). In the United States, there have been documented outbreaks of multidrug-resistant tuberculosis (MDR-TB) in persons with HIV¹-infections. In some of these cases, tuberculosis was transmitted to health-care workers.

CLINICAL COURSE

Infection is via inhalation of *Mycobacterium tuberculosis*, which incites a granulomatous pulmonary reaction. In over 90 percent of patients, infection is contained and lies dormant for long periods. In some patients, especially those who are immunocompromised or who have other diseases, tuberculosis becomes reactivated to cause clinical disease. Clinical manifestations usually include cough with minimal sputum production, low-grade fever, hemoptysis, and weight loss. A variety of infiltrative patterns are seen on chest x-ray, and there may be associated cavitation or mediastinal lymphadenopathy. Acid-fast bacilli are seen on repeated stained smears of sputum in about two thirds of culture-positive patients. Extrapulmonary tuberculosis may occur in any organ, and almost 40 percent of HIV¹-positive patients have disseminated disease ([Weinberger and Weiss, 1999](#)).

TUBERCULOSIS AND PREGNANCY

The considerable influx of women into the United States from Asia, Africa, Mexico, and Central America has been accompanied by an increased frequency of tuberculosis in pregnant women. Additionally, pregnant women who are HIV¹-positive are at greater risk. [Margono and colleagues \(1994\)](#) described their experiences from New York City. At Kings County and Saint Vincent's Hospitals from 1985 through 1990, the rate for tuberculosis during pregnancy was 12 cases per 100,000 deliveries. During 1991 and 1992 this rate rose to 95 per 100,000. There were 16 pregnant women with active tuberculosis, and 7 of 11 tested were HIV-positive.

PREGNANCY OUTCOMES. Prior to antituberculosis therapy, pregnancy was thought to have an adverse effect on the course of tuberculosis ([Anderson, 1997](#)). Contemporaneous experiences are sparse because chemotherapy has diminished adverse effects from severe disease. [Jana and colleagues \(1994\)](#) reported outcomes of 79 pregnancies from India complicated by active pulmonary tuberculosis. There were increased incidences of preterm delivery and low-birthweight and growth-restricted infants, as well as a sixfold increased perinatal mortality rate. Adverse outcomes correlated with late diagnosis, incomplete or irregular treatment, and advanced pulmonary lesions. They also studied outcomes in 33 pregnancies complicated by extrapulmonary tuberculosis ([Jana and co-workers, 1999](#)). While lymphadenitis did not affect outcomes, a third of women with renal, intestinal, and skeletal injections had low-birthweight infants. [Figueroa-Damian and Arrendondo-Garcia \(1998\)](#) reported similar outcomes in 25 pregnant women from Mexico City. In a recent prospective study from London, [Llewelyn and associates \(2000\)](#) reported that 9 of 13 pregnant women had extrapulmonary disease concomitant with delayed diagnoses.

DIAGNOSIS. Current guidelines include skin testing of only women in high-risk groups as shown in [Table 46-9](#). The preferred antigen is purified protein derivative (PPD) in the intermediate strength of 5 tuberculin units. If the intracutaneously applied test is negative, no further evaluation is needed. A positive skin test is interpreted according to risk factors ([American Thoracic Society/Centers for Disease Control, 1990](#)). For *very high-risk* patients—that is, those who are HIV¹-positive, those with abnormal chest radiography, or those who have a recent contact with an active case—5 mm is considered positive. For those at *high risk*—foreign born, intravenous drug users who are HIV-negative, low-income populations, or those with medical conditions that increase the risk for tuberculosis—10 mm is considered positive. For persons with none of these risk factors, 15 mm is defined as positive. If the chest radiograph is negative, then no treatment is necessary until after delivery, when isoniazid chemoprophylaxis is usually given for 1 year. Patients who have been vaccinated with *bacille Calmette-Guerin (BCG)* pose special problems with interpretation of skin testing.

TREATMENT. In nonpregnant tuberculin-positive patients who are younger than 35, and who have no evidence of active disease, isoniazid, 300 mg daily, is given for 1 year. Isoniazid is a category C drug that is considered safe in pregnancy. In pregnant women who are HIV¹-negative, however, most authors recommend that therapy be delayed until after delivery. Because of possibly increased isoniazid-induced hepatitis in postpartum women, some recommend withholding treatment until 3 to 6 months postpartum. Neither postpartum method is as effective as antepartum treatment to prevent active infection ([Boggess and colleagues, 2000](#)).

There are exceptions to delayed treatment in pregnancy. Known recent skin-test converters are treated because the incidence of active infection is 3 percent in the first year. Skin-test positive women exposed to active infection are treated because the incidence of infection is 0.5 percent per year. Finally, HIV¹-positive women are treated because they have an 8 percent annual risk for active disease ([Brost and Newman, 1997](#)). An alternative is to withhold therapy until after 12 weeks in these asymptomatic women. Isoniazid toxicity includes hepatitis, which is more common in patients younger than 35. Although monitoring of liver enzymes indicates that 10 to 20 percent of patients have transient elevation, therapy is not discontinued unless their elevation is fivefold times normal ([Weinberger and Weiss, 1999](#)). Currently, the [Centers for Disease Control and Prevention \(1999b\)](#) do not recommend routine monitoring.

Because of emerging drug resistance, the [Centers for Disease Control \(1993\)](#) now recommends a four-drug regimen for the initial empirical treatment of nonpregnant patients with symptomatic tuberculosis. These are isoniazid, rifampin, and pyrazinamide with ethambutol or streptomycin given until susceptibility studies are done. Drug susceptibility testing is performed on all first isolates. Fortunately, most first-line tuberculostatic drugs do not appear to affect the fetus adversely. An exception is streptomycin, which may cause congenital deafness. Moreover, the safety of pyrazinamide given in early pregnancy has not been established.

The [Centers for Disease Control \(1993\)](#) recommend that the orally prescribed regimen for pregnant women should include:

1. **Isoniazid**, 5 mg/kg, not to exceed 300 mg daily, along with **pyridoxine**, 50 mg daily.
2. **Rifampin**, 10 mg/kg daily, not to exceed 600 mg daily.
3. **Ethambutol**, 5 to 25 mg/kg daily, not to exceed 2.5 g daily.

These drugs are given for a minimum of 9 months. For HIV¹-infected women, the use of rifampin or rifabutin may be contraindicated if certain nucleoside reverse transcriptase inhibitors are being administered ([Centers for Disease Control and Prevention, 2000a](#)). If there is resistance to these drugs, then pyrazinamide therapy is considered.

NEONATAL TUBERCULOSIS. Tubercule bacillemia during pregnancy can infect the placenta. The fetus may also be infected, and although **congenital tuberculosis** is rare, it can prove fatal. Its incidence likely will increase with concomitant HIV¹ infection ([Pillay and Jeena, 1999](#)). In half of cases, infection is acquired hematogenously in the liver or lungs via the umbilical vein. In the other half, infants are infected by aspiration of infected secretions at delivery. In their review,

[Cantwell and associates \(1994\)](#) found only 29 cases of congenital tuberculosis reported in the English literature since 1980. Only 12 of the mothers had active infection. Genital tuberculosis was common in these women, and all 14 who had endometrial biopsy performed showed active infection. [Adhikari and colleagues \(1997\)](#) described 11 culture-positive cases over 1 year from South Africa. Six neonates had congenital tuberculosis, and one died within 3 months. Six mothers were HIV-positive, and one died within 3 months.

Neonatal infection is unlikely if the mother with active disease has been treated before delivery, or if her sputum culture is negative. Because the newborn is quite susceptible to tuberculosis, most authors recommend isolation from the mother suspected of having active disease. If untreated, the risk of disease in the infant born to a woman with active infection is 50 percent in the first year ([Jacobs and Abernathy, 1988](#)). It is not known whether isoniazid chemoprophylaxis is efficacious for the infant. It may be given with or without BCG vaccination. For the symptomatic infant, the treatment regimen is essentially the same as for adults.

SARCOIDOSIS

Sarcoidosis is a chronic, multisystem disease of unknown etiology characterized by an accumulation of T lymphocytes and phagocytes within noncaseating granulomas. Disease appears to be mediated by an exaggerated response for T-helper lymphocytes. Pulmonary involvement is most common, followed by the skin, eyes, and lymph nodes. Its prevalence in the United States is 10 to 40 per 100,000, with equal sex distribution but a 10- to 20-fold predilection for African Americans ([Crystal, 1998](#)). Most patients are between 20 and 40 years old. Their clinical presentation varies, but most commonly dyspnea and a dry cough without constitutional symptoms develop insidiously over months. In about a fourth of patients, disease onset is abrupt, and 10 percent are asymptomatic at discovery.

Over 90 percent of patients have an abnormal chest x-ray. **Interstitial pneumonitis** is the hallmark of pulmonary involvement. About half of affected patients develop permanent radiological changes. **Lymphadenopathy**, especially of the mediastinum, is present in 75 to 90 percent of cases; 25 percent have **uveitis**; and 25 percent have skin involvement, usually manifest as **erythema nodosum**. Any other organ system can be involved. Confirmation of diagnosis is not possible without biopsy, and because the lung may be the only involved organ, tissue acquisition is often difficult.

The overall prognosis for sarcoidosis is good, and in half of patients it resolves without treatment. In the other half, permanent organ dysfunction persists, albeit mild and nonprogressive. About 10 percent die because of their disease. Glucocorticoids are the most widely used treatment; however, permanent organ derangement is seldom reversed by their use. Thus, the decision to treat is based on symptoms, physical findings, chest x-ray, and pulmonary function tests. Unless respiratory symptoms are prominent, therapy is usually withheld for a several-month observation period, and if inflammation does not subside, then prednisone, 1 mg/kg, is given daily for 4 to 6 weeks ([Crystal, 1998](#)).

SARCOIDOSIS AND PREGNANCY

Sarcoidosis uncommonly complicates pregnancy. [De Regt \(1987\)](#) described 14 cases over a 12-year period at Downstate Medical Center, during which time nearly 20,000 women were delivered. Reported beneficial effects of pregnancy are questionable because of the tendency of sarcoidosis to improve spontaneously. Available evidence is suggestive that sarcoidosis seldom affects pregnancy adversely unless there is severe preexisting disease ([Selroos, 1990](#)). [De Regt \(1987\)](#) reported two fatal cases due to extensive disease, one with multiple lung abscesses and the other with severe interstitial fibrosis. [Seballos and associates \(1994\)](#) described a woman with peripartum heart failure from pulmonary and cardiac sarcoidosis. [Boggess and colleagues \(1995\)](#) described two pregnancies in a woman with severe restrictive lung disease from sarcoidosis. [Maisel and Lynam \(1996\)](#) reported a 16-week pregnant woman who died suddenly from granulomatous meningitis with brain stem involvement and obstructive hydrocephaly.

[Selroos \(1990\)](#) reviewed 655 patients with sarcoidosis referred to the Mjølbolsta Hospital District in southern Finland. Of 252 women between 18 and 50 years old, 15 percent had sarcoidosis during pregnancy or within 1 year postpartum. There was no evidence for disease progression in the 26 pregnancies with active disease; three aborted spontaneously and the other 23 women were delivered at term. In 18 pregnancies in 12 women with inactive disease, pregnancy outcome was good and there was no evidence of disease activation. These experiences are similar to those reported by [Agha and colleagues \(1982\)](#) for 35 pregnancies cared for at the University of Michigan Hospital.

Active sarcoidosis is treated using the same guidelines as for the woman who is not pregnant. Severe disease warrants serial determination of pulmonary function. Symptomatic uveitis, constitutional symptoms, and pulmonary symptoms are treated with prednisone, 1 mg/kg per day.

CYSTIC FIBROSIS

Cystic fibrosis is one of the most common serious genetic disorders in Caucasians. It is caused by one of over 800 point mutations on the long arm of chromosome 7 that affect the chloride-ion channel—the *cystic fibrosis transmembrane conductance receptor regulator (CFTR)* ([Chap. 37, p. 986](#)). Its frequency is estimated to be 1 per 1500 Caucasian births and 1 per 17,000 African-American births. Median survival has increased from 14 years in 1969 to 30 years in 1995 ([Ramsey, 1996](#)). Because of improvements in diagnosis and treatment, nearly 80 percent of females with cystic fibrosis now survive to adulthood. Although many are infertile because of delayed sexual development and perhaps abnormal cervical mucus production, pregnancy is not uncommon. The North American Cystic Fibrosis Foundation estimated that 4 percent of cystic fibrosis patients become pregnant each year ([Edenborough and colleagues, 1995](#)). Males who survive to adulthood often have aspermia.

Mutations that result in cystic fibrosis cause altered epithelial cell membrane transport of electrolytes. The disorder is characterized by exocrine gland dysfunction with production of thick, viscid secretions. Eccrine sweat gland abnormalities provide the basis for the diagnostic **sweat test**, characterized by elevated sodium, potassium, and chloride levels in sweat.

Almost all affected patients have lung involvement, which is also the most common cause of death. Bronchial gland hypertrophy with mucous plugging and small-airway obstruction leads to subsequent infection that ultimately causes chronic bronchitis and bronchiectasis. Bacteria that colonize the respiratory tract include *Pseudomonas aeruginosa* in over 90 percent; *Staphylococcus aureus* and *H influenzae* are recovered in a minority of instances. Acute and chronic parenchymal inflammation ultimately causes extensive fibrosis, and along with airway obstruction, there is a ventilation-perfusion mismatch. Pulmonary insufficiency is the end result. Lung or heart-lung transplantation has a 5-year survival rate of 33 percent ([Aurora and associates, 1999](#)).

CYSTIC FIBROSIS AND PREGNANCY

Pulmonary involvement with chronic lung disease, hypoxia, and frequent infections may prove deleterious to pregnancy. **Cor pulmonale** is common, and [Cohen and associates \(1980\)](#) reported that 13 percent of pregnant women with cystic fibrosis developed heart failure. **Pancreatic dysfunction** also can contribute significantly to poor maternal nutrition.

While early reports suggested a deleterious effect of pregnancy on the course of cystic fibrosis, this may have been related to severe disease ([Olson, 1997](#)). [Cohen and colleagues \(1980\)](#) surveyed cystic fibrosis centers and reported information from 129 pregnancies. They found that increased maternal and perinatal mortality was related to severe pulmonary infection. They used the **Schwachman-Kulezycki** or **Taussig** scores of severity, which are based on radiological and clinical criteria. These range from 0 to 100, and a score of 50 or less in nonpregnant patients portends an overall bad prognosis, while a score of 90 or more predicts a good outcome. They concluded that pregnancy should be discouraged unless the score was at least 80. The long-term prognosis should also be considered—in this study, 18 percent of women had died within 2 years.

[Kent and Farquharson \(1993\)](#) reviewed outcomes in 215 pregnancies in 160 women with cystic fibrosis published from 1960 to 1991. Over 80 percent of the pregnancies progressed to 20 weeks. One fourth of these delivered preterm, and the perinatal death rate was 14 percent. The three maternal deaths were in women with the worst pulmonary function. Another 10 women with moderately severe pulmonary function died less than 6 months after delivery. Within 2 years of delivery, 14 percent of the women died.

[Canny and co-workers \(1991\)](#) reported their experiences with 38 pregnancies in 25 women with cystic fibrosis. Prepregnancy treatment was continued, including pancreatic enzyme replacement in the 12 women with pancreatic insufficiency, oral antibiotics, aerosolized bronchodilators, chest physiotherapy, and nutritional support. Admission was required for pulmonary complications during 30 percent of pregnancies. Three women developed gestational diabetes, and another had postpartum pancreatitis. Of 34 completed pregnancies, there were two preterm deliveries, and one growth-restricted term infant was delivered to a woman with severe obstructive lung disease. Only one mother died within 2 years of delivery, in contrast to 18 percent reported in the survey by [Cohen and colleagues \(1980\)](#). They stressed that the women they described were not as ill as many patients with cystic fibrosis. For example, they had a relatively late age at diagnosis and a high incidence of pancreatic sufficiency, both good prognostic factors.

Subsequent reports support that prognosis for both mother and fetus is dependent on lung involvement. [Edenborough and colleagues \(1995, 2000\)](#) described 69 pregnancies in women cared for in 11 cystic fibrosis centers in the United Kingdom. Excluding abortions, all 48 pregnancies resulted in live-born infants, but half were delivered preterm. They reported that if prepregnancy forced expiratory volume in 1 second was less than 60 percent predicted, there was substantive risk of preterm and cesarean delivery, respiratory complications, and early death of the mother. [Gilljam and associates \(2000\)](#) reported only six preterm births of 74 viable pregnancies in 54 women. [Frangolias and colleagues \(1997\)](#) described seven women with stable lung function during pregnancy. [Jankelson and associates \(1998\)](#) reported 13 pregnancies in 11 women, and five of six had normal lung function defined by an FEV₁ of over 80 percent. While these did well, four of five with an FEV₁ of less than 80 percent had worsening pulmonary function and were delivered preterm. Three of these five were dead within 7 years.

MANAGEMENT IN PREGNANCY. Prepregnancy counseling is imperative, and genetic counseling is discussed in [Chapter 39 \(p. 1076\)](#). Women who choose to become pregnant should be followed closely with serial pulmonary function testing and surveillance for superimposed infection, development of diabetes, and heart failure. Women who have a Schwachman-Kulezycki score of over 75, good nutritional status, and an FEV₁ of at least 70 percent usually tolerate pregnancy well. Careful attention is given to postural drainage and bronchodilator therapy. Inhaled recombinant human deoxyribonuclease I improves lung function by reducing sputum viscosity ([Olson, 1997](#)). Pancreatic insufficiency is treated by oral pancreatic enzyme replacement. Immediate hospitalization is recommended if complications develop, especially pulmonary infection. For labor and delivery, epidural analgesia is recommended, especially for operative delivery. Treatment of cor pulmonale consists of bronchodilators, oxygen, and diuretics.

CARBON MONOXIDE POISONING

Carbon monoxide is ubiquitous, and most nonsmoking adults have a carbon monoxyhemoglobin saturation of 1 to 3 percent. In cigarette smokers, levels may be as high as 5 to 10 percent. Toxic levels are frequently encountered in inadequately ventilated areas warmed by space heaters. Carbon monoxide is an odorless, tasteless gas that has a high affinity and binding for hemoglobin, thus displacing oxygen and impeding its transfer.

Pregnant women, and especially their fetuses, do not tolerate excessive carbon monoxide inhalation. Symptoms usually appear when carboxyhemoglobin concentration is 20 to 30 percent. Concentrations over 50 to 60 percent produce severe symptoms and may be fatal for the mother; presumably, lesser concentrations are fatal for the fetus. Because hemoglobin F has a higher affinity for carbon monoxide, fetal carboxyhemoglobin levels are 10 to 15 percent higher than those in the mother ([Longo, 1977](#)).

When a patient is breathing room air, the half-life of carboxyhemoglobin is 4 to 6 hours, but in 100 percent oxygen it is about 1 hour. **Hyperbaric oxygen** at 3 atmospheres of pressure decreases this to about 20 minutes. Treatment of carbon monoxide poisoning is supportive along with administration of inspired 100 percent oxygen ([Tomaszewski, 1999](#)). Hyperbaric oxygen is generally recommended in pregnancy, and [Elkharrat and colleagues \(1991\)](#) reported successful treatments in 44 pregnant women. [Silverman and Montano \(1997\)](#) also reported successful management of a woman whose abnormal neurological and cardiopulmonary findings abated in a parallel fashion with the associated fetal heart rate variable decelerations.

TABLE 46-1. Factors That Increase the Risk of Death or Complications with Community-acquired Pneumonia

Coexisting Conditions

Chronic lung disease, diabetes, renal failure, heart failure, chronic liver disease, postsplenectomy states, neurological disease, neoplastic disease, or chronic alcohol abuse

Previous Hospitalization within 1 Year

Suspicion of aspiration
Altered mental states

Physical Findings

Respiratory rate > 30/min, hypotension, hypothermia or temperature > 38.3°C (101°F)
Extrapulmonary disease, or confusion

Laboratory Findings

Leukopenia (< 4000/ μ L), PO₂ 60 mm Hg or CO₂ retention, bacteremia, elevated serum creatinine, anemia, or evidence for sepsis or organ dysfunction

Radiological Findings

More than 1-lobe involvement, cavitation, rapid spreading, or pleural effusion
Modified from the American Thoracic Society (1993) and Fine and colleagues (1996).

TABLE 46-5. Long-term Control Medications for Asthma

Medication	Dose	Comments
Systemic corticosteroids		
Methylprednisolone	a. 7.5-60 mg PO daily or every other day	For long-term treatment of severe asthma
Prednisolone Prednisone	b. "Burst" of 40-60 mg PO daily for 3-10 days	Effective for initiating therapy or with gradual deterioration—use until 80% PEFR personal best, taper not necessary
Inhaled corticosteroids		
Beclomethasone		
42 µg/puff	4-20 puffs/day	Low-dose 4-12 puffs/day High-dose 20+ puffs/day
84 µg/puff	2-10 puffs/day	Low-dose 2-6 puffs/day High-dose 10+ puffs/day
Budesonide		
200 µg/dose	1-3+ inhalations/day	Low-dose 1-2 inhalations/day High-dose 3+ inhalations/day
Triamcinolone		
100 µg/puff	4-20 puffs/day	Low-dose 4-10 puffs/day High-dose 20+ puffs/day
Cromolyn		
MDI 1 mg/puff	2-4 puffs tid-qid	One dose prior to exercise or allergen exposure good for 1-2 hr
Nebulizer 20-mg solution		
Theophylline	1 ampule tid-qid Starting dose 10 mg/kg/day with 300 mg maximum Maintenance dose maximum is 800 mg/day	Adjust dose for serum level 5-15 µg/mL

MDI = metered-dose inhaler; PEFR = peak expiratory flow rate.

Modified from National Institutes of Health (1997).

TABLE 46-6. Adrenergic Drugs Used for Treatment of Asthma

Drug	Administration	Recommended Dosages
Short-acting Epinephrine (α , β_1 , β_2)	Subcutaneous	0.3-0.5 mL of 1:1000 solution q 20 min \times 3
Isoetharine (β_2)	Inhaled	200-300 μ g/puff; 1-2 puffs q 4 h
	Inhaled	
	Metered dose Aerosolized	340 μ g/puff; 3-7 puffs q 3-4 h 0.5 mL of 1% solution, diluted 1:3 with saline
Isoproterenol (β_1 , β_2)	Inhaled	1:100 solution, 3-7 inhalations q 4-6 h
	Intravenous	0.05-5 μ g/min by infusion
Metaproterenol (β_2)	Inhaled	
	Metered dose	650 μ g/puff; 2-3 puffs q 3-4 h
	Nebulizer	0.3 mL of 5% solution q 4 h
Terbutaline (β_2)	Subcutaneous	250 μ g q 15 min \times 3
	Oral	2.5 mg q 4-6 h
Long-acting Salmeterol inhaled	Metered	21 μ g/puff; 2 puffs q 12 h
Albuterol SR	Blister	50 μ g/blister; 1 q 12 h
	Oral	4 mg q 12 h

SR = sustained release.

47. Renal and Urinary Tract Disorders

Although some diseases of the kidney and urinary tract may be associated with pregnancy by chance, pregnancy often predisposes to the development of urinary tract disorders, an example being acute pyelonephritis. In other cases, pregnancy may predispose to worsening of renal disease and its sequelae, as with lupus nephritis complicated by hypertension. In the not too distant past, obstetrical dogma was that pregnancy was contraindicated in the woman with significant underlying renal disease. As experience was gained, however, it became apparent that most women with these disorders will go through pregnancy without serious sequelae.

URINARY TRACT CHANGES DURING PREGNANCY

Significant changes in both structure and function take place in the urinary tract during normal pregnancy ([Chap. 8, p. 186](#)). Urinary tract dilatation is one of the most significant anatomical alterations induced by pregnancy. It involves dilatation of the renal calyces and pelves, as well as the ureters. [Faundes and co-workers \(1998\)](#) used ultrasound to measure the renal calyces during pregnancy and confirmed dilatation in about half with the right side more frequently and severely affected ([Fig. 47-1](#)). Some of the women demonstrated dilatation before the uterus reached the pelvic brim at about 14 weeks, implicating hormonal relaxation of the muscular layers of the urinary tract. There was further dilatation at 21 weeks due to mechanical compression of the ureters, especially on the right side. Most—all but 6 percent—of the women with pregnancy-induced dilatation of the urinary tract demonstrated resolution within 2 to 4 days of delivery. Interestingly, the fetal urinary tract mimics the maternal dilatation ([Graif and colleagues, 1992](#)).

An important consequence of dilatation and obstruction is potentially serious upper urinary infections. Another factor predisposing to infection is increased vesicoureteral reflux. These normal changes associated with pregnancy also may lead to erroneous interpretation of studies done to evaluate suspected pathological obstruction.

Evidence for hypertrophy of renal function is apparent very soon after conception. It appears to be mediated by pregnancy-induced intrarenal vasodilatation. Effective renal plasma flow and glomerular filtration are increased on the average by 40 and 65 percent, respectively. These changes have clinical relevance when interpreting renal function studies; for example, serum concentrations of creatinine and urea are decreased substantively. Other alterations include those related to maintaining normal acid-base homeostasis, osmoregulation, and fluid and electrolyte retention.

ASSESSMENT OF RENAL DISEASE DURING PREGNANCY

Interpretation of the **urinalysis** is essentially unchanged during pregnancy, except for the occasional glucosuria that is discovered. Although protein excretion normally is increased, it seldom reaches levels to be detected by usual screening methods. [Higby and colleagues \(1994\)](#) reported 24-hour protein excretion to be 115 mg with the 95 percent confidence level at 260 mg/day. There were no significant differences by trimester. They also showed that albumin excretion is minimal and ranges from 5 to 30 mg/day. Most investigators agree that proteinuria must exceed 300 to 500 mg/day to be considered abnormal for pregnancy. Unless precautions are taken to prevent contamination, there usually is an admixture of vaginal secretions when the specimen is collected; thus, a clean-catch specimen should be taken to verify any pathological proteinuria detected.

If the serum creatinine persistently exceeds 0.9 mg/dL (75 μ mol/L), then intrinsic renal disease should be suspected. A carefully collected, timed urine specimen can be used to estimate the glomerular filtration rate by creatinine clearance. **Ultrasonography** provides imaging of renal size and relative consistency, as well as elements of obstruction ([Fig. 47-1](#)). Full-sequence **intravenous pyelography** is not done routinely, but injection of contrast media with one or two abdominal x-rays may be indicated by the clinical situation. The usual clinical indications for **cystoscopy** are followed. Although [Packham and Fairley \(1987\)](#) reported **renal biopsy** to be safe and helpful in guiding treatment in 111 pregnant women with renal disease, we agree with others that this procedure can usually be postponed until pregnancy is completed ([Lindheimer and colleagues, 2000](#)). If therapy would be changed by biopsy results, then it should be considered.

ORTHOSTATIC PROTEINURIA. Abnormal amounts of protein are sometimes detectable in urine formed while the pregnant woman is ambulatory but not when recumbent. No other evidence for renal disease is apparent. Such orthostatic or *postural proteinuria* has been observed in up to 5 percent of normal young adults. The pregnant woman with orthostatic proteinuria should be evaluated for bacteriuria, abnormal urinary sediment, reduced glomerular filtration rate, and hypertension. In the absence of these abnormalities, especially if protein excretion is not constant, orthostatic proteinuria is probably inconsequential.

PREGNANCY AFTER UNILATERAL NEPHRECTOMY

Because the excretory capacity of two kidneys is much in excess of ordinary needs, and because the surviving kidney usually undergoes hypertrophy with increased excretory capacity, women with one normal kidney most often have no difficulty in pregnancy. Indeed, pregnancy in these women is associated with significant augmentation of renal hemodynamics ([Baylis and Davison, 1991](#)). Before advising a woman with one kidney about the risk of future pregnancy, a thorough functional evaluation of the remaining organ is essential.

URINARY TRACT INFECTIONS

These are the most common bacterial infections encountered during pregnancy. Although **asymptomatic bacteriuria** is usual, symptomatic infection may involve the lower tract to cause **cystitis**, or it may involve the renal calyces, pelvis, and parenchyma to cause **pyelonephritis**.

Organisms that cause urinary infections are those from the normal perineal flora. There is now evidence that some strains of *Escherichia coli* have pili that enhance their virulence ([Svanborg-Eden, 1982](#)). Also called *adhesins* or *P-fimbriae*, these appendages allow bacterial attachment to glycoprotein receptors on uro-epithelial cell membranes. Other markers for virulence include strains that produce hemolysin and have the papG gene that encodes the P-fimbriae tip adhesin ([Hooton and co-workers, 2000](#)). Although pregnancy itself does not seem to enhance these virulence factors, urinary stasis apparently does, and along with vesicoureteral reflux in some women, it predisposes to symptomatic upper urinary infections.

In the early puerperium, bladder sensitivity to intravesical fluid tension is often decreased as a consequence of the trauma of labor as well as epidural or spinal analgesia. Sensations of bladder distention are also likely diminished by discomfort caused by a large episiotomy, periurethral lacerations, or vaginal wall hematomas. Following delivery, especially when oxytocin infusion is stopped, diuresis follows with copious urine production and bladder distention. Overdistention, coupled with catheterization to provide relief, commonly leads to urinary infection.

ASYMPTOMATIC BACTERIURIA

This refers to persistent, actively multiplying bacteria within the urinary tract without symptoms. The reported prevalence of bacteriuria in nonpregnant women is 5 to 6 percent ([Hooton and colleagues, 2000](#)). The incidence during pregnancy varies from 2 to 7 percent, and depends on parity, race, and socioeconomic status. The highest incidence has been reported in African-American multiparas with sickle-cell trait, and the lowest incidence has been found in affluent white women of low parity.

Bacteriuria is typically present at the time of the first prenatal visit, and after an initial negative urine culture, 1 percent or less of women develop urinary infection ([Whalley, 1967](#)). A clean-voided specimen containing more than 100,000 organisms per mL is considered evidence for infection. Although smaller numbers of bacteria may represent contamination, lower colony counts may sometimes represent active infection, especially in the presence of symptoms. Thus, it seems prudent to treat lower concentrations, because pyelonephritis may occur with counts of only 20,000 to 50,000/mL of a single uropathogen ([Lucas and Cunningham, 1993](#)).

SIGNIFICANCE. If asymptomatic bacteriuria is not treated, about 25 percent of infected women subsequently develop acute symptomatic infection during that pregnancy. Eradication of bacteriuria with antimicrobial agents has been shown to prevent most of these clinically evident infections. Although it is reasonable to perform routine screening for bacteriuria in women at high risk, screening via urine culture may not be cost effective when the prevalence is low. Less expensive tests such as the leukocyte esterase-nitrite dipstick have been shown to be cost effective with prevalences of 2 percent ([Rouse and colleagues, 1995](#)). [Millar and associates \(2000\)](#) reported that screening using enzymatic detection of catalase activity in the urine was ineffective. Another approach for the low-risk population is to perform screening cultures selected by historical factors.

Covert bacteriuria has been associated in some studies with a number of adverse pregnancy outcomes. In early studies by [Kass \(1962\)](#), the incidence of preterm births and perinatal mortality was increased among bacteriuric women given placebo compared with treated 84 women. [Kincaid-Smith and Bullen \(1965\)](#) also reported

an increased incidence of low-birthweight infants among untreated bacteriuric women, but they were unable to reduce this with antimicrobial therapy. Other investigators did not corroborate a relationship between bacteriuria and low-birthweight infants ([Table 47-1](#)). From evidence currently available it seems unlikely that asymptomatic bacteriuria is a prominent factor in the genesis of low-birthweight or preterm infants.

In other studies, bacteriuria has been linked to an increased incidence of pregnancy hypertension and anemia. Using multivariate analysis for a perinatal registry cohort of 25,746 mother-infant pairs, [Schieve and colleagues \(1994\)](#) reported increased risks for low birthweight, preterm delivery, hypertension or preeclampsia, and maternal anemia. These findings are at variance with those shown in [Table 47-2](#). [Gilstrap and colleagues \(1981b\)](#) compared pregnancy outcomes in 248 pregnant woman in whom bacteriuria was localized to the bladder or kidney and found no association with anemia, hypertension, or low-birthweight infants.

Bacteriuria persists after delivery in many of these women, and there is also a significant number with pyelographic evidence of chronic infection, obstructive lesions, or congenital urinary abnormalities ([Kincaid-Smith and Bullen, 1965](#); [Whalley and associates, 1965](#)). Recurrent symptomatic infections are common.

TREATMENT. Women with asymptomatic bacteriuria may be given treatment with any of several antimicrobial regimens. Selection can be on the basis of in vitro susceptibilities, but most often it is empirical. Treatment for 10 days with nitrofurantoin macrocrystals, 100 mg daily, has proved effective in most women. Other regimens include ampicillin, amoxicillin, a cephalosporin, nitrofurantoin, or a sulfonamide given four times daily for 3 days ([Table 47-3](#)). Single-dose antimicrobial therapy for bacteriuria has also been used with success ([Andriole and Patterson, 1991](#)). The recurrence rate for all of these regimens is about 30 percent. Failure of single-dose regimens may be an indication of upper tract infection and the need for more protracted therapy such as nitrofurantoin, 100 mg at bedtime for 21 days ([Lucas and Cunningham, 1994](#)). For women with persistent or frequent bacteriuria recurrences, suppressive therapy for the remainder of pregnancy may be indicated. One regimen that has been successful is nitrofurantoin, 100 mg at bedtime.

CYSTITIS AND URETHRITIS

There is evidence that bladder infection during pregnancy develops without antecedent covert bacteriuria ([Harris and Gilstrap, 1981](#)). Typically, cystitis is characterized by dysuria, urgency, and frequency. There are few associated systemic findings. Usually there is pyuria as well as bacteriuria. Microscopic hematuria is common, and occasionally there is gross hematuria from hemorrhagic cystitis ([Fakhoury and co-workers, 1994](#)). Although asymptomatic infection is associated with renal bacteriuria in half of cases, more than 90 percent of the cases of cystitis are limited to the bladder ([Harris and Gilstrap, 1981](#)). Although cystitis is usually uncomplicated, the upper urinary tract may become involved by ascending infection. Certainly, 40 percent of pregnant women with acute pyelonephritis have preceding symptoms of lower-tract infection ([Gilstrap and associates, 1981a](#)).

TREATMENT. Women with cystitis respond readily to any of several regimens. [Harris and Gilstrap \(1981\)](#) reported a 97 percent cure rate with a 10-day ampicillin regimen. Sulfonamides, nitrofurantoin, or a cephalosporin also are effective when given for 10 days. Recently, as with covert bacteriuria, there has been a trend to use a 3-day course of therapy. The regimens summarized in [Table 47-3](#) will generally prove satisfactory for cystitis. Single-dose therapy as described for asymptomatic bacteriuria has been shown effective for both nonpregnant and pregnant women, but concomitant pyelonephritis must be confidently excluded.

Frequency, urgency, dysuria, and pyuria accompanied by a "sterile" urine culture may be the consequence of urethritis caused by *Chlamydia trachomatis*, a common pathogen of the genitourinary tract. Mucopurulent cervicitis usually coexists and erythromycin therapy is effective ([Chap. 57, p. 1493](#)).

ACUTE PYELONEPHRITIS

Renal infection is the most common serious medical complication of pregnancy, occurring in approximately 2 percent of pregnant women. The potential seriousness of acute pyelonephritis during pregnancy can be underscored by the observation of [Mabie and associates \(1997\)](#) that acute pyelonephritis was the leading cause of septic shock during pregnancy. The population incidence varies and depends on the prevalence of covert bacteriuria and whether it is treated. For example, at Parkland Hospital, more than 95 percent of women attend prenatal clinics where bacteriuria screening is performed and treatment given for the 8 percent who are infected. [Gratacos and associates \(1994\)](#) reported a significant reduction in the incidence of pyelonephritis after they instituted a screening program.

Renal infection is more common after midpregnancy. It is unilateral and right-sided in more than half of cases, and bilateral in a fourth. In most women, infection is caused by bacteria that ascend from the lower tract. Between 75 and 90 percent of renal infections are caused by bacteria that have P-fimbriae adhesins ([Stenqvist and associates, 1987](#)).

CLINICAL FINDINGS. The onset of pyelonephritis is usually rather abrupt. Symptoms include fever, shaking chills, and aching pain in one or both lumbar regions. There may be anorexia, nausea, and vomiting. The course of the disease may vary remarkably with fever to as high as 40°C or more and hypothermia to as low as 34°C. Tenderness usually can be elicited by percussion in one or both costovertebral angles. The urinary sediment frequently contains many leukocytes, frequently in clumps, and numerous bacteria. In a survey of 190 women admitted to Parkland Hospital, *E coli* was isolated from the urine in 77 percent, *Klebsiella pneumoniae* in 11 percent, and *Enterobacter* or *Proteus* each in 4 percent ([Cunningham, 1988](#)). Culture results were similar from 391 women with antepartum pyelonephritis treated at Los Angeles County-University of Southern California Medical Center ([Wing and colleagues, 2000](#)). **Importantly, about 15 percent of women with acute pyelonephritis also have bacteremia.**

Although the diagnosis usually is apparent, pyelonephritis may be mistaken for labor, chorioamnionitis, appendicitis, placental abruption, or infarcted myoma, and in the puerperium, for metritis with pelvic cellulitis.

Almost all clinical findings in these women are ultimately caused by endotoxemia, and so are the serious complications of acute pyelonephritis ([Chap. 43](#)). A frequent and sometimes dramatic finding is thermoregulatory instability characterized by high spiking fever as high as 42°C followed by hypothermia as low as 34°C ([Fig. 47-2](#)). [Twickler and associates \(1994\)](#) have shown a significantly decreased systemic vascular resistance and increased cardiac output in women with acute infection. These changes are mediated by *cytokines* elaborated by macrophages that include *interleukin-1*, previously termed *endogenous pyrogen*, or *tumor necrosis factor* ([Parrillo, 1993](#)).

Plasma creatinine should be measured early in the course of therapy. As shown in [Figure 47-3](#), acute pyelonephritis in some pregnant women causes a considerable reduction in the glomerular filtration rate that is reversible. From 1 to 2 percent of women with antepartum pyelonephritis develop varying degrees of respiratory insufficiency caused by endotoxin-induced alveolar injury and pulmonary edema ([Cunningham and associates, 1987](#); [Sanchez-Ramos and colleagues, 1995](#)). In some women, pulmonary injury is severe with resultant **acute respiratory distress syndrome**. Occasionally, tracheal intubation with mechanical ventilation is lifesaving ([Fig. 47-4](#)).

[Graham and associates \(1993\)](#) confirmed that institution of antimicrobial treatment in these women was followed by increased uterine activity. This likely is due to endotoxin release. [Towers and co-workers \(1991\)](#) reported that **8 percent of women with acute pyelonephritis who were given β -agonist tocolysis, developed respiratory insufficiency.** This is related to plasma colloid osmotic pressure decrease, alveolar capillary membrane injury, and sodium and fluid retaining properties of β -agonists ([Lamont, 2000](#)).

Endotoxin-induced **hemolysis** is also common, and about one third of these women develop acute anemia ([Cox and colleagues, 1991](#)). Recent evidence is indicative that acute pyelonephritis does not affect erythropoietin production either acutely or during the next several days of infection ([Cavenee and colleagues, 1994](#)).

MANAGEMENT. One scheme for management of the pregnant woman with acute pyelonephritis is shown in [Table 47-4](#). Although we routinely obtain cultures of urine and blood, [Wing and co-workers \(2000\)](#) have recently shown in prospective trials that they are of limited clinical utility. **Intravenous hydration to ensure adequate urinary output is essential.** Because bacteremia and endotoxemia are common, these women should be watched carefully to detect symptoms of endotoxin shock or its sequelae. Urinary output, blood pressure, and temperature are monitored closely. High fever should be treated, usually with a cooling blanket. Routine renal ultrasonography has not been shown to be useful and should be reserved for those women unresponsive to initial treatment ([Seidman and colleagues, 1998](#)).

These serious urinary infections usually respond quickly to intravenous hydration and antimicrobial therapy. The choice of drug is empirical, and ampicillin, plus gentamicin, cefazolin, or ceftriaxone have been shown to be 95 percent effective in randomized trials ([Wing and colleagues, 1998, 2000](#)). Ampicillin resistance of *E coli* has become common and only half of strains are sensitive in vitro to ampicillin, but most are sensitive to cefazolin ([Millar and Cox, 1997](#); [Wing and associates, 2000](#)). For these reasons, many clinicians prefer to give gentamicin or another aminoglycoside with ampicillin. Serial determinations of serum creatinine are important if nephrotoxic drugs are given. Finally, some prefer a cephalosporin or extended-spectrum penicillin, which have been shown to be effective in 95 percent of infected women ([Millar and Cox, 1997](#); [Sanchez-Ramos and associates, 1995](#)).

Clinical symptoms for the most part resolve during the first 2 days of therapy; but even though the symptoms promptly abate, many authors recommend therapy for a total of 7 to 10 days. Cultures of urine usually become sterile within the first 24 hours. Because changes in the urinary tract induced by pregnancy persist, reinfection is possible. If subsequent cultures of the urine are positive, we give nitrofurantoin, 100 mg at bedtime, for the remainder of pregnancy.

OUTPATIENT MANAGEMENT. [Wing and associates \(1999\)](#) described a randomized clinical trial in which they compared oral versus intravenous antimicrobial therapy for 92 highly selected women with antepartum pyelonephritis. They reported no significant differences in clinical responses or pregnancy outcomes between inpatients and outpatients. Importantly, two thirds of women were not considered candidates for outpatient therapy. Of those treated as outpatients, 30 percent were unable to adhere to their treatment regimen. All women in this trial received in-hospital intramuscular ceftriaxone, two 1-g doses 24 hours apart, before those randomized to early discharge were permitted to leave the hospital. Studies such as this suggest that outpatient management of pregnant women with acute pyelonephritis is applicable to very few women and it mandates close evaluation both before and after hospital discharge.

MANAGEMENT OF NONRESPONDERS. Almost 95 percent of pregnant women will be afebrile by 72 hours ([Cunningham and associates, 1973](#); [Wing and colleagues, 2000](#)). If clinical improvement is not obvious by 48 to 72 hours, then the woman should be evaluated for urinary tract obstruction. A search is made for abnormal ureteral or pyelocaliceal distention. Most women with continuing infection and serious sequelae will have no evidence for obstruction, but some are found to have obstruction from calculi. Many investigators prefer renal sonography to detect underlying lesions, but its sensitivity is decreased in pregnancy and stones may not be visualized ([Butler and associates, 2000](#); [Maikranz and colleagues, 1987](#)). Pyelocaliceal dilatation, urinary calculi, and possibly an intrarenal or perinephric abscess or phlegmon may be visualized ([Cox and Cunningham, 1988](#)). Sonar is not always successful in localizing these lesions; thus a negative examination should not prompt cessation of the workup in a woman with continuing urosepsis.

In some cases, a plain abdominal radiograph is indicated, because nearly 90 percent of renal stones are radiopaque. Possible benefits far outweigh any minimal fetal risk from radiation. If negative, then intravenous pyelography, modified to limit the number of radiographs taken after contrast injection, is recommended. The "one-shot pyelogram," in which a single radiograph is obtained 30 minutes after contrast injection, usually provides adequate imaging of the collecting system so that stones or structural anomalies can be detected ([Butler and colleagues, 2000](#)).

Passage of a double-J ureteral stent will relieve the obstruction in most cases ([Rodriguez and Klein, 1988](#)). If unsuccessful, then percutaneous nephrostomy is done. If this fails, surgical removal of renal stones is required for resolution of infection. Retrograde pyelography may disclose an end-stage obstructed kidney with pyonephrosis as a cause of continuing sepsis. In these cases, calculi frequently coexist, and nephrectomy may be lifesaving.

FOLLOW-UP. Recurrent infection, both covert and symptomatic, is common and can be demonstrated in 30 to 40 percent of women following completion of treatment for pyelonephritis ([Cunningham and associates, 1973](#)). Unless measures are taken to ensure urine sterility, then nitrofurantoin, 100 mg at bedtime, is given for the remainder of the pregnancy. [Van Dorsten and co-workers \(1987\)](#) reported that this regimen reduces recurrence of bacteriuria to 8 percent.

CHRONIC PYELONEPHRITIS

This disease is chronic interstitial nephritis thought to be caused by bacterial infection. In many cases, classical radiological scarring is accompanied by ureteral reflux with voiding; thus the term **reflux nephropathy**. Chronic infection is frequently not symptomatic, and in advanced cases, symptoms are those of renal insufficiency. Fewer than half of women with chronic pyelonephritis have a clear history of preceding cystitis, acute pyelonephritis, or obstructive disease. The pathogenesis of this disease therefore is obscure, but it is doubtful that it is simply from persistent bacterial infection. Certainly, very few individuals with recurrent clinical episodes of urinary infections develop chronic infections or progressive renal involvement.

Maternal and fetal prognosis depends on the extent of renal destruction. [El-Khatib and colleagues \(1994\)](#) and [Jungers and colleagues \(1996\)](#) reported outcomes in 697 pregnancies in 290 women with reflux nephropathy. Impaired renal function and bilateral renal scarring were associated with increased maternal complications. When chronic pyelonephritis or any other chronic renal lesion is complicated by bacteriuria during pregnancy, there is an associated risk of superimposed acute pyelonephritis, which may lead to further deterioration. [Martinell and colleagues \(1990\)](#) found that almost half of women with renal scarring following childhood urinary infection had bacteriuria when pregnant. Renal injury as a consequence of chronic urinary tract infection beginning in childhood is much less common than it was early in the 20th century, probably as a result of improved health care ([Hellerstein, 1999](#)).

NEPHROLITHIASIS

Urinary stones are more common in men than women, and their average age of onset is in the third decade. Calcium salts make up about 80 percent of renal stones, and in half of these, idiopathic hypercalciuria is the most common predisposing cause ([Asplin and colleagues, 1998](#)). Hyperparathyroidism should be excluded. Familial occurrence is frequent, and patients with a previous stone form another stone every 2 to 3 years. Struvite stones are associated with infection, and often *Proteus* is cultured from the urine. Uric acid stones are even less common. Stones of the calcium oxalate variety are the most common encountered during pregnancy ([Maikranz and colleagues, 1994](#)).

Patients with calcium stones caused by hypercalciuria frequently respond to thiazide diuretics, with diminished stone formation. Patients with stone disease should be advised to keep well hydrated. In general, obstruction, infection, intractable pain, or heavy bleeding are indications for stone removal. Placing a flexible basket via cystoscopy to ensnare the calculus has been used with the greatest frequency, and this method is reasonable for use in pregnant women. **Lithotripsy** has replaced surgical therapy in many cases. This can be employed by extracorporeal means, percutaneous ultrasonic lithotripsy, or by ureteroscopic laser ablation of stones. Understandably, there is little information concerning its use during pregnancy.

STONE DISEASE DURING PREGNANCY

Because of their predilection for men and older patients, renal and ureteral lithiasis are relatively uncommon complications of pregnancy. From their review of 14 series, [Hendricks and co-workers \(1991\)](#) cite an incidence of about 1 per 2000 pregnancies. [Butler and colleagues \(2000\)](#) found a 1 per 3300 incidence in over 186,000 deliveries at Parkland Hospital. Presumably, pregnant women have fewer symptoms when they pass stones because of urinary tract dilatation ([Hendricks and colleagues, 1991](#)). These were not our findings in 73 episodes of nephrolithiasis in 57 pregnant women in whom the most common presenting symptom in 90 percent was pain. Most of these had flank pain, and only 23 percent had gross hematuria ([Butler and co-workers, 2000](#)).

Although women who have formed renal stones previously are at risk of doing so again, [Maikranz and associates \(1994\)](#) found no evidence that pregnancy increased this risk. Moreover, stone disease does not appear to have any adverse effects on pregnancy outcome except for an increased frequency of urinary infections. **Although urinary calculi seldom cause severe symptomatic obstruction during pregnancy, persistent pyelonephritis despite adequate antimicrobial therapy should prompt a search for renal obstruction, which most frequently is due to nephrolithiasis.**

DIAGNOSIS AND MANAGEMENT. Sonography may be helpful to confirm a suspected renal stone, but pregnancy hydronephrosis may obscure these findings ([Fig. 47-5](#)). [Butler and colleagues \(2000\)](#) reported that 21 of 35 (60 percent) renal sonograms done initially were positive in pregnant women with stone disease. If there is abnormal dilatation without stone visualization, then x-rays may be useful to identify stones. We prefer the one-shot pyelogram. Transabdominal color Doppler ultrasonography to detect absence of ureteral "jets" into the bladder has been suggested in the workup of suspected urolithiasis in pregnant women ([Asrat and colleagues, 1998](#)).

Treatment depends on the symptoms and the duration of pregnancy. Intravenous hydration and analgesics are always given. Almost half of pregnant women with symptomatic stones have associated infection which is treated vigorously. In 75 percent of the cases, there is improvement with conservative therapy and the stone usually passes spontaneously. The other 25 percent will need an invasive procedure such as ureteral stenting, percutaneous nephrostomy, laser lithotripsy, basket extraction, or occasionally surgical exploration ([Butler and colleagues, 2000](#); [Maikranz and colleagues, 1994](#)). [Carlan and associates \(1995\)](#) and [Scarpa and colleagues \(1996\)](#) used transurethral laser in seven pregnant women and a ballistic lithotripter in another two women to fragment stones.

GLOMERULOPATHIES

The kidney, especially the glomerulus and its capillaries, is subject to a large number and variety of acute and chronic diseases. They may result from a single stimulus such as poststreptococcal glomerulonephritis, or from a multisystem disease such as systemic lupus erythematosus. According to [Brady and colleagues, \(1998\)](#), there are five major clinical glomerulopathic syndromes: acute rapidly progressive glomerulonephritis, nephrotic syndrome, asymptomatic abnormalities of the urinary sediment, and chronic glomerulonephritis. The majority of these diseases are encountered in young women of childbearing age, and thus they may complicate pregnancy. Many of these disorders first become apparent because of chronic renal insufficiency.

ACUTE GLOMERULONEPHRITIS

This disorder may result from any of several causes, including those following infectious diseases, multisystem diseases, or primary disorders unique to the glomerulus (Table 47-5). All are characterized by an abrupt onset of hematuria and proteinuria accompanied by varying degrees of renal insufficiency and salt and water retention causing edema, hypertension, and circulatory congestion.

Acute poststreptococcal glomerulonephritis is prototypical of these syndromes and is of obstetrical interest because it was confused with the renal involvement of eclampsia up until the mid-19th century. Lever (1843) discovered then that the proteinuria of eclampsia was different from that due to "Brights disease" because it disappeared after delivery (Purkerson and Vekerdy, 1999).

Although poststreptococcal glomerulonephritis rarely develops acutely during pregnancy, its management is similar to acute glomerulonephritis from any cause. If it arises during the second half of pregnancy, in most cases it is clinically indistinguishable from preeclampsia. There are insufficient data to predict fetal or maternal prognosis. The prognosis and treatment of the other causes of acute glomerulonephritis listed in Table 47-5 depend on their etiology. Renal biopsy may be necessary in determining etiology as well as to direct management (Lindheimer and Cunningham, 1994). For example, Yankowitz and colleagues (1992) reported successful management of a pregnancy complicated by *Goodpasture syndrome*, characterized by autoantibodies to basement membrane antigens, pulmonary hemorrhage, and glomerulonephritis.

Women with a history of poststreptococcal glomerulonephritis that has healed may undergo additional pregnancies without any appreciable increase in the incidence of complications. Some patients with acute glomerulonephritis never completely recover, and **rapidly progressive glomerulonephritis** leads to end-stage renal failure. Up to half of adults with sporadic poststreptococcal disease develop **chronic glomerulonephritis** with slowly progressive renal disease.

EFFECT OF GLOMERULONEPHRITIS ON PREGNANCY. Most cases of glomerulonephritis are not caused by poststreptococcal infection. In some cases, the underlying etiology is not found. Whatever the cause, glomerulonephritis has a profound effect on pregnancy outcome. Packham and colleagues (1989) reported the results of 395 pregnancies in 238 women who had been previously diagnosed with *primary* glomerulonephritis. The most common lesions on biopsy were membranous glomerulonephritis, IgA glomerulonephritis, and diffuse mesangial glomerulonephritis. Most of these women had normal renal function before becoming pregnant. The overall fetal loss was 26 percent; the perinatal mortality rate after 28 weeks was 80 per 1000. One fourth were delivered preterm, and 15 percent of fetuses were growth restricted. Overall, about half of these women developed hypertension; one quarter did so before 32 weeks, and it was severe in three fourths that did. Proteinuria worsened in 60 percent of these women. Factors that portended the worst perinatal prognosis included impaired renal function, early or severe hypertension, and nephrotic-range proteinuria.

RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

In some cases, acute glomerulonephritis does not resolve, and rapidly progressive glomerulonephritis progresses to end-stage renal failure within weeks to months. Patients with this form of disease may have a positive test for antineutrophil cytoplasmic antibody (ANCA) and demonstrate extensive extracapillary crescents within the glomerulus on renal biopsy (Lindheimer and Cunningham, 1994). Because extensive extracapillary or **crescentic glomerulonephritis** is commonly identified, the two terms are often used interchangeably. Common causes of rapidly progressive disease are the same as those listed in Table 47-5. About 45 percent of cases are caused by immune-complex disease, 45 percent by pauci-immune glomerulonephritis, and 10 percent by antiglomerular basement membrane disease.

CHRONIC GLOMERULONEPHRITIS

In many cases the cause is unknown, but it may follow any of the primary lesions shown in Table 47-5. Chronic glomerulonephritis is characterized by progressive renal destruction over a period of years or decades, eventually producing the **end-stage kidney**. Usually, persistent proteinuria and hematuria accompany a gradual decline in renal function. Microscopically, the renal lesions are categorized as proliferative, sclerosing, or membranous.

According to Brady and associates (1998), chronic glomerulopathies may be detected in any of several ways:

1. Proteinuria or abnormal urinary sediment are detected by screening.
2. Routine blood screening shows anemia or elevated creatinine.
3. Bilaterally small kidneys are discovered on imaging.
4. During the course of evaluation for chronic hypertension.
5. If it exacerbates.

In some cases, women with symptoms and signs of preeclampsia-eclampsia, but without resolution postpartum, are found to have chronic glomerulonephritis.

The evolution, management, and prognosis of chronic glomerulonephritis depends on its etiology. In some patients, 10 to 20 years may elapse before end-stage renal failure supervenes. Renal biopsy may be helpful to establish prognosis.

NEPHROTIC SYNDROME

The nephrotic syndrome, or **nephrosis**, is a spectrum of renal disorders of many causes. Some of these are shown in Table 47-6, and the overlap with causes of acute glomerulonephritis in Table 47-5 is obvious. Nephrotic syndrome is characterized by proteinuria in excess of 3 g/day, hypoalbuminemia, hyperlipidemia, and edema. Most patients have microscopic renal abnormalities and may have accompanying evidence for renal dysfunction. The defects in the barriers of the glomerular capillary wall that allow excessive filtration of plasma proteins are caused by primary glomerular disease, or they may follow immunological or toxic injury or metabolic (diabetes) or vascular diseases.

Management of the nephrotic syndrome depends on its etiology. Edema is managed cautiously, especially during pregnancy. Jakobi and associates (1995) have described problems associated with massive vulvar edema that may complicate the nephrotic syndrome (Fig. 47-6). Dietary protein of high biological value is encouraged; however, high-protein diets only increase proteinuria. Thromboembolism occurs with some frequency, and includes arterial as well as venous thromboses. Renal vein thrombosis is particularly worrisome. The value, if any, of prophylactic anticoagulation is unclear. Some cases of nephrosis from primary glomerular disease will respond to corticosteroid or cytotoxic drug therapy. In most of those cases caused by infection or drugs, proteinuria recedes when the underlying cause is corrected.

NEPHROTIC SYNDROME COMPLICATING PREGNANCY. When the nephrotic syndrome complicates pregnancy, the maternal and fetal prognosis, as well as the appropriate treatment, depend on the underlying cause of the disease and the extent of renal insufficiency. Whenever possible, the specific cause should be ascertained and renal function assessed. In this regard, when the cause is not apparent, percutaneous renal biopsy may be of value.

Chronic proteinuria usually increases during pregnancy. Katz and associates (1980) observed that nearly half of women with chronic renal disease either developed proteinuria, or it worsened. In two thirds of their patients, as well as a similar number described by Stettler and Cunningham (1992), protein excretion exceeded 3 g/day. Similarly, Packham and colleagues (1989) reported that 60 percent of women with one of the primary glomerulopathies had increased proteinuria during pregnancy. Despite this, women without appreciably diminished renal function will usually have some augmentation of renal function (Cunningham and colleagues, 1990).

A review of reported cases of nephrosis indicates that the majority of women who are not hypertensive and do not have severe renal insufficiency will usually have a successful pregnancy outcome, particularly since glucocorticoids have been available. In other cases, however, in which there is evidence for renal insufficiency, moderate to severe hypertension, or both, the prognosis for mother and fetus is poor. Our experiences from Parkland Hospital with women who had proteinuria antecedent to pregnancy indicate that it is not a benign association (Stettler and Cunningham, 1992). Protein excretion in 65 pregnancies averaged 4 g/day, and a third of these women had classical nephrotic syndrome. Some degree of renal insufficiency was found in 75 percent of the women, 40 percent had chronic hypertension, and 25 percent had persistent anemia. Importantly, preeclampsia developed in 60 percent, and 45 percent of infants were delivered preterm. When

abortions were excluded, however, 53 of 57 infants were born alive. In all 21 women who subsequently underwent renal biopsy, histological evidence of renal disease was found. Long-term follow-up indicated that at least 20 percent of women had progressed to end-stage renal disease, requiring dialysis or transplantation. [Hemmelder and associates \(1995\)](#) provided data that disease is accelerated during pregnancy in women with substantive proteinuria.

POLYCYSTIC KIDNEY DISEASE

In the adult this is an autosomally dominant disease linked to the alpha-hemoglobin gene complex and the phosphoglycerate kinase genes on the short arm of chromosome 16. The condition is genetically heterogeneous, and prenatal diagnosis is now available. The disease is found in 1 in 500 autopsies, accounts for 1 in 3000 hospital admissions, and causes 10 percent of all end-stage renal disease.

Symptoms usually appear in the third or fourth decade. Flank pain, hematuria, nocturia, proteinuria, and associated calculi and infection are common findings. Hypertension develops in three fourths of patients, and progression to end-stage renal disease is a major problem. Superimposed acute renal failure results from infection or obstruction from ureteral angulation by cyst displacement.

Asymptomatic **hepatic cysts** coexist in 30 percent of patients with polycystic kidneys. [Hossack and colleagues \(1988\)](#) studied 163 nonpregnant patients and reported substantively increased **cardiac valvar lesions** detected by echocardiography. The incidence of **mitral valve prolapse** was increased 13-fold over that of the control group, and there was excessive mitral, aortic, and tricuspid incompetence. Importantly, about 10 percent of patients die from an associated **intracranial berry aneurysm**.

POLYCYSTIC KIDNEY DISEASE AND PREGNANCY

As with most chronic renal diseases, pregnancy outcome in women with polycystic kidney disease will depend on the degree of associated hypertension and renal insufficiency. Upper urinary tract infections are common. An in-depth study of the apparent effects of this disease on pregnancy and vice versa was provided by [Chapman and co-workers \(1994\)](#). A total of 235 affected women had 605 pregnancies. Pregnancy outcomes were compared with 108 unaffected family members during 244 pregnancies. Overall perinatal complication rates were similar (33 versus 26 percent), but hypertension, including preeclampsia, was more common in the affected women. Perinatal complications were more common in affected women who were over 30 years of age, and in those who developed preeclampsia. Pregnancy does not seem to accelerate the natural disease course ([Lindheimer and colleagues, 2000](#)).

CHRONIC RENAL DISEASE

A number of kidney diseases listed in [Tables 47-5](#) and [47-6](#) may become chronic. When counseling the woman with chronic renal disease regarding fertility and the risk of a complicated pregnancy, it is important to determine the degree of functional impairment and the presence or absence of hypertension. The prognosis for a successful pregnancy outcome in general is not related to the underlying disorder. Some projection of pregnancy prognosis can be made by arbitrarily considering patients in one of three categories of functional impairment ([Lindheimer and associates, 2000](#)). These include those women with normal or *mild impairment* of renal function, defined by serum creatinine of less than 1.5 mg/dL and minimal hypertension; *moderate impairment* of renal function, defined as a serum creatinine of 1.5 to 3.0 mg/dL; and *severe renal insufficiency*, defined as a serum creatinine of greater than 3.0 mg/dL.

According to [Lazarus and Brenner \(1998\)](#), from 1982 through 1991, the most common causes of end-stage renal disease were diabetes and hypertension. Glomerulonephritis was the third most common. In many cases of chronic renal disease, biopsy will be necessary to determine the underlying cause. In some cases, this is done before pregnancy. [Packham and Fairley \(1987\)](#) performed 111 percutaneous biopsies in 104 pregnant women before the third trimester and reported a 5 percent complication rate. [Lindheimer and colleagues \(2000\)](#) believe that biopsy is usually best reserved until after pregnancy, unless it is perceived that biopsy results will significantly alter the management of renal disease.

PREGNANCY COMPLICATED BY CHRONIC RENAL DISEASE

Most women with chronic renal disease complicating pregnancy have reasonably normal renal function. Importantly, preexisting hypertension along with the degree of renal insufficiency are predictive of pregnancy outcome. **However, in women with chronic renal disease, even if renal function is normal and the woman normotensive, pregnancy outcome is still not always good.** Despite the high incidence of hypertension and preeclampsia, preterm and growth-restricted infants, and other problems, the National High Blood Pressure Education Working Group (2000) concluded that the prognosis has substantively improved.

PHYSIOLOGICAL CHANGES. In women with mild renal insufficiency, pregnancy is usually accompanied by a rise in renal plasma flow and glomerular filtration rate ([Katz and colleagues, 1980](#)). These changes are thought to be induced by renal vasodilation, and because this already is maximal with advanced renal disease, they are less evident in women with more severe renal dysfunction. In pregnant women studied at Parkland Hospital, only half of those with moderate renal insufficiency demonstrated augmented glomerular filtration rate ([Cunningham and colleagues, 1990](#)). None of those with severe disease showed augmentation of renal function.

Nonpregnant women with chronic renal insufficiency have normal blood volumes. During pregnancy, blood volume expansion is dependent on the severity of their disease, and it is proportional to the serum creatinine ([Fig. 47-7](#)). In women with mild to moderate dysfunction, there is normal pregnancy-induced hypervolemia that averages 50 percent ([Cunningham and associates, 1990](#)). However, in women with severe renal insufficiency, volume expansion is attenuated, and averages only about 25 percent. Finally, although there is some degree of pregnancy-induced erythropoiesis in these women, it is not proportional to the plasma volume increase; thus, preexisting anemia is intensified.

PREGNANCY AND CHRONIC RENAL DISEASE WITH PRESERVED FUNCTION. There are a number of studies that allow an estimation of risk of pregnancy for the woman with chronic renal disease. [Katz and associates \(1980\)](#) reviewed pregnancy outcomes in 89 women who had chronic renal disease but generally good renal function. Excluding abortions, of 121 pregnancies, perinatal mortality was 11 percent, 20 percent of infants were delivered preterm, and 24 percent were growth restricted. Importantly, superimposed preeclampsia was common and abruptio placentae developed in three instances. [Surian and colleagues \(1984\)](#) described the clinical course of 123 pregnancies in 86 women with biopsy-proven glomerular disease. Only a few of these women had renal dysfunction. In 40 percent there were obstetrical or renal complications, or both. Hypertension developed in 20 percent, and it persisted in half of these postpartum. In 8 percent of the women, renal function deteriorated, and this persisted in one half.

[Packham and co-workers \(1989\)](#), in a study cited previously, described their large experience from Melbourne with 238 women and 395 pregnancies complicated by preexisting primary glomerulonephritis. Only a few had preexisting renal insufficiency. All had undergone biopsy, and diffuse mesangial proliferative disease and IgA nephritis comprised 70 percent of the lesions. During pregnancy, 15 percent of these women had impaired renal function and 60 percent had worsening proteinuria. Although only 12 percent had hypertension antedating pregnancy, over half became hypertensive during pregnancy. Hypertension before 20 weeks complicated 25 percent of these pregnancies, and 20 percent of all pregnancies had severe hypertension. About 5 percent developed irreversible worsening of renal function during pregnancy. The overall fetal loss was 26 percent. The overall perinatal mortality rate was 140 per 1000, and after 28 weeks, it was 80 per 1000. Factors associated with increased perinatal mortality and preterm delivery were impaired renal function, early or severe hypertension, and nephrotic-range proteinuria. In their absence, perinatal mortality was still 50 per 1000.

Other retrospective studies from Japan ([Abe, 1991](#)) and France ([Jungers and colleagues, 1991](#)) of large numbers of pregnancies in women with chronic primary glomerulonephritis substantiate these conclusions.

PREGNANCY WITH CHRONIC RENAL INSUFFICIENCY. [Hou and colleagues \(1985\)](#) described the outcomes of 25 pregnancies in 23 women studied because of moderate renal insufficiency defined by baseline serum creatinine ranging from 1.2 to 1.7 mg/dL. Pregnancy-induced or aggravated hypertension developed in slightly more than half of these women, and because of this nearly 60 percent were delivered preterm.

[Cunningham and associates \(1990\)](#) described the outcomes of 25 pregnancies in 23 women studied because of moderate renal insufficiency defined by baseline serum creatinine ranging from 1.2 to 1.7 mg/dL. Pregnancy-induced or aggravated hypertension developed in slightly more than half of these women, and because of this nearly 60 percent were delivered preterm. They also reported their experience with 37 pregnancies complicated by moderate (serum creatinine 1.4 to 2.5 mg/dL) or severe (serum creatinine greater than 2.5 mg/dL) renal insufficiency. Common complications in these women included chronic hypertension (70 percent), anemia (75 percent), preeclampsia (60 percent), preterm delivery (35 percent), and fetal growth restriction (30 percent). Perinatal outcome was surprisingly good, and of 31 pregnancies reaching 26 weeks, 30 resulted in live-born infants and all survived. Birthweight correlated inversely with serum creatinine concentration.

[Jones and Hayslett \(1996\)](#) described similar outcomes in 82 pregnancies in 67 women with moderate to severe chronic renal insufficiency. Hypertension complicated

half of the pregnancies and 40 percent developed nephrotic-range proteinuria. Although 93 percent of the infants survived, 60 percent were preterm and 37 percent were growth restricted. [Davison and Lindheimer \(1999\)](#) have summarized perinatal outcomes in over 4100 pregnancies in more than 3000 women from 1954 to 1997. These women had mild, moderate, or severe renal insufficiency. Although the rate of preterm delivery remained high, there was a marked improvement in perinatal mortality over the five decades ([Table 47-7](#)).

MANAGEMENT. Women with chronic renal disease should have frequent prenatal visits to determine blood pressure. Serial measurements, the intervals determined by severity of findings, are done to estimate renal function, and protein excretion is monitored if indicated. Women should be screened and treated for bacteriuria to decrease the risk of pyelonephritis. Although protein-restricted diets are prescribed for nonpregnant patients with chronic renal disease, these are not recommended during pregnancy ([Lindheimer and colleagues, 2000](#)). Anemia associated with chronic renal insufficiency responds to recombinant erythropoietin given subcutaneously; however, hypertension is a well-documented side effect ([Chap. 49](#)). The appearance of hypertension is managed as described in [Chapter 24](#), and suspected fetal growth restriction as in [Chapter 29](#).

Except for an increased risk of hypertension and superimposed preeclampsia, women with relatively normal renal function and no hypertension before pregnancy usually have a relatively normal pregnancy. As renal impairment worsens, so does the likelihood of pregnancy complications. At least half of women with renal insufficiency will develop hypertension. Worsening of hypertension or superimposed preeclampsia develops in 80 percent of those with moderate insufficiency and 86 percent who have severe disease ([Cunningham and co-workers, 1990](#); [Packham and associates, 1989](#)).

FOLLOW-UP. A long-standing unresolved issue is whether pregnancy accelerates chronic renal insufficiency. [Jungers and associates \(1995\)](#) found no adverse effect of pregnancy on actuarial survival in 360 women with chronic glomerulonephritis. Conversely, [Abe \(1991\)](#) concluded that pregnancy may accelerate antecedent disease in women with moderate dysfunction. It seems reasonable to conclude that, at least in most women, **in the absence of superimposed preeclampsia or severe placental abruption**, pregnancy does not appreciably accelerate deterioration in renal function. Importantly, because of the inevitable likelihood of long-term progression of the chronic disease, the ultimate maternal prognosis is guarded. In the study by [Cunningham and associates \(1990\)](#), at least 20 percent of women with moderate to severe disease had developed end-stage renal failure by a mean of 4 years. Similarly, [Stettler and Cunningham \(1992\)](#) reported that at least 20 percent of women with chronic proteinuria discovered during pregnancy had progressed to end-stage renal failure when followed for several years.

PREGNANCY AFTER RENAL TRANSPLANTATION

Between 1988 and 1996, almost 94,000 renal transplantations were performed in the United States ([Hariharan and co-workers, 2000](#)). The half-life for grafts from living donors is now 36 years and that for cadaveric grafts is 20 years. These survival rates approximately doubled between 1988 and 1996, due in large part to the introduction of cyclosporine for the prevention of acute and chronic rejection and the introduction of muromonab-CD3 (OKT3 monoclonal antibody) for the treatment of acute rejection. In recent years, use of newer immunosuppressive drugs such as mycophenolate mofetil and tacrolimus has been associated with further reduction in the incidence of acute rejection episodes, although experience with these newer drugs is very limited ([Hou, 1999](#)). Importantly, resumption of renal function after transplantation promptly restores fertility to reproductive-age women.

[Davison \(1994\)](#) reviewed the outcomes in 3382 pregnancies in 2409 women, 80 percent of whom had had cadaveric transplants. Most were treated with azathioprine and prednisone. The incidence of spontaneous and therapeutic abortion was 35 percent. Of pregnancies that continued beyond the first trimester, over 90 percent had a successful outcome. Beginning early in pregnancy, the glomerular filtration rate in these women usually increased in proportion to that seen in normal women. Although proteinuria developed in 40 percent of these women, it was not significant in the absence of hypertension.

In pregnancies reviewed by [Davison \(1994\)](#), preeclampsia developed in 30 percent and signs of kidney rejection were observed in about 10 percent. Without renal biopsy, however, rejection may be difficult to distinguish from acute pyelonephritis, recurrent glomerulopathy, or severe preeclampsia. Serious infections, most likely related to immunosuppressive therapy, complicated some pregnancies. Urinary infections were diagnosed in 40 percent and the incidence of viral infections was increased. Prematurely ruptured membranes and preterm labor were common, and about half of live-born infants were delivered preterm. Fetal growth restriction averaged 20 percent. Fortunately, although respiratory distress syndrome was common among the preterm infants, it was seldom fatal. Fetal malformations were not increased. The newborns, as well as the mothers, were at increased risk of infection because of maternal immunosuppressive therapy.

[Armenti and colleagues \(1998\)](#), in observations from the National Transplantation Pregnancy Registry (NTPR), reported an excess of preterm and low-birthweight infants, as well as hypertension and cesarean deliveries, although fetal outcomes were generally satisfactory. From these experiences, Davison and [Lindheimer \(2000\)](#) recommend that these women satisfy a number of requisites before attempting pregnancy:

1. They should be in good general health without severe hypertension for at least 2 years after transplantation, because graft rejection is more common during this period.
2. There should be stable renal function without severe renal insufficiency and no evidence of graft rejection or persistent proteinuria.
3. Drug therapy is reduced to maintenance levels; that is, prednisone dosage of 15 mg/day or less; azathioprine at 2 mg/kg/day or less; and cyclosporine at 5 mg/kg/day or less.

Cyclosporine, now given routinely to renal transplantation recipients, decreases glomerular filtration rate and also may cause hypertension. In nonpregnant patients, cyclosporine may be associated with loss of renal function, hyperkalemia, hyperuricemia, hypertension, and rarely, a hemolytic uremic-type syndrome ([Lindheimer and Cunningham, 1994](#)). [Thomas and associates \(1997\)](#) reported that cyclosporine blood levels declined during pregnancy, although this was not associated with rejection episodes. Concern persists over the possibility of late effects in offspring subjected to immunosuppressive therapy in utero. These include malignancy, germ cell dysfunction, and malformations in the offspring's children.

Finally, although pregnancy-induced renal hyperfiltration theoretically may impair long-term graft survival, [Sturgiss and Davison \(1995\)](#) found no evidence for this in a case-controlled study of 34 allograft recipients followed for a mean of 15 years.

MANAGEMENT. Close surveillance is necessary. Covert bacteriuria must be treated, and if recurrent, suppressive treatment for the remainder of pregnancy is given. Serial serum hepatic enzyme concentrations and blood counts are monitored for toxic effects of azathioprine and cyclosporine. Gestational diabetes is more common if corticosteroids are taken and glucose tolerance testing is done at about 26 weeks. Overt diabetes must be excluded.

Renal function is monitored, at first with serum creatinine determinations, but if abnormal, determination of glomerular filtration rate is preferable. According to [Davison and Lindheimer \(1999\)](#), a decline of less than 30 percent in the glomerular filtration rate during the third trimester is normal. If a significant decline is detected, then its cause must be determined. Possibilities include acute rejection, cyclosporine toxicity, preeclampsia, and urinary tract obstruction. Imaging studies and possibly kidney biopsy may be indicated.

Throughout pregnancy, the woman is carefully monitored for development or worsening of underlying hypertension, and especially superimposed preeclampsia. Management of hypertension during pregnancy is the same as for nontransplanted patients. The kidney dilates minimally to moderately as do normal kidneys ([Levine and colleagues, 1995](#)). Evidence for graft infection or rejection should prompt admission for aggressive management. Because of the significantly increased incidences of fetal growth restriction and preterm delivery, vigilant fetal surveillance is indicated ([Chap. 40](#)). Although cesarean delivery is reserved for obstetrical indications, occasionally the transplanted kidney will obstruct labor. The cesarean delivery rate approaches 50 percent ([Armenti and co-workers, 1999](#)).

DIALYSIS DURING PREGNANCY

Most often, significantly impaired renal function is accompanied by infertility. With chronic hemodialysis or peritoneal dialysis, however, fertility may be restored. [Okundaye and associates \(1998\)](#) surveyed dialysis units listed by the Health Care Financing Administration to determine the frequency and course of pregnancies in women receiving dialysis between 1992 and 1995. Approximately 40 percent of the units responded, and 241 women were identified who conceived either after starting or during dialysis. Hemodialysis was used in approximately 60 percent of these women and the remainder received peritoneal dialysis. Almost 80 percent of the women had some degree of hypertension, and it was severe in 13 percent. Over 95 percent of the women were anemic, defined as a hematocrit less than 30 percent. There were 11 infants with congenital malformations. Pregnancy outcomes are shown in [Table 47-8](#). Early pregnancy losses and preterm births were common. Infant survival appeared to be worse in women who conceived after starting dialysis (40 percent) compared with those who commenced dialysis during an already established pregnancy (74 percent). These investigators, as well as [Bagon and colleagues \(1998\)](#), suggest that increased dialysis time may improve pregnancy outcome. The type of dialysis—hemodialysis versus peritoneal—did not appear to significantly influence pregnancy outcome.

ACUTE RENAL FAILURE

The incidence of renal failure associated with pregnancy has decreased substantively over the past 30 years. [Nzerue and colleagues \(1998\)](#) identified 21 cases of acute renal failure in pregnancy at Grady Memorial Hospital between 1986 and 1996. The incidence was 2 per 10,000 women delivered. Diseases and conditions associated with renal failure are shown in [Table 47-9](#). Preeclampsia-eclampsia was the most common associated condition and was diagnosed in 38 percent of the women. Maternal mortality was 16 percent and maternal morbidity was common. The latter included end-stage kidney disease, seizures, hyponatremia, disseminated intravascular coagulation, and pulmonary edema. The stillbirth rate was 38 percent and a third of live-born infants were delivered preterm.

Data from the Renal Unit in Leeds, England, underscore the changing indications for dialysis for acute renal failure in obstetrical patients ([Turney and colleagues, 1989](#)). Whereas in earlier years obstetrical cases comprised 35 percent of patients requiring dialysis, more recently they accounted for only 10 percent. Almost all of the 142 obstetrical cases were contributed to or caused by abortion (25 percent), hemorrhage (35 percent), or preeclampsia (50 percent). The immediate mortality rate with acute renal failure was 20 percent. Importantly, after legalization of abortion in England in 1968, cases of obstetrical acute renal failure decreased by 30 percent.

[Sibai and associates \(1990\)](#) reported experiences from the University of Tennessee in 31 women with acute renal failure complicating hypertensive disorders of pregnancy. While 18 had "pure" preeclampsia, the remainder had antecedent chronic hypertension, parenchymal renal disease, or both. Half required dialysis, and three of these women died as a direct result of renal failure. About half of the women had suffered placental abruption and almost 90 percent had postpartum hemorrhage. [Frangieh and co-workers \(1996\)](#) reported that 3.8 percent of eclamptic women from the same institution had acute renal failure. This same group also reported that 3 percent of 69 women with *HELLP syndrome* (syndrome of hemolysis, elevated liver enzymes, and low platelet count) developed renal failure ([Audibert and colleagues, 1996](#)). Early identification and proper management of renal failure in women with pure preeclampsia does not result in residual renal damage.

MANAGEMENT. Identification of acute renal failure and its cause(s) is important ([Thadhani and colleagues, 1996](#)). In most women, renal failure develops postpartum so management is not complicated by fetal considerations. Oliguria is an important sign of acutely impaired renal function. Unfortunately, potent diuretics such as furosemide can increase urine flow without correcting but rather intensifying some causes of oliguria. In obstetrical cases, both prerenal and intrarenal factors are commonly operative. For example, with total placental abruption, severe hypovolemia is common from massive concealed hemorrhage. Superimposed preeclampsia may cause oliguria. Intense consumptive coagulopathy commonly triggered by an abruption might impede intrarenal microcirculation. More likely, however, consumptive coagulopathy causes even more blood loss from lacerations and surgical incisions, resulting in further renal hypoperfusion.

When azotemia is evident and severe oliguria persists, hemodialysis should be initiated before marked deterioration of general well-being occurs. Early dialysis appears to reduce appreciably mortality and may enhance the extent of recovery of renal function. After healing has taken place, renal function usually returns to normal or near normal.

PREVENTION. Acute tubular necrosis may often be prevented by the following means:

1. Prompt and vigorous replacement of blood in instances of massive hemorrhage, as in placental abruption, placental previa, uterine rupture, and postpartum uterine atony.
2. Termination of pregnancies complicated by severe preeclampsia and eclampsia with careful blood replacement if loss is excessive.
3. Close observation for early signs of septic shock in women with pyelonephritis, septic abortion, amnionitis, or sepsis from other pelvic infections.
4. Avoidance of potent diuretics to treat oliguria before initiating appropriate efforts to assure cardiac output adequate for renal perfusion.
5. Avoidance of vasoconstrictors to treat hypotension, unless pathological vasodilation is unequivocally the cause of the hypotension.

Bilateral necrosis of the renal cortex is uncommon. It complicates between 15 and 30 percent of all cases of acute renal failure associated with obstetrical causes ([Grunfeld and Pertuiset, 1987](#); [Turney and colleagues, 1989](#)). Most of the reported cases have followed such complications as placental abruption, preeclampsia-eclampsia, or endotoxin-induced shock. Histologically, the lesion appears to result from thrombosis of segments of the renal vascular system. The lesions may be focal, patchy, confluent, or gross. Clinically, renal cortical necrosis follows the course of acute renal failure with oliguria or anuria, uremia, and generally death within 2 to 3 weeks unless dialysis is initiated. Differentiation from acute tubular necrosis during the early phase is not possible. The prognosis depends on the extent of the necrosis, because recovery is a function of the amount of renal tissue spared.

OBSTRUCTIVE RENAL FAILURE

Rarely, bilateral ureteral compression by a very large pregnant uterus is greatly exaggerated, causing ureteral obstruction and, in turn, severe oliguria and azotemia. [Brandes and Fritsche \(1991\)](#) reviewed 13 cases that were the consequence of a markedly overdistended gravid uterus. They described a woman with twins who developed anuria and a serum creatinine level of 12.2 mg/dL at 34 weeks. After amniotomy, urine flow at 500 mL/hr was followed by rapid return to normal of the serum creatinine. [Eckford and Gingell \(1991\)](#) described 10 women in whom ureteral obstruction was relieved by stenting. The stents were left in place for a mean of 15.5 weeks and removed 4 to 6 weeks postpartum. [Sadan and associates \(1994\)](#) reported a similar experience in eight women who underwent ureteral stent placement during pregnancy for moderate to severe hydronephrosis. Mean gestational age at insertion was 29 weeks, and the stents remained in situ for a mean of 9 weeks. Renal function remained normal.

We have observed this phenomenon on several occasions ([Satin and colleagues, 1993](#)). Partial ureteral obstruction may be accompanied by fluid retention and significant hypertension. When the obstructive uropathy is relieved, diuresis ensues and hypertension dissipates. In one woman with massive hydramnios (9.4 L) and an anencephalic fetus, amniocentesis and removal of some of the amniotic fluid was followed promptly by diuresis, lowering of the plasma creatinine concentration, and improvement of hypertension. In our experiences, women with previous urinary tract surgery are more likely to have such obstructions. [Austenfeld and Snow \(1988\)](#) and [Mansfield and colleagues \(1995\)](#) also emphasized the high incidence of urinary infections in women who have undergone ureteral reimplantation. Conversely, [Vordermark and associates \(1990\)](#) reviewed published experiences with pregnancy following major urinary reconstruction, and found minimal complications.

IDIOPATHIC POSTPARTUM RENAL FAILURE

In 1968, Robson and associates described what they believed to be a new syndrome of **acute irreversible renal failure** that developed within the first 6 weeks postpartum. Pregnancy and delivery appeared to have been normal in the seven cases reported, and none of the known causes of renal failure was found. The pathological changes identified by renal biopsy were necrosis and endothelial proliferation in glomeruli, plus necrosis, thrombosis, and intimal thickening of the arterioles. No vascular abnormalities were demonstrated in the other visceral organs in the four cases in which autopsy was performed. Morphological changes in the erythrocytes consistent with microangiopathic hemolysis and thrombocytopenia were usually present. These findings are similar to those reported for the **postpartum hemolytic uremic syndrome**. Moreover, they are also similar to those in which renal failure is identified as part of the syndrome of **thrombotic thrombocytopenic purpura**. These syndromes are collectively termed **thrombotic microangiopathies**, and are considered in detail in [Chapter 49](#).

TABLE 47-3. Antimicrobial Agents Used for Treatment of Pregnant Women with Asymptomatic Bacteriuria

Single Dose

Amoxicillin, 3g
Ampicillin, 2 g
Cephalosporin, 2 g
Nitrofurantoin, 200 mg
Sulfonamide, 2 g
Trimethoprim-sulfamethoxazole, 320/1600 mg

Three-day Course

Amoxicillin, 500 mg three times daily
Ampicillin, 250 mg four times daily
Cephalosporin, 250 mg four times daily
Nitrofurantoin, 50-100 mg four times daily; 100 mg twice daily
Sulfonamide, 500 mg four times daily

Other

Nitrofurantoin, 100 mg four times daily for 10 days
Nitrofurantoin, 100 mg at bedtime for 10 days

Treatment Failures

Nitrofurantoin, 100 mg four times daily for 21 days

Suppression for Bacterial Persistence or Recurrence

Nitrofurantoin, 100 mg at bedtime for remainder of pregnancy

48. Gastrointestinal Disorders

During normal pregnancy, the gastrointestinal tract and its appendages undergo changes, both anatomical and functional, that can appreciably alter the criteria for diagnosis and treatment of several diseases to which they are susceptible. For example, nausea and vomiting are frequent symptoms early in normal pregnancy, but if these symptoms are erroneously attributed to normal physiological changes, then gastrointestinal disease may be overlooked. Conversely, persistent nausea and vomiting in late pregnancy should always prompt a search for underlying pathology. In another example, most obstetricians, but not most internists or gastroenterologists, are aware that upper abdominal pain—epigastric or right upper quadrant—can be an ominous sign of severe preeclampsia. During advanced pregnancy, gastrointestinal symptoms become more difficult to assess, and physical findings are often obscured by the large uterus which displaces abdominal organs and alter the location of pain and tenderness.

LAPAROTOMY AND LAPAROSCOPY

Laparotomy and surgical treatment may be lifesaving for certain conditions, acute appendicitis being the most common. Citing data from the Swedish Registry through 1981, [Mazze and Kallen \(1989\)](#) reported that abdominal exploration by laparotomy or laparoscopy was performed in 1331 of 720,000 pregnancies—about 1 in every 500 pregnancies. [Kort and associates \(1993\)](#) reported that a total of 78 women in over 49,500 births had nonobstetrical surgery during pregnancy, an incidence of 1 in 635. The most common indications for surgery were appendicitis, adnexal masses, and cholecystitis.

During the past decade, laparoscopy has been shown safe during at least the first half of pregnancy. [Reedy and associates \(1997\)](#) updated the Swedish Registry which through 1993 had data from slightly over 2 million pregnancies. Of these, 2181 underwent laparoscopy and 1522 laparotomy for nonobstetrical indications—about 1 in every 800 pregnancies. As expected, laparoscopic procedures were mostly performed before 20 weeks ([Chap. 42, p. 1145](#) and [Fig. 42-1](#)). The most common nongynecological procedures include cholecystectomy and appendectomy ([Reedy and colleagues, 1998](#)). For more details, as well as surgical technique, see [Chapter 26](#) in *Operative Obstetrics* by [Gilstrap and colleagues \(2001\)](#).

DIAGNOSTIC TECHNIQUES

Fiberoptic endoscopic instruments have revolutionized the diagnosis and management of many gastrointestinal conditions. These instruments are particularly well-suited for use during pregnancy. Endoscopy permits evaluation of the esophagus, stomach, and duodenum ([Van Dam and Brugge, 1999](#)). With specialized instruments, the proximal jejunum can be studied, and the ampulla of Vater can be cannulated to perform *endoscopic retrograde cholangiopancreatography (ERCP)*¹. [Cappell and Sidhom \(1993\)](#) described experiences using panendoscopy in 20 pregnant women. These women were evenly distributed by trimester and in 14 (70 percent) a lesion was diagnosed—seven had esophagitis, two duodenal ulcers, three gastritis, and two had Mallory-Weiss tears. No significant complications of endoscopy were encountered. In another study, [Cappell and Sidhom \(1995\)](#) described successful use of *flexible sigmoidoscopy* in 24 pregnant women. *Colonoscopy* is used to view the entire colon and the distal ileum, and is invaluable in diagnosis and management of inflammatory bowel disease.

There are a number of noninvasive imaging techniques, and of these, abdominal ultrasonography has a crucial role in evaluation of some of these diseases, especially the gallbladder. Computed tomography must be limited in its application because of radiation exposure ([Chap 42, p. 1151](#)). Because of its safety and resolution, magnetic resonance imaging commonly is used instead for evaluating the abdomen and retroperitoneal space during pregnancy.

NUTRITIONAL SUPPORT

Specialized nutritional support can be delivered by enteral feedings, usually via a nasogastric tube, or parenterally, by peripheral or central venous access. When possible, enteral alimentation is preferable because it has few dangerous complications. In obstetrical patients, there are very few conditions that prohibit enteral nutrition as a first effort to prevent catabolism.

The purpose of parenteral feeding, or hyperalimentation, is to provide nutrition when the intestinal tract must be kept quiescent. Peripheral venous access may be adequate for short-term supplemental nutrition, which derives calories from isotonic fat solutions. Jugular or subclavian venous catheterization is necessary for total parenteral nutrition, because its hyperosmolarity requires rapid dilution in a high-flow system. These solutions provide up to 24 to 40 kcal/kg, principally as a hypertonic glucose solution. [Heyland and colleagues \(1998\)](#) reviewed 26 randomized trials with over 2200 nonpregnant patients who were given parenteral nutrition or standard therapy. In critically ill or postoperative patients, overall mortality was not influenced by parenteral nutrition.

PARENTERAL NUTRITION DURING PREGNANCY. Shown in [Table 48-1](#) are some reported uses of total parenteral nutrition for a variety of indications in 81 pregnant women. Gastrointestinal disorders were the most common indication, and the duration of parenteral feeding averaged 33 days. Complications are frequent and may be severe. Major mechanical complications include pneumothorax, hemothorax from injury to subclavian vessels, brachial plexus injury, and catheter malpositions. [Greenspoon and colleagues \(1989\)](#) described a maternal death from cardiac tamponade 7 days after successful placement of a subclavian venous catheter for hyperalimentation in a woman with hyperemesis gravidarum.

[Russo-Stieglitz and associates \(1999\)](#) reported results from parenteral nutrition during 26 pregnancies. Mean duration of therapy was 31 days with a range of 2 to 105 days. They observed a 50 percent complication rate with central catheters, and sepsis accounted for half of these complications. Early metabolic complications may be avoided by slowly increasing the dietary prescription to avoid fluid overload, osmotic diuresis, and massive electrolyte shifts due to insulin secretion. Late metabolic complications include gallstones and hepatic cholestasis.

DISORDERS OF THE UPPER GASTROINTESTINAL TRACT

HYPEREMESIS GRAVIDARUM

Nausea and vomiting of moderate intensity are especially common until about 16 weeks ([Chap. 10, p. 242](#)). [Klebanoff and colleagues \(1985\)](#) reported that slightly over half of 9000 women had vomiting in early pregnancy. [Jewell and Young \(2000\)](#) surveyed the Cochrane Database System and confirmed a salutary effect of antiemetics. When severe and unresponsive to simple therapy, the condition is termed *hyperemesis gravidarum*, which fortunately has become uncommon. This syndrome is defined loosely as vomiting sufficiently severe to produce weight loss, dehydration, acidosis from starvation, alkalosis from loss of hydrochloric acid in vomitus, and hypokalemia. In some cases, transient hepatic dysfunction develops (p. 1283). Hyperemesis appears to be related to high or rapidly rising serum levels of chorionic gonadotropin or estrogens ([Goodwin and associates, 1994](#); [van de Ven, 1997](#)). An association with seropositivity to *Helicobacter pylori*—the causative agent of peptic ulcer disease—has been described by [Frigo and co-workers \(1998\)](#).

[Godsey and Newman \(1991\)](#) studied 140 women admitted for hyperemesis to the Medical University of South Carolina Hospital. In 27 percent of these women, multiple admissions were necessary. Vomiting may be prolonged, frequent, and severe. We have encountered women with severe prerenal azotemia with serum creatinine as high as 5 mg/dL. Serious complications include **Mallory-Weiss tears** and **esophageal rupture**. [Schwartz and Rossoff \(1994\)](#) described a woman whose retching led to bilateral pneumothoraces and pneumomediastinum. [Robinson and colleagues \(1998\)](#) described serious epistaxis caused by vitamin K deficiency coagulopathy in a woman with refractory hyperemesis at 15 weeks. A number of cases complicated by **Wernicke encephalopathy** from thiamine deficiency have been reported. Complications from this have included blindness, convulsions, and coma ([Hillbom, 1999](#); [Rees, 1997](#); [Tesfaye, 1998](#), and their associates).

MANAGEMENT. First-line methods of outpatient treatment are discussed in [Chapter 10 \(p. 242\)](#). [Murphy and Chez \(2000\)](#) recently reviewed alternative therapies. When these fail, intravenous crystalloid solutions are used to correct dehydration, electrolyte deficits, and acid-base imbalances. This requires appropriate amounts of sodium, potassium, chloride, lactate or bicarbonate, glucose, and water, all of which should be administered parenterally until vomiting has been controlled.

Antiemetics such as promethazine, prochlorperazine, and chlorpromazine are given to alleviate nausea and vomiting. [Nageotte and colleagues \(1996\)](#) reported success with intravenous droperidol-diphenhydramine. For severe disease, metoclopramide may be given parenterally. This stimulates motility of the upper intestinal tract without stimulating gastric, biliary, or pancreatic secretions. Its antiemetic properties apparently result from central antagonism of dopamine receptors. [Safari and co-workers \(1998\)](#) conducted a randomized trial comparing oral methylprednisolone with promethazine. Immediate salutary effects were apparent in both groups, but the group receiving this steroid had significantly fewer readmissions. More recently, serotonin antagonists have been used to treat severe nausea in nonpregnant patients, but their use in pregnancy is limited ([Briggs and colleagues, 1998](#)).

With persistent vomiting, appropriate steps should be taken to diagnose and treat other diseases, such as gastroenteritis, cholecystitis, pancreatitis, hepatitis, peptic

ulcer, pyelonephritis, and fatty liver of pregnancy. In some instances, social and psychological factors contribute to the illness ([Deuchar, 1995](#)). With correction of these latter circumstances, the woman usually improves remarkably while hospitalized, only to relapse after discharge. Positive assistance with psychological and social problems is beneficial.

With prolonged vomiting, consideration is given for nutritional support. As previously discussed, nutrition is best provided by the enteral route if possible. [Hsu and colleagues \(1996\)](#) described enteral nutrition utilizing a Dobbhoff nasogastric feeding tube after acute nausea and vomiting had subsided. In some women with persistent and severe disease, parenteral nutrition may be necessary ([van de Ven, 1997](#)).

REFLUX ESOPHAGITIS

Heartburn, also called pyrosis, is a common symptom in late pregnancy. The retrosternal burning sensation is caused by esophagitis from gastroesophageal reflux related to relaxation of the lower esophageal sphincter ([Hytten, 1991](#)). Common heartburn is seldom severe enough to warrant diagnostic investigation. Raising the head of the bed and ingestion of oral antacids usually suffices to relieve symptoms. If severe symptoms persist despite these simple measures, an H₂-receptor antagonist is prescribed. Both cimetidine and ranitidine are considered safe ([Briggs and associates, 1998](#)). If there is then no relief, endoscopy should be considered.

HIATAL HERNIA

[Rigler and Eneboe \(1935\)](#) performed upper gastrointestinal x-ray series in 195 unselected pregnant women in the last trimester. Almost 20 percent of 116 multiparas compared with 5 percent of 79 nulliparas had a hiatal hernia. When 10 women with a pregnancy-associated hernia were reexamined 1 to 18 months postpartum, only three had a persistent hernia. Such hernias may be produced by an intermittent but prolonged increase in intra-abdominal pressure.

The relationship of hiatal hernia with reflux esophagitis, and thus symptoms, is not clear. [Cohen and Harris \(1971\)](#) demonstrated no relationship between reflux and hernia, and showed that the lower esophageal sphincter functioned effectively even when displaced intrathoracically. Nevertheless, during pregnancy these hernias may cause vomiting, epigastric pain, and even bleeding from ulceration. [Curran and colleagues \(1999\)](#) described a 30-week pregnancy complicated by gastric outlet obstruction from a paraesophageal hernia that they successfully repaired.

DIAPHRAGMATIC HERNIA

Symptomatic diaphragmatic hernias rarely complicate pregnancy. These are herniations of abdominal contents through either the foramen of Bochdalek or the foramen of Morgagni. [Kurznel and associates \(1988\)](#) reviewed 18 symptomatic cases reported during pregnancy. All of these women had acute obstruction, and maternal mortality was 45 percent. They recommend repair during pregnancy even if the woman is asymptomatic. [Flick and associates \(1999\)](#) reported a case in which a woman had sustained a car accident several months before pregnancy. At 23 weeks she experienced symptomatic bowel herniation into the chest through a traumatic diaphragmatic defect. [Ortega-Carnicer \(1998\)](#) and [Watkin \(1993\)](#) and their colleagues described women with spontaneous rupture of the diaphragm during delivery.

ACHALASIA

This is a motor disorder of esophageal smooth muscle in which the lower sphincter does not relax properly with swallowing, and there are abnormal esophageal contractions. The cause is defective innervation of the smooth muscle of the esophagus and lower esophageal sphincter. Symptoms are dysphagia, chest pain, and regurgitation. Diagnosis is usually confirmed by demonstrating a bird's beak narrowing at the distal esophagus via barium esophagogram. Endoscopy may reveal esophageal dilatation, and manometry is confirmatory. Endoscopy is used to exclude secondary causes, particularly gastric carcinoma.

Surprisingly, pregnancy does not seem to worsen this condition. [Mayberry and Atkinson \(1987\)](#) described 20 pregnant women and reported no excessive reflux esophagitis compared with nonpregnant women with achalasia. Of 16 women who became pregnant after symptoms developed, 11 had no change in symptomatology, two improved, and three worsened. [Kalish and associates \(1999\)](#) described a 32-week pregnant woman whose achalasia was worsened by severe *Candida* esophagitis.

MANAGEMENT. Soft foods and anticholinergic drugs are prescribed. If symptoms persist, balloon dilatation is used, which may be complicated by perforation or hemorrhage. Almost 85 percent of nonpregnant patients respond to such treatment. [Satin and colleagues \(1992\)](#) and [Fiest and associates \(1993\)](#) reported successful outcomes with the use of pneumatic dilatation in two women with achalasia in pregnancy.

PEPTIC ULCER

In young women, peptic ulcer disease more often involves the duodenum rather than stomach. Ulcers may be caused by chronic gastritis induced by *Helicobacter pylori* and peptic ulcer disease ([de Boer and Tytgat, 2000](#)). They may also arise from use of aspirin and other nonsteroidal anti-inflammatory drugs. Acid secretion is also important, thus explaining the temporary efficacy of antisecretory agents.

During pregnancy, gastric secretion is reduced, motility is decreased, and there is considerably increased mucus secretion ([Hytten, 1991](#)). It is thus not surprising that active peptic ulcer disease is uncommon during pregnancy. In the past 30 years at Parkland Hospital, during which time we have cared for over 300,000 pregnant women, we have encountered very few women with symptomatic peptic ulcers. Even women with symptomatic ulcers antedating pregnancy most often note considerable improvement during pregnancy. [Clark \(1953\)](#) studied 313 pregnancies in 118 women with proven ulcer disease and reported a clear remission in almost 90 percent. These benefits were short lived, and within 3 months of delivery, symptoms recurred in over half. By the end of 2 years, almost every woman had suffered a recurrence.

Antacids are first-line therapy and H₂-receptor blockers are prescribed for those who do not respond. Proton-pump inhibitors such as omeprazole are not recommended during pregnancy ([Briggs and colleagues, 1998](#)). Sucralfate is the aluminum salt of sulfated sucrose that provides a protective coating at the ulcer base. Only about 10 percent of the aluminum salt is absorbed, and it is considered safe. If antibacterial therapy for *H. pylori* is indicated, there are a number of treatment regimens that do not include tetracycline ([de Boer and Tytgat, 2000](#)). Endoscopy is performed if indicated.

UPPER GASTROINTESTINAL BLEEDING

Occasionally, persistent vomiting may be accompanied by worrisome upper gastrointestinal bleeding. The obvious concern is that there is a bleeding peptic ulceration; however, most of these women have minute linear mucosal tears near the gastroesophageal junction, or so-called *Mallory-Weiss tears*. These women usually respond promptly to conservative measures that include iced-saline irrigations, topical antacids, and intravenously administered H₂-blockers. In some instances, blood transfusions are needed. If indicated, endoscopy is used for diagnosis and perhaps hemostasis ([Van Dam and Brugge, 1999](#)). It should not be withheld because of pregnancy. It may be important to distinguish this from the more dangerous *Boerhaave syndrome*, which is esophageal rupture caused by greatly increased esophageal pressure from retching.

DISORDERS OF THE SMALL BOWEL AND COLON

PHYSIOLOGY. The small bowel has diminished motility during pregnancy. [Lawson and colleagues \(1985\)](#) showed that small bowel transit time was significantly prolonged in pregnant women (125 to 140 minutes) compared with nonpregnant controls (75 to 90 minutes). The colon undergoes muscular relaxation as well, and this is accompanied by increased absorption of water and sodium. Both of these predispose to constipation.

CONSTIPATION. The incidence of constipation during pregnancy is related to dietary fiber intake ([Everson, 1992](#)). In women with low-fiber diets, almost 40 percent complain of constipation at some time during pregnancy, and 20 percent do so in the third trimester. Such symptoms are usually only mildly bothersome, but we have on several occasions encountered pregnant women who developed megacolon from impacted stool. These women almost invariably had abused stimulatory laxatives. Preventative measures include a high-fiber diet along with bulk-forming laxatives.

INFLAMMATORY BOWEL DISEASE

These disorders include at least two forms of intestinal inflammation, ulcerative colitis and Crohn disease. The latter also is known as regional enteritis, Crohn ileitis, and granulomatous colitis. As shown in [Table 48-2](#), these two diseases share common factors, and sometimes it is impossible to distinguish the two if Crohn disease

involves the colon. In general, however, the salient clinical and laboratory features shown in [Table 48-2](#) permit a confident diagnostic differentiation between these two. The etiology of both is enigmatic, but their pathogenesis has been partially elucidated. There appears to be a genetic predisposition toward both diseases with increased incidence in twins and first-degree relatives. An association with inflammatory bowel disease has been found with certain HLA alleles. Although suspected, neither an infectious nor an immune-mediated etiology has been proven.

ULCERATIVE COLITIS. Disease is confined to the superficial layers of the colon, typically beginning at the rectum and extending proximally for a variable distance. Sigmoidoscopic findings include mucosal granularity and friability, which are interspersed with mucosal ulcerations and a mucopurulent exudate. The extent of inflammation is proportional to symptoms, and bloody diarrhea is the cardinal presenting finding. The disease is characterized by exacerbations and remissions. *Toxic megacolon* is a particularly dangerous complication that necessitates colectomy in half of cases ([Sheth and LaMont, 1998](#)). *Extraintestinal manifestations* include arthritis, uveitis, and erythema nodosum. The risk of cancer is high and approaches 1 percent per year.

Management of ulcerative colitis is medical, and sulfasalazine is used for maintenance as well as active colitis ([Glickman, 1998](#)). One active metabolite is 5-aminosalicylic acid, which inhibits prostaglandin synthase. [Wahl and colleagues \(1998\)](#) have also shown that the parent compound inhibits activation of nuclear factor kappa B (NF- κ B), which is a control mediator of the immune response. Prednisone is used for more severe active disease that does not respond to 5-aminosalicylic derivatives. Immunosuppressive drugs including azathioprine and cyclosporine have been used in conjunction with prednisone in nonpregnant patients with success. Finally, cyclosporine is beneficial to treat severely ill patients who otherwise would have a colectomy. Proctocolectomy is performed for recalcitrant disease, with permanent ileostomy or an ileoanal anastomosis with one of the newly devised continent ileal pouches.

CROHN DISEASE. This inflammatory disease has more protean manifestations than ulcerative colitis. It involves not only the bowel mucosa but also the deeper layers and, sometimes, there is transmural involvement ([Table 48-2](#)). The disease is typically segmental. About 30 percent of patients have small bowel involvement, 25 percent have isolated colon involvement, and 40 percent have both, usually with the terminal ileum and colon involved.

Complaints include abdominal pain and diarrhea, and obstructive symptoms are common. The disease is chronic and marked by exacerbations and remissions. Almost 30 percent of patients require surgery during the first year after the diagnosis is made; thereafter, 5 percent per year require surgery. Indeed, Crohn disease is the most common surgical disease of the small bowel ([Evers and associates, 1999](#)). Complications include fistula formation and perineal communications that interfere with vaginal delivery ([Forsnes and co-workers, 1999](#); [Illyckji and colleagues, 1999](#)). Reactive arthritis is common, and the risk of cancer, while not as great as with ulcerative colitis, is increased substantively.

No regimen is universally effective for maintenance of asymptomatic periods. Sulfasalazine is effective for symptomatic disease in some patients. The newer 5-aminosalicylate formulations are better tolerated ([Rampton, 1999](#)). Prednisone therapy controls active disease but is less effective for small bowel involvement ([Glickman, 1998](#)). [Thomsen and colleagues \(1998\)](#) reported promising results with oral budesonide. Immunosuppressive drugs, including azathioprine and 6-mercaptopurine, are used more successfully than with ulcerative colitis. [Brynskov and colleagues \(1989\)](#) reported that oral cyclosporine was effective to control corticosteroid-resistant active disease in nonpregnant patients. Methotrexate is used successfully in steroid-dependent cases, and low-dose methotrexate maintains a remission ([Feagan and associates, 2000](#)). [Belluzzi and associates \(1996\)](#) reported a salutary effect of fish-oil capsules in preventing recurrences. Exciting new research centers around monoclonal antibodies directed against tumor necrosis factor, a proinflammatory cytokine ([Present and colleagues, 1999](#)). Also, growth hormone, which stimulates intestinal growth and repair may be beneficial ([Slonim and co-workers, 2000](#)).

Because cure is unlikely with resection of affected bowel, conservative surgery is indicated for complications, including no response to medical therapy. Unfortunately, resection is associated with a 50 percent recurrence requiring further surgery within 10 years ([Rampton, 1999](#)).

INFLAMMATORY BOWEL DISEASE AND PREGNANCY. Chronic inflammatory bowel disease, either ulcerative colitis or Crohn disease, is relatively common in women of childbearing age. [Donaldson \(1985\)](#) concluded the following:

1. Pregnancy does not increase the likelihood of an attack of inflammatory bowel disease. If the disease is quiescent in early pregnancy, then flares are uncommon, but if they develop, they may be severe.
2. Active disease at conception increases the likelihood of poor pregnancy outcome.
3. Diagnostic evaluations, including limited radiological studies, should not be postponed if their results are likely to affect management.
4. Many of the usual treatment regimens, including corticosteroids, may be continued during pregnancy, and, if indicated, surgery should be performed.

Pregnancy outcomes were recently described by [Kornfeld and co-workers \(1997\)](#) in a population-based cohort study of 756 Swedish women with preexisting inflammatory bowel disease. Preterm birth, low birthweight, fetal growth restriction, and cesarean delivery were all increased 1.5- to 2-fold in affected women. Perinatal mortality, however, was not increased. Previously, [Fedorkow and colleagues \(1989\)](#) and [Baird and associates \(1990\)](#) reported similar findings from retrospective controlled studies. These findings are in contrast to those described subsequently.

ULCERATIVE COLITIS. In an extensive review of more than 1000 cases, [Miller \(1986\)](#) reported that ulcerative colitis quiescent at conception was worsened during pregnancy in about a third of cases ([Table 48-3](#)). Women with active disease at the time of conception had a worse prognosis, and almost half worsened during pregnancy. Therapy is the same as for nonpregnant patients. Maintenance is continued with 5-aminosalicylic acid derivatives and flares can be treated with corticosteroids. [Habal and associates \(1993\)](#) described the successful use of 5-aminosalicylic acid for 17 pregnant women during 19 pregnancies.

Ulcerative colitis seems to have few adverse effects on pregnancy outcome. [Modigliani \(2000\)](#) reviewed 2398 pregnancy outcomes published since 1965. He concluded that pregnancy outcomes were not substantively different from the general obstetrical population. The incidences of spontaneous abortion, preterm delivery, and stillbirths were remarkably low. These findings contradict those of [Kornfeld and colleagues \(1997\)](#) described earlier for both types of inflammatory bowel disease.

When colitis worsens during pregnancy, the cause may be psychogenic. Reassurance is therefore an important part of management. Parenteral nutrition can be employed in women with severe and prolonged exacerbations. [Watson and Gaines \(1987\)](#) and [Boulton and colleagues \(1994\)](#) reported two women in whom colectomy was performed during the third trimester for corticosteroid-resistant disease. According to [Farouk and colleagues \(2000\)](#), long-term function of an ileal pouch-anal anastomosis is not impaired by childbirth.

CROHN DISEASE. Pregnancy does not have adverse effects on the course of Crohn disease. [Miller \(1986\)](#) reported findings very similar to those described previously with ulcerative colitis—that is, disease quiescent at conception carries a good prognosis ([Table 48-3](#)). [Woolfson and colleagues \(1990\)](#) reported similar results, and they found that abdominal surgery was required during pregnancy in 5 percent of the women. [Forsnes and associates \(1999\)](#) have described diagnosis of an enterovesical fistula diagnosed in a 15-week pregnant woman.

Crohn disease does not seem to have an overwhelmingly deleterious effect on pregnancy outcome. In their 20-year literature review, [Korelitz \(1998\)](#) reviewed the literature and found that there were good perinatal outcomes in the absence of active disease. While active disease is associated with adverse outcomes, an important factor is response to therapy. These findings are in contrast to those described earlier by [Kornfeld and associates \(1997\)](#). In a Danish study of 510 infants born to women with Crohn disease, [Fonager and colleagues \(1998\)](#) also found a twofold risk of low-birthweight infants and preterm birth.

Parenteral hyperalimentation has been used successfully for women with severe recurrences of inflammatory bowel disease during pregnancy ([Kirby and associates, 1988](#); [Russo-Stieglitz and colleagues, 1999](#)).

OSTOMY AND PREGNANCY

Women with a colostomy or an ileostomy may develop complications during pregnancy. [Gopal and colleagues \(1985\)](#) described 82 pregnancies in 66 women following ostomy, usually done for inflammatory bowel disease. Although stomal dysfunction was common, it responded to conservative management in all cases. Bowel obstruction developed in six women, and in three, surgery was necessary. Ileostomy prolapse was surgically corrected in three women during pregnancy or at cesarean delivery, and in a fourth woman during the puerperium. The cesarean delivery rate was 37 percent, and a third of these were done because of prior abdominoperineal resection.

Over the past decade, colectomy with mucosal proctectomy and ileal pouch-anal anastomosis has become the surgical procedure of choice for ulcerative colitis and familial colonic polyposis. Disadvantages include frequent bowel movements, nocturnal fecal soilage in almost half of patients, and *pouchitis* ([Kodner and colleagues, 1999](#)). [Juhasz and co-workers \(1995\)](#) described subsequent pregnancies in women who had this anastomosis. While stool frequency, pad soilage, and incontinence temporarily worsened during pregnancy, these abated postpartum. [Farouk and associates \(2000\)](#) found that childbirth did not worsen long-term function. These investigators as well as others have concluded that vaginal delivery is acceptable in these women.

INTESTINAL OBSTRUCTION

Bowel obstruction during pregnancy is probably not more common than in the general population. [Meyerson and colleagues \(1995\)](#) reported an incidence of 1 in 17,000 deliveries in over 150,000 women delivered over a 20-year period at two Detroit hospitals. From their review, [Perdue and associates \(1992\)](#) found incidences that varied from 1 in 1500 to 1 in 66,500 deliveries. As shown in [Table 48-4](#), most cases—probably 60 to 70 percent—are due to adhesions from previous pelvic surgery, including cesarean deliveries. Volvulus is another common cause, and in a third of the cases reported by [Harer and Harer \(1958\)](#), cesarean delivery was necessary to obtain proper exposure. Volvulus of the cecum and small bowel have been reported in late pregnancy or early in the puerperium ([Carral and colleagues, 1998](#); [Ranjan and Boulton, 1993](#)). [Woywodt and Kiss \(1999\)](#) described a woman with severe geophagia who developed sigmoid obstruction with perforation, sepsis, and death. Spontaneous small bowel obstruction may also develop during pregnancy ([Ventura-Braswell and associates, 1998](#); [Wax and Christie, 1993](#)).

Intestinal obstruction is a grave complication of pregnancy and results most frequently from pressure of the growing uterus on intestinal adhesions. According to [Davis and Bohon \(1983\)](#), there are three times when obstruction is more likely: around midpregnancy, when the uterus becomes an abdominal organ; at term, when the fetal head descends; and immediately postpartum, when there is an acute change in the uterine size. From their review, [Perdue and colleagues \(1992\)](#) found that 80 percent of pregnant women had nausea and vomiting. Importantly, abdominal pain, either continuous or colicky, was found in 98 percent. Abdominal tenderness was encountered in 70 percent. They reported abnormal bowel sounds in only 55 percent.

Limited x-ray examinations, including plain abdominal films, and those following administration of soluble contrast medium should be performed if obstruction is suspected. [Perdue and associates \(1992\)](#) reported that 38 of 42 pregnant women in whom x-rays were performed had radiographic evidence of obstruction.

The mortality rate with intestinal obstruction can be very high, principally because of errors in diagnosis, delayed diagnosis, reluctance to operate during pregnancy, and inadequate preparation for surgery ([Firstenberg and Malangoni, 1998](#)). Of 66 pregnancies, [Perdue and associates \(1992\)](#) described a 6 percent maternal mortality rate and a 26 percent fetal mortality rate. Two of the four women who died had adhesive obstruction late in pregnancy; one each had sigmoid or cecal volvulus.

Colonic pseudo-obstruction, or *Ogilvie syndrome*, is caused by adynamic colonic ileus, and about 10 percent of all reported cases follow delivery. The syndrome is characterized by massive abdominal distention with cecal dilatation. Although unusual, the large bowel may rupture, and decompression is recommended when the bowel becomes distended to 10 to 12 cm. In most cases, colonoscopy for decompression is effective but if peritonitis is suspected, laparotomy may be indicated. We have had success with colonic decompression by colonoscopy, and [Moore and associates \(1986\)](#) have described this in a woman 2 days following cesarean delivery. [Ponec and associates \(1999\)](#) reported that slow intravenous infusion of 2 mg neostigmine resulted in prompt decompression. Subsequently, [Amaro and Rogers \(2000\)](#) confirmed that 17 of 18 patients responded immediately to this treatment.

APPENDICITIS

Suspected appendicitis is one of the most common indications for surgical abdominal exploration during pregnancy. [Mazze and Kallen \(1991\)](#) described findings from 720,000 Swedish registry deliveries and reported that 778 (about 1 in 1000 pregnancies) of these women underwent appendectomy during pregnancy. Appendicitis was confirmed in 65 percent, or about 1 in 1500 pregnancies.

Pregnancy often makes the diagnosis of appendicitis more difficult because:

1. Anorexia, nausea, and vomiting that accompany normal pregnancy are also common symptoms of appendicitis.
2. As the uterus enlarges, the appendix commonly moves upward and outward toward the flank, so that pain and tenderness may not be prominent in the right lower quadrant ([Fig. 48-1](#)).
3. Some degree of leukocytosis is the rule during normal pregnancy.
4. During pregnancy especially, other diseases may be confused with appendicitis, such as pyelonephritis, renal colic, placental abruption, and degeneration of a uterine myoma.
5. Pregnant women, especially those late in gestation, frequently do not have symptoms considered "typical" for nonpregnant patients with appendicitis.

As the appendix is pushed progressively higher by the growing uterus, containment of infection by the omentum becomes increasingly unlikely, and appendiceal rupture is more likely to cause generalized peritonitis. In the recent report by [Tracey and Fletcher \(2000\)](#), over half of pregnant women had perforative appendicitis. Acute appendicitis in late pregnancy has the worst prognosis, and indeed, in some older series maternal mortality approached 5 percent ([Sharp, 1994](#)). Increased fetal and maternal morbidity and mortality is almost invariably due to surgical delay.

DIAGNOSIS AND MANAGEMENT. Persistent abdominal pain and tenderness are the most reproducible findings. While most investigators have reported that pain migrates upward with appendiceal displacement with progressing pregnancy, [Mourad and associates \(2000\)](#) did not find this. They reported that 80 percent of 45 pregnant women had pain in the right lower quadrant regardless of trimester.

Graded compression using ultrasound imaging was effective in the diagnosis of appendicitis in nonpregnant patients ([Puylaert and colleagues, 1987](#)). While [Landwehr and associates \(1996\)](#) correctly diagnosed appendicitis in four of five pregnant women using this method, we have found that cecal displacement and uterine imposition makes precise examination difficult. [Rao and colleagues \(1998\)](#) performed appendiceal computed tomography in 100 consecutive nonpregnant patients with suspected appendicitis and found the technique to be 98 percent accurate ([Fig. 48-2](#)). Tomography needs to be evaluated in pregnant women before its widespread application.

If appendicitis is suspected, treatment is immediate surgical exploration. Even though diagnostic errors sometimes lead to removal of a normal appendix, it is better to operate unnecessarily than to postpone intervention until generalized peritonitis has developed.

In most reports, the diagnosis is verified in about half of women who undergo surgical exploration ([Sharp, 1994](#)). In the Swedish study of 778 women with suspected appendicitis, the diagnosis was confirmed in 65 percent ([Mazze and Kallen, 1991](#)). In the first trimester, 77 percent of diagnoses were correct; however, in the latter two trimesters, only 57 percent of diagnoses were confirmed at surgery.

In nonpregnant patients, laparoscopy is done routinely for suspected acute appendicitis. [Hellberg and colleagues \(1999\)](#) randomized 500 nonpregnant patients with suspected acute appendicitis to either method. They concluded that the laparoscopic approach was safe and associated with faster postoperative recovery. Certainly in the first half of pregnancy, laparoscopy for suspected appendicitis is acceptable ([Affleck and co-workers, 1999](#)). Others have questioned the safety of creating a pneumoperitoneum with carbon dioxide, which may cause fetal acidosis and adversely affect fetal cardiovascular function ([Amos and associates, 1996](#)). As discussed on page 1274, the experiences with laparoscopy of [Reedy and colleagues \(1997\)](#) from the Swedish Registry are reassuring (see also [Chap. 42, p. 1145](#)). They found similar perinatal outcomes in nearly 2000 laparoscopic procedures compared with over 1500 laparotomies in women less than 20 weeks.

Intravenous antimicrobials are given, and [Firstenberg and Malangoni \(1998\)](#) recommend a second-generation cephalosporin or third-generation penicillin. Unless there is gangrene, perforation, or a periappendiceal phlegmon, antimicrobial therapy can be discontinued after surgery. If generalized peritonitis does not develop, then the prognosis is quite good. Seldom is cesarean delivery indicated at the time of appendectomy. Uterine contractions are common with peritonitis and, although some authors recommend tocolytic agents, we do not. [De Veciana and colleagues \(1994\)](#) reported that increased intravenous fluid administration and tocolytic use increased the risk for pulmonary injury with antepartum appendicitis.

Undiagnosed appendicitis often stimulates labor. The large uterus frequently helps to contain infection locally, but after delivery when the uterus rapidly empties, the

walled-off infection is disrupted with spillage of free pus into the peritoneal cavity. In these cases, an acute surgical abdomen is encountered within a few postpartum hours.

Simply because it is coincidental, appendicitis during the early puerperium is rare. In some cases, especially with early appendicitis, diagnosis is particularly difficult because of the normally robust leukocytosis as well as the frequency of other puerperal disorders with similar signs and symptoms. Anorexia with any evidence of peritoneal irritation, such as distention and adynamic ileus, should suggest appendicitis. Puerperal pelvic infections typically do not cause peritonitis.

EFFECTS ON PREGNANCY. Appendicitis increases the likelihood of abortion or preterm labor, especially if there is peritonitis. [Mazze and Kallen \(1991\)](#) found that spontaneous labor ensued with greater frequency if surgery for appendicitis was performed after 23 weeks. In the 45 cases described by [Mourad and associates \(2000\)](#), uterine contractions were reported in 19 of 23 women who were 24 weeks or greater. Fetal loss is increased in most series, and overall it is about 15 percent. In the Swedish study, fetal loss was 22 percent if surgery was performed after 23 weeks. [Mays and colleagues \(1995\)](#) have suggested a link between maternal-fetal sepsis and neonatal neurological injury in pregnancy complicated by appendicitis. In another long-term study, [Viktrup and Hee \(1998\)](#) found that appendicitis during pregnancy was not associated with subsequent infertility.

DISEASES OF THE LIVER

It is customary to divide liver diseases into those coincidental to pregnancy, those specifically related to pregnancy, and chronic liver disease that antedates pregnancy. Many disorders complicating pregnancy are coincidental, for example, acute viral hepatitis or drug-induced hepatic failure. There are some diseases that are induced by pregnancy that resolve following delivery. These include intrahepatic cholestasis of pregnancy, acute fatty liver of pregnancy, hepatocellular damage due to severe preeclampsia, and hepatic dysfunction from hyperemesis gravidarum. Finally, pregnancy may be superimposed on chronic hepatitis or cirrhosis, esophageal varices, or liver transplantation.

HEPATIC PHYSIOLOGY. Pregnancy normally induces appreciable changes in some of the tests as well as physical findings that are usually employed to assess liver function ([Table 48-5](#)). Palmar erythema and spider angiomas may develop. Histological findings of liver biopsy specimens taken from normal pregnant women were not different when compared with nonpregnant subjects ([Ingerslev and Teilum, 1945](#)).

HYPEREMESIS GRAVIDARUM

Pernicious nausea and vomiting are discussed on page 1275. The liver may be involved, and biopsy findings are either normal or show some fatty changes ([Knox and Olans, 1996](#)). There may be mild hyperbilirubinemia, and serum hepatic transaminase levels are elevated in up to half of women who are hospitalized. Enzyme levels seldom exceed 200 U/L.

INTRAHEPATIC CHOLESTASIS OF PREGNANCY

Cholestasis of pregnancy also has been referred to as recurrent jaundice of pregnancy, cholestatic hepatitis, and icterus gravidarum. It is characterized clinically by pruritus, icterus, or both. The major histological lesion is intrahepatic cholestasis with centrilobular bile staining without inflammatory cells or proliferation of mesenchymal cells. The cause is unknown, and it was assumed to be stimulated in susceptible persons by high estrogen concentrations. [Leslie and colleagues \(2000\)](#), however, recently reported that maternal plasma estrogens are decreased in affected women compared with matched controls. [Reyes and Sjovall \(2000\)](#) have proposed that there is a defect in secretion of sulfated progesterone metabolites. There is evidence that obstetrical cholestasis is related to the many gene mutations that control hepatocellular-transport systems ([Trauner and associates, 1998](#)). Because of these genetic influences, the incidence of cholestasis varies. It is common in Chile and Sweden, and according to [Reyes \(1997\)](#), it complicated 4 percent of pregnancies in Chile in 1995. In other countries, its incidence is probably about 1 in 500 to 1000 pregnancies.

PATHOGENESIS. Presumably, a number of estrogen-induced changes account for cholestasis in susceptible women. Some drugs that similarly decrease the canalicular transport maximum for bile acids will aggravate the disorder. For example, we have encountered cholestatic jaundice in several pregnant women who were taking azathioprine following renal transplantation.

Bile acids are cleared incompletely by the liver and accumulate in plasma of women with cholestasis. Serum concentration of total bile acids may be elevated 10- to 100-fold ([Lunzer and associates, 1986](#)). Hyperbilirubinemia results from retention of conjugated pigment, but total plasma concentrations rarely exceed 4 to 5 mg/dL. The serum alkaline phosphatase is usually elevated more so than for normal pregnancy. Serum transaminase activities are normal to moderately elevated, and seldom exceed 250 U/L. Liver biopsy shows mild cholestasis with intracellular bile pigments and canalicular bile plugging without necrosis. These changes disappear after delivery, but often recur in subsequent pregnancies or when an oral estrogen-containing contraceptive is taken.

CLINICAL PRESENTATION. Most women with cholestasis develop pruritus in late pregnancy although the syndrome occasionally occurs in the second trimester. [Kirkinen and Ryyanen \(1995\)](#) reported a woman at 13 weeks with typical cholestasis who had hyperplacentosis associated with a triploid fetus. Generalized pruritus is usually the presenting symptom, but there are no accompanying skin changes unless there are excoriations from scratching. The differential diagnosis of skin eruptions is considered in [Chapter 54 \(p. 1431\)](#). A minority of women—perhaps 10 percent—develop jaundice within several days following pruritus. There are no constitutional symptoms.

Several other disorders should be considered. The absence of hypertension and proteinuria militate against liver disease associated with preeclampsia. Ultrasound examination will often serve to exclude biliary obstruction by gallstones. If serum transaminase levels are not appreciably elevated and the woman is asymptomatic, then viral hepatitis is not likely. However, as discussed subsequently, [Locatelli and colleagues \(1999\)](#) have shown a significantly higher rate of cholestasis in otherwise asymptomatic women seropositive for hepatitis C (16 percent) compared with seronegative controls (0.8 percent).

MANAGEMENT. Pruritus associated with cholestasis is caused by elevated serum bile salts, and may be quite troublesome. Orally administered *antihistamines* may provide some relief. *Cholestyramine* may be effective; however, our observations as well as those of [Fisk and colleagues \(1988\)](#) do not support this. Absorption of fat-soluble vitamins, already impaired, is worsened with cholestyramine. Thus, impaired coagulation from vitamin K deficiency may develop unless supplemented. [Sadler and associates \(1995\)](#) described spontaneous intracranial hemorrhage in a 29-week fetus whose mother—and presumably the fetus—developed hypoprothrombinemia with cholestyramine therapy. [Matos and colleagues \(1997\)](#), however, described a 37-week stillbirth from the same cause in an untreated woman with mild disease.

Retrospective observations showed that *ursodeoxycholic acid* quickly relieved pruritus and lowered serum hepatic enzyme levels in women with obstetric cholestasis ([Kilby and associates, 1998](#)). [Palma and colleagues \(1997\)](#) subsequently found it safe and effective in a small blinded placebo trial. [Nicastri and co-workers \(1998\)](#) reaffirmed these findings and further reported that addition of S-adenosylmethionine improved results with ursodeoxycholic acid.

[Hirvioja and colleagues \(1992\)](#) reported prompt relief of pruritus in 10 women given **dexamethasone**, 12 mg daily for 7 days. They postulated that associated diminished estrogen synthesis caused relief of pruritus as well as lowered serum transaminase levels.

EFFECT OF CHOLESTASIS ON PREGNANCY. Most observations indicate that adverse pregnancy outcomes are increased in women with cholestatic jaundice. [Rioseco and co-workers \(1994\)](#) retrospectively compared outcomes in 320 affected pregnancies with normal controls. Although meconium-stained amniotic fluid (25 versus 16 percent) and preterm delivery (12 versus 4 percent) were increased significantly, they attributed equivalent perinatal mortality to close pregnancy surveillance. Conversely, [Alsulyman and associates \(1996\)](#) retrospectively studied 79 women followed with weekly nonstress testing and amniotic fluid assessment. Compared with controls, women with cholestasis more often had abnormal testing that prompted delivery (25 versus 8 percent). They also had more frequent meconium passage (44 versus 8 percent), and the two fetal deaths were associated with thick meconium and a normal antepartum test within 5 days.

ACUTE FATTY LIVER OF PREGNANCY

Acute liver failure may be caused by fulminant viral hepatitis, drug-induced hepatic toxicity, or acute fatty liver of pregnancy. The latter is also called **acute fatty metamorphosis** or **acute yellow atrophy**, and it is an uncommon complication that often has proved fatal for both mother and fetus. In its worst form, the incidence is probably about 1 in 10,000 pregnancies. [Reyes and associates \(1994\)](#) reported the incidence to be 1 in 15,000 in Santiago, Chile, while [Castro and colleagues \(1996a\)](#) found it to be 1 in 7000 in Los Angeles.

Gross examination of the liver in fatal cases shows a small, soft, yellow, and greasy organ. The prominent histological abnormalities consist of swollen hepatocytes in

which the cytoplasm is filled with microvesicular fat with central nuclei and periportal sparing and minimal hepatocellular necrosis ([Fig. 48-3](#)).

ETIOLOGY AND PATHOGENESIS. Current evidence suggests that recessively inherited mitochondrial abnormalities of fatty acid oxidation predispose a woman to fatty liver in pregnancy. From some reports, if the fetus is homozygous, the mother manifests liver failure. [Sims and co-workers \(1995\)](#) described a familial deficiency of long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) caused by a single codon mutation. Affected homozygous children had Reye-like syndromes, and some of these heterozygous women suffered fatty liver of pregnancy. There are other less common single-gene mutations that cause deficiency of β -oxidation enzymes. [Isaacs and colleagues \(1996\)](#) described a compound heterozygous fetus associated with maternal fatty liver in a heterozygous woman.

It would also appear that heterozygous [LCHAD](#)²-deficient mothers are at risk for obstetrical complications even if their fetus is heterozygous or normal. [Tyni and colleagues \(1998\)](#) reviewed 79 pregnancies in 18 mothers with abnormal LCHAD heterozygosity. In 29 pregnancies, there was a homozygous LCHAD-deficient fetus, and preeclampsia and HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets) were confined to this group. Almost half of LCHAD-deficient fetuses were growth restricted compared with only 10 percent of LCHAD-normal or carrier fetuses. In some of these there was growth restriction with no other complications. Earlier, [Minakami and co-workers \(1988\)](#) had linked biopsy-proven fatty metamorphosis in Japanese women with preeclampsia, with and without liver dysfunction. These women were studied before recognition of the gene mutations for β -oxidation enzymes.

Recurrent fatty liver in subsequent pregnancy is uncommon, but a few cases have been described ([MacLean and co-workers, 1994](#); [Reyes and associates, 1994](#); [Usta and colleagues, 1994](#)). This is more likely if the woman has a homozygously affected fetus ([Treem and associates, 1994](#); [Tyni and colleagues, 1998](#)).

CLINICAL FINDINGS. Acute fatty liver usually manifests late in pregnancy, although [Monga and Katz \(1999\)](#) described a typical case that began at 22 weeks. [Castro and colleagues \(1996a\)](#) reported a mean gestational age of 37.5 weeks (range 31 to 42) in 28 women with the syndrome. For inexplicable reasons, the disease is more common in nulliparas. It likely is more common with a male fetus, and 15 percent of cases have a multifetal gestation ([Davidson and associates, 1998](#)). Typically, there is onset over several days to weeks of malaise, anorexia, nausea and vomiting, epigastric pain, and progressive jaundice. In many women, vomiting is the major symptom. In perhaps half of these women, there is hypertension, proteinuria, and edema—signs suggestive of preeclampsia. Laboratory abnormalities include hypofibrinogenemia and prolonged clotting studies, hyperbilirubinemia of usually less than 10 mg/dL, and serum transaminase levels of 300 to 500 U/L ([Table 48-6](#)). Peripheral blood shows hemoconcentration and leukocytosis, frequently mild thrombocytopenia, and evidence for hemolysis. [Castro and associates \(1996a\)](#) also described markedly reduced antithrombin III levels.

Various imaging techniques have been purported to confirm the clinical diagnosis of acute fatty metamorphosis ([Watson and Seeds, 1990](#)). [Castro and associates \(1996b\)](#) found poor sensitivity with sonography (3/11), computed tomographic scanning (5/10), and magnetic resonance imaging (0/5). [Usta and colleagues \(1994\)](#) also observed that only 2 of 10 women studied with computed tomography had positive findings.

In many women, the syndrome worsens after diagnosis. Marked hypoglycemia is common, and obvious hepatic coma develops in 60 percent, severe coagulopathy in 55 percent, and evidence for renal failure in about half. Fetal death is common at this severe stage. Fortunately, either the disease is self-limited, or as generally accepted, delivery arrests rapid deterioration of liver function. During recovery, evidence for transient diabetes insipidus and acute pancreatitis is common and ascites is almost universal. Recovery usually is complete.

We have encountered a number of women with what appears to be a **forme fruste** of this disorder. Clinical involvement is relatively minor and laboratory aberrations—usually hemolysis and decreased fibrinogen levels—call attention to an abnormality. It is unlikely that there is a spectrum of liver involvement, and that liver failure is not universal and only represents the most extensive involvement. Probably many milder cases go unnoticed or they are attributed to preeclampsia.

COAGULOPATHY. The pathogenesis of the coagulopathy that complicates fatty liver of pregnancy results from increased consumption of procoagulants as well as impaired production by the liver. Shown in [Table 48-6](#) are laboratory data suggestive of consumptive coagulopathy in 62 women with acute fatty liver. Almost all had low plasma fibrinogen levels. These are accompanied by variable elevations of fibrin split products or D-dimers. In a few cases, profound thrombocytopenia develops ([Table 48-6](#)). There usually is evidence for hemolysis, which can be severe. Echinocytes are the predominant red cell abnormality, presumably caused by impaired hepatic synthesis of various lipid components of the erythrocyte membrane ([Cunningham and colleagues, 1985](#)).

EFFECTS ON PREGNANCY. When there is severe hepatic dysfunction, there is frequently severe maternal hypovolemia and acidosis. Four of 14 women with acute fatty liver described by [Usta and associates \(1994\)](#) had encephalopathy. In the past, maternal mortality approached 75 percent, however, the contemporaneous outlook is much better. In the 62 women shown in [Table 48-6](#), there were only two maternal deaths. Also in the past, fetal mortality was reported to be nearly 90 percent, but this now is about 15 to 20 percent.

MANAGEMENT. Because spontaneous resolution usually follows delivery, many clinicians assume that delivery is essential for cure. Because of maternal acidosis that develops from liver failure in severe cases, some fetuses are dead when the diagnosis is made, and many others tolerate the stresses of even normal labor poorly. Procrastination in effecting delivery can increase the risk of coma and death from hyperammonemia, which is often further complicated by hypoglycemia, renal failure, acidosis, and severe hemorrhage.

Some authors recommend cesarean delivery to minimize the time until restoration of hepatic function begins. Cesarean delivery in the presence of a severe coagulopathy, however, may prove dangerous for the mother. Other problems might be encountered with an abdominal incision in circumstances in which severe hypoproteinemia and ascites are likely complications. Transfusions with variable amounts of fresh-frozen plasma, cryoprecipitate, whole blood, packed red cells, and platelets are usually necessary if surgery is performed or if lacerations complicate vaginal delivery ([Chap. 25, p. 653](#)).

Following delivery, hepatic dysfunction resolves. In the interim, intensive medical support is required. Maternal deaths are reported to be caused by sepsis, hemorrhage, aspiration, renal failure, pancreatitis, and gastrointestinal bleeding. Therapy is directed toward these complications. If hepatic failure does not resolve, liver transplantation is an alternative ([Franco and colleagues, 2000](#); [Ockner and associates, 1990](#)). According to [Kennedy and co-workers \(1994\)](#), diabetes insipidus, presumably due to elevated vasopressinase concentrations, is common, and in our experiences, it develops in over half of affected women.

THE LIVER IN PREECLAMPSIA-ECLAMPSIA

The liver may be involved in women with severe preeclampsia and eclampsia ([Chap. 24, p. 579](#)). The lesion is unique and consists of periportal hemorrhage, fibrin deposition, and hepatocyte disruption with necrosis ([Riely and Fallon, 1999](#)). Both the degree of dysfunction and the histological changes that develop can vary considerably. Typically, upper abdominal pain—epigastric or right upper quadrant—signals potentially dangerous liver involvement. Thrombocytopenia commonly accompanies elevations in serum transaminase levels. Although aspartate aminotransferase levels vary from 50 to 3000 U/L, typically they are less than 500 U/L. Serum bilirubin levels sometimes are mildly elevated. Intrahepatic and subcapsular hemorrhage may develop and become so intense as to rupture the liver and produce extensive and fatal hemorrhage.

These complications were first described by [Pritchard and colleagues in 1954](#). [Weinstein \(1982\)](#) later named this the **HELLP syndrome to describe hemolysis (H), elevated liver enzymes (EL), and low platelets (LP)**³. There is clinical evidence that this syndrome may overlap with that of acute fatty liver of pregnancy.

PATHOGENESIS. Like other organs, most pathological lesions of liver involvement with preeclampsia are explicable on the basis of ischemia. This is perhaps enigmatic because the liver receives only a third of its blood supply from the hepatic artery, which can even be ligated without major sequelae ([Stain and co-workers, 1996](#)). The portal venous system is the major source of blood to the liver.

The exact incidence of liver involvement with preeclampsia is unknown, but it seems to be related to the severity of disease. For example, elevated serum transaminase levels are more common if thrombocytopenia is also identified. In some cases, however, the liver may be the only organ with obvious major involvement. Certainly, as illustrated by data shown in [Table 48-7](#), liver involvement is common in fatal cases. [Rolfes and Ishak \(1986\)](#) reviewed findings in 97 women who died from preeclampsia-eclampsia and who were autopsied at the Armed Forces Institute of Pathology. There were hepatic histological abnormalities in 72 percent and 13 percent had infarctions. Other findings were periportal fibrin deposition, hemorrhage, and hepatocellular necrosis ([Fig. 48-4](#)).

CLINICAL PRESENTATION. In most women with preeclamptic liver disease, there will be obvious pregnancy-induced hypertension. Although the liver is more likely to be affected if there is epigastric pain, most women have no symptoms relating to the liver, and laboratory assessment discloses elevated serum transaminase levels. In most cases, these seldom exceed 200 to 500 U/L ([Watson and Seeds, 1990](#)). Similarly, serum bilirubin levels seldom exceed 2 to 4 mg/dL. Hepatic failure with encephalopathy and consumptive coagulopathy are not usual features of preeclamptic liver disease. Indeed, in the 97 fatal cases described by [Rolfes and Ishak \(1986\)](#), hepatic failure was diagnosed in only four.

When the diagnosis of pregnancy-induced hypertension is equivocal, preeclamptic liver involvement must be differentiated from fatty liver and hepatitis. As discussed, women with fatty liver of pregnancy often have hypertension and proteinuria, and the degree of liver dysfunction is the differentiating factor. Women with hepatitis usually do not have hypertension.

Management of women with preeclampsia and liver involvement almost always includes prompt delivery. Laboratory abnormalities usually peak by 24 to 48 hours postpartum, and hepatic enzyme abnormalities, lactic dehydrogenase, and platelet counts begin to normalize typically within about 2 to 3 days ([Martin and colleagues, 1991](#)).

HEPATIC HEMATOMA AND RUPTURE. Hemorrhage from hepatic and subcapsular hematomas are two feared complications of liver involvement with preeclampsia. [Smith and colleagues \(1991\)](#) reported an incidence of 1 in 45,000 pregnancies at Baylor College of Medicine. Our experiences from Parkland Hospital are similar. [Stain and co-workers \(1996\)](#) reported an incidence of 1 in 15,000 at Los Angeles County—University of Southern California Medical Center. Although liver rupture may develop spontaneously in an otherwise normal pregnant woman, the majority of cases are associated with preeclampsia and eclampsia ([Ralston and Schwaitzberg, 1998](#); [Rolfes and Ishak, 1986](#)). As discussed in [Chapter 24 \(p. 579\)](#), women with HELLP⁴ syndrome are at much higher risk ([Sheikh and associates, 1999](#)). [Moen and associates \(1993\)](#) described a case associated with cocaine abuse in a woman at 30 weeks.

In typical cases, the hematoma usually develops on the diaphragmatic surface of the right lobe. Intrahepatic hematomas may also develop. It is likely that many of these go unrecognized. In other cases, there are right upper quadrant pain and tenderness, and the diagnosis can be confirmed by computed tomography ([Fig. 48-5](#)).

If the hematoma is intrahepatic and intact, close observation is reasonable. In some cases, however, liver rupture stimulates further bleeding which causes hemorrhagic shock and a distended abdomen that prompt surgical intervention before diagnostic studies can be performed. In these cases, management includes resuscitation and correction of associated coagulopathy along with surgical exploration. Hysterotomy is done if the woman is undelivered. Local hemostasis may be attempted with suture, cautery, or Argon laser. If unsuccessful, temporary packing, hepatic artery ligation, or partial hepatic resection are performed ([Ralston and Schwaitzberg, 1998](#)). Bleeding usually is severe. [Smith and associates \(1991\)](#) reported that packing was associated with an overall 80 percent survival compared with 25 percent if lobectomy was done. Conversely, [Stain and colleagues \(1996\)](#) reported that arterial ligation was preferable. We managed an eclamptic woman with hepatic rupture who required many surgical procedures for hemostasis and was given over 200 units of blood products; fortunately, she survived. [Hunter and colleagues \(1995\)](#) resorted to liver transplantation in a woman with uncontrollable hemorrhage following hematoma rupture.

Maternal mortality is high with overt rupture. Of eight cases reported by [Stain and co-authors \(1996\)](#), three died. [Ralston and Schwaitzberg \(1998\)](#) cited about 60 percent mortality from their review.

VIRAL HEPATITIS

Hepatitis is the most common serious liver disease encountered in pregnant women. There are at least five distinct types of viral hepatitis: hepatitis A; hepatitis B; hepatitis D caused by the hepatitis B-associated delta agent; hepatitis C; and hepatitis E. Hepatitis C is transmitted by serum and hepatitis E is enterically transmitted. A sixth agent, hepatitis G virus, also called GBV-C, is transmitted by blood transfusion, detected serologically, but may not cause liver disease. All but hepatitis B are RNA viruses.

During their acute phases, these forms of hepatitis are often clinically similar. Interestingly, the viruses are not actually hepatotoxic; it is the immune response to them that causes hepatocellular necrosis ([Dienstag and Isselbacher, 1998](#)). In many cases, infections are subclinical, but if clinically apparent, symptoms may precede jaundice by 1 to 2 weeks. Symptoms include nausea and vomiting, headache, and malaise. Low-grade fever is more common with hepatitis A. When jaundice develops, symptoms usually improve, but there may be pain and tenderness over the liver. Serum aminotransferase levels vary, and their peaks do not correspond with disease severity. Peak levels of 400 to 4000 U/L are usually reached by the time jaundice develops ([Dienstag and Isselbacher, 1998](#)). Serum bilirubin levels usually peak at 5 to 20 mg/dL, and they typically continue to rise despite falling aminotransferase levels. There usually is complete clinical and biochemical recovery within 1 to 2 months in all cases of hepatitis A and most cases of hepatitis B.

The Centers for Disease Control have issued guidelines to minimize infectivity of patients hospitalized for viral hepatitis. It recommends that feces, secretions, and bedpans and other articles in contact with the intestinal tract be handled with glove-protected hands. These precautions need not be continued once hepatitis A is excluded. Extra precautions, such as double gloving during delivery and surgical procedures, are wise in cases of hepatitis B and C.

COMPLICATIONS. The case fatality rate for nonpregnant patients with acute hepatitis is 0.1 percent, and for those ill enough to be hospitalized, it is as high as 1 percent. Most fatalities are due to *fulminant hepatic necrosis*, which in later pregnancy must be distinguished from acute fatty liver. About half of patients with fulminant hepatitis have infection with the B virus, and many of these are associated with the delta agent. Hepatic encephalopathy is the usual presentation of patients with fulminant hepatitis, and mortality is 80 percent.

A small number of patients with hepatitis A infection have *relapsing hepatitis*, in which there is recurrence of symptoms and biochemical abnormalities weeks to months after recovery from acute infection. Some form of chronic hepatitis B infection follows acute disease in 5 to 10 percent of cases. Most of these patients will be asymptomatic carriers, but others have low-grade chronic persistent hepatitis or chronic active hepatitis with or without cirrhosis. Hepatitis C infection is associated with a high incidence of persistently abnormal biochemical tests, chronic active hepatitis, and cirrhosis.

HEPATITIS A. Previously called infectious hepatitis, this infection is caused by a 27-nm RNA picornavirus. It is transmitted by the fecal-oral route. Individuals developing this disease shed virus in their feces, and during the relatively brief period of viremia their blood is also infectious. The infection is usually spread by ingestion of contaminated blood or water, and the incubation period is about 2 to 7 weeks. The signs and symptoms are not very specific, and it may go undiagnosed. The majority of cases are anicteric. Although usually mild, occasionally fulminant hepatitis develops. This is more common if there is underlying chronic hepatitis C ([Vento and colleagues, 1998](#)).

Serological confirmation can be done even when serum transaminase levels are still elevated. Early detection is by identification of IgM antibody ([Table 48-8](#)). Although this indicates acute infection, it may persist for several months. During convalescence, IgG antibody predominates; it persists and is responsible for immunity from subsequent hepatitis A infection. The formalin-inactivated vaccine is reported to be over 90 percent effective. The [Centers for Disease Control and Prevention \(1999\)](#) recommends consideration for vaccination of susceptible persons traveling to high-risk countries, illicit drug users, those with chronic liver disease or clotting-factor disorders, and food handlers. [Duff and Duff \(1998\)](#) recently reviewed its use.

HEPATITIS A AND PREGNANCY. In developed countries, the effects of hepatitis A on pregnancy are not dramatic. At least in some underprivileged populations, however, both perinatal and maternal deaths are substantively increased. Treatment consists of a balanced diet and diminished activity. We have long followed the policy of hospitalizing all pregnant women with hepatitis until it is clear that they are able to eat and drink, and that liver function is improving, or at least not continuing to deteriorate. Women with less severe illness may be managed as outpatients ([American College of Obstetricians and Gynecologists, 1998](#)).

There is no evidence that hepatitis A virus is teratogenic. Risk of transmission to the fetus is negligible, but vertical transmission at the time of delivery was documented to cause an outbreak of hepatitis A in a neonatal intensive care unit ([Watson and colleagues, 1993](#)). The risk of preterm birth appears to be increased somewhat for pregnancies complicated by hepatitis A.

The pregnant woman recently exposed by close personal or sexual contact to a person with hepatitis A should be given prophylaxis with 1 mL immune globulin.

HEPATITIS B. Once referred to as serum hepatitis, this infection is found worldwide but is endemic in some regions, especially in Asia and Africa. Hepatitis B is a DNA hepadnavirus that is a major cause of acute hepatitis and its serious sequelae, namely chronic hepatitis, cirrhosis, and hepatocellular carcinoma. The latter is so common that the World Health Organization considers hepatitis B to be second only to tobacco among human carcinogens. The most serious consequences are the result of chronic infection, which occurs in 5 to 10 percent of infected adults and 70 to 90 percent of infected infants. According to the [Centers for Disease Control and Prevention \(1998b\)](#), reported cases decreased by 50 percent from 1990 to 1998. Only half of cases are icteric and symptomatic. There are an estimated 1 million chronic carriers.

A variety of immunological markers to hepatitis B have been identified in patients with acute or chronic disease, in those who have had the disease and now are immune, and in chronic carriers. The hepatitis B virus (Dane particle), core antigen (HB_cAg), surface antigen (HB_sAg), e antigen (HB_eAg), and their corresponding antibodies are all detectable by various techniques. The virus is unique in that concentrations of viral antigen and particles in serum and other body fluids may reach

10 trillion per milliliter.

Hepatitis B infections are found most often among intravenous drug abusers, homosexuals, health-care personnel, and patients who have been treated often with blood products, such as hemophiliacs. It is transmitted by infected blood or blood products, and in saliva, vaginal secretions, and semen; thus, it is a sexually transmitted disease. The e antigen correlates with infectivity and the presence of intact viral particles.

After infection with hepatitis B, the first virological marker is HB_sAg (Fig. 48-6). Infection is diagnosed by detection of HB_sAg in serum. Although HB_eAg invariably is present during early acute hepatitis, its persistence indicates chronic infection. Approximately 90 percent of persons with hepatitis B infections recover completely. Of the 10 percent who are chronically infected, about a fourth develop chronic liver disease.

HEPATITIS B AND PREGNANCY. Neither the prevalence nor the clinical course of hepatitis B infection in the mother, including fulminant hepatitis, is altered by pregnancy, at least in developed countries. Treatment is supportive, and as with hepatitis A, the likelihood for preterm delivery is increased.

Transplacental viral transfer from the mother to the fetus is associated with acute hepatitis but not chronic seropositivity. With acute infection in the first trimester, 10 percent of fetuses are infected, and in the third trimester this number is 80 to 90 percent ([American College of Obstetricians and Gynecologists, 1998](#)). With chronic maternal infection, perinatal transmission is by ingestion of infected material during delivery or exposure subsequent to birth, for example, breast feeding. Some infected infants are asymptomatic, others develop fulminant disease, and nearly 85 percent become chronic carriers. Vertical transmission correlates closely with maternal HB_eAg status. Mothers with hepatitis B surface and e antigens are very likely to transmit the disease to their infants, whereas those who are negative for e antigen but positive for anti-HB_e antibody do not appear to transmit the infection.

PREVENTION OF NEONATAL INFECTION. The [Centers for Disease Control \(1990\)](#) estimate that about 18,000 infants were born in the United States in 1987 to HB_sAg-positive women. Without immunoprophylaxis given at delivery, nearly 4000 will become chronically infected with hepatitis B. Infection of the newborn whose mother chronically carries the virus can usually be prevented by the administration of hepatitis B immune globulin very soon after birth, followed promptly by hepatitis B vaccine. As discussed in [Chapter 10 \(p. 240\)](#), concern for adverse effects of this vaccine appear to be unfounded according to the U.S. Food and Drug Administration ([Niu and colleagues, 1999](#)).

The [Centers for Disease Control \(1991\)](#), as well as the [American College of Obstetricians and Gynecologists \(1998\)](#), recommend hepatitis B serological screening for all prenatal patients. For inner-city lower socioeconomic groups, the prevalence of seropositivity for hepatitis B virus is about 1 percent. It is somewhat lower for military populations and private patients. In a study of over 7700 pregnant women, [Webb and associates \(1996\)](#) reported a prevalence of 0.85 percent for hepatitis B. [Rindfusz and colleagues \(1996\)](#), in a seroprevalence study of immunodeficiency virus, hepatitis B, and hepatitis C, found a rate of 2 percent. As emphasized by [Duff \(1994\)](#), selective screening will identify only 30 to 50 percent of seropositive women.

For high-risk mothers who test antigen negative, vaccine can be provided during pregnancy. [Ingardia and colleagues \(1999\)](#) observed that seroprotection in pregnant women (45 percent) was lower than the 60 to 70 percent cited for nonpregnant individuals. For women who test positive, offspring should be given hepatitis B immune globulin and recombinant vaccine. A second and third dose of vaccine are given to the child at 1 and 6 months of age.

HEPATITIS D. Also called delta hepatitis, this is a defective RNA virus that is a hybrid particle with a hepatitis B surface antigen coat and a delta core. The virus must co-infect with hepatitis B and cannot persist in serum longer than hepatitis B virus. Transmission is similar to hepatitis B viral infection. Chronic infection with B and D hepatitis produces more severe disease and up to 75 percent of those affected develop cirrhosis. Neonatal transmission has been reported, but hepatitis B vaccination usually prevents delta hepatitis.

HEPATITIS C. This is a single-stranded RNA virus of the family Flaviviridae. Transmission of hepatitis C infection appears to be identical to hepatitis B. While it is more prevalent in intravenous drug abusers, hemophiliacs, and those with high-risk sexual behavior, only half of anti-HCV positive persons have risk factors ([Alter and co-workers, 1999](#)). The [Centers for Disease Control and Prevention \(1998a\)](#) cites a seroprevalence of 1.8 percent, or 4 million infected Americans. After acute infection, anti-C antibody is not detected for an average of 15 weeks, and in some cases it is not detectable for a year. Antibody does not prohibit transmission, and [Conry-Cantilena and colleagues \(1996\)](#) found that 86 percent of 213 anti-HCV positive persons had hepatitis C virus RNA and thus were infective.

The incidence of persistent disease is common after hepatitis C infection. About half of patients have abnormal liver tests for more than a year. In two thirds of these, biopsy shows chronic active hepatitis, which in 20 to 30 percent will progress to cirrhosis within 20 to 30 years.

Screening of blood donors for hepatitis C virus has markedly decreased the incidence of post-transfusion hepatitis. According to [Dienstag and Isselbacher \(1998\)](#), the incidence of transfusion-related hepatitis has fallen to imperceptible levels since screening has been done with second-generation anti-HCV assays.

EFFECT ON PREGNANCY. There is no reason to believe that antepartum hepatitis C infection is different compared with nonpregnant women. Importantly, 75 percent of anti-HCV positive individuals have chronic disease. [Bohman and colleagues \(1992\)](#) reported a 2.3 percent seroprevalence rate in pregnant women at Parkland Hospital. Risk factors included intravenous drug use, sexually transmitted diseases, increased age and parity, history of transfusions, multiple sex partners, and sex partners who used intravenous drugs. In a similar population from San Juan, Puerto Rico, [Deseda and associates \(1995\)](#) found a 1.9 percent prevalence. [Silverman and colleagues \(1993\)](#) found a seroprevalence of 4.3 percent in pregnant women from a university hospital in Philadelphia. Women attending public clinics had an incidence of 5.2 percent whereas only 1.5 percent of private patients were anti-HCV positive. In another serosurvey of high-risk prenatal patients, [Leikin and co-workers \(1994\)](#) reported a seroprevalence rate of 4.6 percent.

Perinatal outcome is not adversely affected in anti-HCV positive women compared with seronegative controls. Importantly, however, hepatitis C infection is transmitted vertically to the fetus-infant. There have now been a number of studies that have addressed this, and the vertical transmission rate varies between 3 and 6 percent ([Conte, 2000](#); [Hillemanns, 2000](#); [Ohto, 1994](#); [Resti, 1998](#), and all their colleagues). As in adult-to-adult transmission, antibody is not protective, and [Floreani and co-workers \(1996\)](#) found that 65 percent of anti-HCV positive mothers also had hepatitis C virus RNA.

Currently, there are no methods to prevent transmission at birth ([American College of Obstetricians and Gynecologists, 1998](#)). Because of this, the [Centers for Disease Control and Prevention \(1998a\)](#) do not recommend screening in pregnant women; however, neonates of known anti-HCV-positive mothers should be tested and provided follow-up. [Burns and Minkoff \(1999\)](#) recommend selective screening based on risk factors. Women found to be anti-HCV-positive are offered counseling and identified for long-term follow-up.

HEPATITIS E. This is a waterborne RNA virus that is enterically transmitted. Epidemiologically it has features resembling hepatitis A; for example, it causes epidemic outbreaks in undeveloped countries. Serological confirmation is currently not widely available. Most cases are transmitted by contaminated water supplies, and the disease is not easily communicable by person-to-person contact. Preliminary evidence in infected pregnant women suggests a high incidence of vertical transmission, including transplacentally ([Khuroo and colleagues, 1995](#)). There is some evidence that it is more severe in pregnancy, especially when acquired late ([Baker, 2000](#)).

HEPATITIS G. Bloodborne infection with this flavivirus-like RNA virus is usually with hepatitis C co-infection. It does not increase the severity of infection, and while it can cause chronic infection, its contribution to acute or chronic liver disease requires better definition ([Dienstag and Isselbacher, 1998](#)). In a Scottish study, 0.08 percent of over 180,000 nonremunerated blood donors were seropositive ([Jarvis and associates, 1996](#)). Infant transmission has been described by [Feucht \(1996\)](#) and [Inaba \(1997\)](#) and their colleagues.

CHRONIC HEPATITIS

This is a disorder of varying etiology that is characterized by continuing hepatic necrosis, active inflammation, and fibrosis that may lead to cirrhosis and ultimately liver failure. It has only been in the last decade that the extent of chronic liver disease due to acute viral hepatitis has been appreciated. By far, most cases are due to chronic infection with either hepatitis B or C viruses. Another cause is autoimmune chronic hepatitis, characterized by high serum titers of homogeneous antinuclear antibodies. In both forms, there is evidence that a cellular immune reaction is interactive with a genetic predisposition.

As discussed earlier, most cases of acute viral hepatitis B and C go clinically unnoticed. Similarly, most cases of chronic hepatitis are asymptomatic and frequently are suspected from elevated serum transaminase levels done for screening, for example, during blood donation or life insurance application. When present, symptoms are nonspecific and usually include fatigue. Diagnosis is made by liver biopsy. In some patients, cirrhosis with liver failure or bleeding varices is the presenting finding.

There is now considerable experience with treatment of chronic viral hepatitis with one of the *interferons*. These are cytokines with antiviral, antiproliferative, and immunoregulatory effects. Treatment for 6 months has been shown to decrease viremia and improve histological findings in about 40 percent of patients, but the relapse rate is 20 percent. The synthetic nucleoside *ribavirin*, while not very effective alone, improves the efficacy of interferon therapy ([Davis and associates, 1998](#); [McHutchinson and co-workers, 1998](#)). The nucleoside analog *lamivudine* was also found to be effective in about 50 percent of patients ([Dienstag and colleagues, 1999](#); [Lai and associates, 1998](#)).

CHRONIC HEPATITIS AND PREGNANCY. Pregnancy is uncommon when disease is severe because anovulation is common. Most young women, however, are either asymptomatic or have only mild liver disease. For the seropositive, asymptomatic woman, there usually is no problem with pregnancy. With known (symptomatic) chronic active hepatitis, interaction with pregnancy will depend primarily on the intensity of the disease and whether there is portal hypertension ([Lee, 1992](#)). The few women whom we have managed have done well, but because their long-term prognosis is poor, they should be counseled regarding abortion and sterilization. As discussed on page 1284, [Locatelli and co-workers \(1999\)](#) have observed a higher incidence of cholestatic jaundice in hepatitis C seropositive women (16 percent) compared with negative controls (0.8 percent).

In women with autoimmune chronic hepatitis, corticosteroids, alone or combined with azathioprine, have increased fertility and survival. Their pregnancy outcome is also related to severity of disease ([Levine, 2000](#)).

CIRRHOSIS

Hepatic cirrhosis is characterized by irreversible chronic injury to the liver parenchyma with extensive fibrosis and regenerative nodules. In all patients, *Lannec cirrhosis* from chronic exposure to alcohol is the most common cause. In young women, however, and thus most pregnant women, *postnecrotic cirrhosis* from chronic B or C viral hepatitis is the most common cause. Other causes include biliary cirrhosis from long-standing obstruction and cardiac cirrhosis from chronic right-sided heart failure. [Fung and Li \(1999\)](#) described a pregnant woman with biliary cirrhosis from recurrent pyogenic cholangitis. Although cirrhosis is the final common pathway for a variety of hepatic injuries, the clinical manifestations are inseparable. These include jaundice, edema, coagulopathy, metabolic abnormalities, and portal hypertension along with its sequela of gastroesophageal varices and splenomegaly.

CIRRHOSIS AND PREGNANCY. Women with cirrhosis are very likely to be infertile. Traditionally, perinatal loss is high, and maternal prognosis grave. Esophageal varices were prone to bleed, with fatal hemorrhage as the consequence. [Schreyer and associates \(1982\)](#) reviewed 69 pregnancies in 60 women with cirrhosis without shunts and 28 pregnancies in another 23 women with cirrhosis who had undergone portal decompression shunting. Severe variceal hemorrhage was increased sevenfold in nonshunted women compared with those who had undergone such procedures (24 versus 3 percent). [Pajor and Lehoczky \(1994\)](#) cared for 11 cirrhotic women during pregnancy. Although all survived, transient hepatic failure developed in six, variceal hemorrhage in six, and 6 of 12 infants were growth restricted. [Aggarwal and associates \(1999\)](#) reported nine pregnancies in seven women with cirrhosis. Half were delivered preterm, and one woman died.

ESOPHAGEAL VARICES

Portal venous hypertension that results from cirrhosis or from extrahepatic portal vein obstruction is associated with esophageal varices. Postnecrotic hepatitis and chronic alcoholism with cirrhosis and hepatic sinusoidal resistance account for almost all cases of portal hypertension in young women. A seemingly equal number of cases of esophageal varices, at least in pregnant women, are caused by extrahepatic portal hypertension in which there is resistance to flow in portal or splenic veins. About half of these are idiopathic, but a number arise as a complication of thrombosis from umbilical vein catheterization when the woman was a neonate.

Whatever its underlying cause, portal vein pressure rises from its normal value of 10 to 15 mm Hg to exceed 30 mm Hg. This leads to formation of a collateral circulation, which carries blood to the systemic circulation. Drainage is via the gastric, intercostal, and other veins ultimately to the esophageal system, where varices develop. Bleeding is usually from varices near the gastroesophageal junction. About a third of patients bleed, and the mortality is 50 percent with the first episode. Most bleed again, with a 30 percent mortality. Bleeding can be torrential. Acute therapy consists of early endoscopy for diagnosis with *band ligation* for control of hemorrhage ([Stanley and Hayes, 1997](#)). In some cases, *sclerotherapy* by intravariceal injection may facilitate banding. *Balloon tamponade* of severe bleeding using a triple-lumen tube can be lifesaving. Emergency shunting is used in 10 to 20 percent of patients in whom hemorrhage is not controlled by endoscopy. This interventional radiology procedure, known as *transjugular intrahepatic portosystemic stent shunting (TIPSS)*, can also control bleeding from gastric varices.

VARICES AND PREGNANCY. Bleeding from esophageal varices causes much of the maternal mortality associated with cirrhosis. [Hillemanns and colleagues \(1996\)](#) described a maternal death at 20 weeks when portal hypertension caused rupture of a splenic artery aneurysm. There is concern that vaginal delivery with increased portal pressures from Valsalva maneuvers will increase the risk of bleeding ([Lee, 1992](#)). [Britton \(1982\)](#) reviewed outcomes in 160 pregnancies complicated by cirrhosis, varices, or both ([Table 48-9](#)). Bleeding was common when pregnancy was complicated by varices, regardless of whether these were associated with cirrhosis. Mortality, however, was higher if varices were associated with cirrhosis. Specifically, maternal mortality from bleeding in women with cirrhosis was 18 percent, but it was only 2 percent in those without cirrhosis. Perinatal mortality was high in both groups.

MANAGEMENT. Treatment during pregnancy is the same as for the nonpregnant patient. For the woman with known varices, β -blocking drugs such as propranolol are given to reduce portal pressure and hence the risk of bleeding. Endoscopic band ligation can be done for acute bleeding ([Starkel and associates, 1998](#)). It also can be done prophylactically, and [Zeeman and Moise \(1999\)](#) described a woman who underwent banding at 15, 26, and 31 weeks to prevent bleeding. Sclerotherapy has also been successfully used during pregnancy ([Iwase and colleagues, 1994](#); [Pauzner and associates, 1991](#)). There is little experience in pregnancy with TIPSS.

ACUTE ACETAMINOPHEN OVERDOSAGE

Acetaminophen is commonly used during pregnancy. Overdosage from suicidal attempts may lead to acute liver failure. Early symptoms of overdosage are nausea, vomiting, diaphoresis, malaise, and pallor. After a latent period of 24 to 48 hours, liver failure begins to develop, and usually begins to resolve in 5 days.

The antidote is *N*-acetylcysteine, and it must be given promptly. The drug is thought to act by increasing glutathione levels, which facilitates metabolism of the toxic metabolite. The need for treatment is based on projections of possible plasma hepatotoxic levels as a function of the time of acute ingestion. Many clinicians use the nomogram established by [Rumack and Matthew \(1975\)](#). Plasma levels are obtained 4 hours after ingestion, and if greater than 120 $\mu\text{g/mL}$, treatment is given. If plasma determinations are not available, empirical treatment is given if the dose exceeded 7.5 g. An oral loading dose of 140 mg/kg of *N*-acetylcysteine is followed by 17 maintenance doses of 70 mg/kg every 4 hours for 72 hours total treatment time.

After 14 weeks, the fetus has some cytochrome P-450 activity, which is necessary for metabolism of acetaminophen to the toxic metabolite. [Riggs and colleagues \(1989\)](#) reported data from the Rocky Mountain Poison and Drug Center and described follow-up experiences in 60 such women. The likelihood of maternal and fetal survival was better if the antidote was given soon after overdosage. At least one 33-week fetus appears to have died as a direct result of hepatotoxicity 2 days after ingestion. The case reported by [Wang and associates \(1997\)](#) describes similar acetaminophen levels in maternal and cord blood of about 41 $\mu\text{g/mL}$, which confirms placental transfer. Both mother and infant died from hepatorenal failure within $1/2$ to 3 days after ingestion.

LIVER TRANSPLANTATION

The first successful pregnancy in a liver transplantation recipient was reported by [Walcott and associates \(1978\)](#). Since then, a number of women with successful pregnancies following transplantation have been described. The Pittsburgh group reported experiences with 12 pregnancies in 11 women ([Laifer and colleagues, 1990](#)). While most had stable serum hepatic transaminase levels, three women had acute or chronic rejection or hepatitis. Pregnancy complications included hypertension in half the women, anemia in 25 percent, and preterm delivery in 80 percent. Neuropsychiatric complications were also common. [Ville and co-workers \(1993\)](#) described pregnancy outcomes in 19 French women after liver transplantation. Of 11 viable pregnancies, all were delivered at term, although hypertension developed in three and liver dysfunction in one. [Skannal and associates \(1995\)](#) described a successful outcome in a woman with a combined liver-kidney transplant.

[Radomski and associates \(1995\)](#) presented results from the National Transplantation Pregnancy Registry. They described outcomes in 38 pregnancies in 29 transplantation recipients. More than 80 percent of infants were live-born, and only 40 percent were preterm. [Raves \(1998\)](#) described 19 pregnancies in 16 German women who underwent liver transplantation. There were six abortions, 12 term babies, and one preterm. Three term infants were growth restricted. Of 13 viable infants, five had hypertension and two had transient serum transaminase level increases.

DISEASES OF THE GALLBLADDER AND PANCREAS

CHOLELITHIASIS AND CHOLECYSTITIS

In the United States, 20 percent of women over 40 have gallstones. Most stones contain cholesterol, and its oversecretion into bile is thought to be a major factor in the pathogenesis. Biliary sludge, which may increase during pregnancy, is an important precursor to gallstone formation. The cumulative risk of a patient with silent gallstones to require surgery for symptoms or complications is about 1 to 2 percent per year; it is 10 percent at 5 years, and 18 percent at 15 years ([Greenberger and Isselbacher, 1998](#)). For these reasons, prophylactic cholecystectomy is not warranted for asymptomatic stones.

A number of nonsurgical approaches have been used for gallstone disease. These include oral bile acid therapy with chenodeoxycholic acid, extracorporeal shock wave lithotripsy, and contact dissolution with methyl tertbutyl ether placed directly into the gallbladder. There is no experience with any of these methods during pregnancy, and they are currently not recommended.

Acute cholecystitis usually develops when there is obstruction of the cystic duct. Bacterial infection plays a role in 50 to 85 percent of these acute inflammatory conditions. In over half of patients with acute cholecystitis, a history of previous right-upper-quadrant pain from cholelithiasis is elicited. With acute disease, pain is accompanied by anorexia, nausea and vomiting, low-grade fever, and mild leukocytosis. Ultrasonography can be used to visualize stones as small as 2 mm, and false-positive and false-negative rates for diagnosing gallstones are about 2 to 4 percent ([Greenberger and Isselbacher, 1998](#)). Ultrasonic examination confirms gallstones in up to 90 percent of patients ([Fig. 48-7](#)).

Symptomatic gallbladder diseases include acute cholecystitis, biliary colic, jaundice, and acute pancreatitis. In most of these cases, cholecystectomy is warranted ([Bateson, 1999](#)). Whereas acute cholecystitis responds to medical therapy, contemporary consensus is that early cholecystectomy is indicated ([Greenberger and Isselbacher, 1998](#)). In acute cases, medical therapy consisting of nasogastric suction, intravenous fluids and antimicrobials, and analgesics is instituted before surgical therapy. According to a [National Institutes of Health Consensus Conference \(1993\)](#), laparoscopic cholecystectomy has become the treatment of choice for most patients. Data from most centers indicate a twofold increased incidence of major biliary, vascular, and bowel complications when the laparoscopic technique is compared with open cholecystectomy ([Fletcher and co-workers, 1999](#)).

GALLBLADDER DISEASE DURING PREGNANCY. Most findings are supportive of the view that pregnancy increases the risk of gallstones. After the first trimester, both gallbladder volume during fasting and residual volume after contracting in response to a test meal are twice as great as in nonpregnant subjects ([Braverman and colleagues, 1980](#)). Incomplete emptying may result in retention of cholesterol crystals, a prerequisite for cholesterol gallstones. Biliary sludge, probably a forerunner to gallstones, was immediately seen ultrasonically in one fourth of nearly 300 postpartum women. [Maringhini and co-workers \(1987\)](#) used similar techniques and showed that 30 percent of women developed sludge during pregnancy. In many cases this resolves within a year.

MANAGEMENT. Acute cholecystitis during pregnancy or the puerperium is initially managed in a manner similar to that for nonpregnant women. In the past, most practitioners favored medical therapy. [Landers and colleagues \(1987\)](#) at the University of California, San Francisco, first reported their experiences with 30 women with cholecystitis for an incidence of about 1 in 1000 deliveries. Gallstones were found in 96 percent of women, and although most presented for care before the third trimester, 25 women were treated conservatively, but four of these failed such therapy. [Glasgow and co-workers \(1998\)](#) from the same institution later reported experiences with another 47 pregnant women with symptomatic gallstones. Conservative therapy was attempted in all, but 36 percent required surgery.

[Dixon and colleagues \(1987\)](#) performed cholecystectomies in 18 of 44 women with acute cholecystitis or cholelithiasis with biliary colic. The women treated surgically did well; however, 15 of the 26 managed medically had recurrent symptoms during pregnancy. Multiple hospitalizations were common in the latter group, and two women required prolonged parenteral nutrition during late pregnancy. [Davis and co-workers \(1995\)](#) and [Lee and associates \(2000\)](#) described a total of 77 cases of cholecystitis and cited better outcomes with primary surgical management.

Because of these factors—namely, cholecystitis is a surgical disease; it has a high recurrence rate during the same pregnancy; and when it recurs later in gestation, preterm labor is more likely and cholecystectomy technically more difficult—our management at Parkland Hospital has evolved to a more aggressive surgical approach. This is particularly true for the woman with concomitant biliary pancreatitis (see later discussion).

LAPAROSCOPIC CHOLECYSTECTOMY. Uncomplicated laparoscopic cholecystectomy in a 31-week pregnant woman was first described by [Pucci and Seed \(1991\)](#). Subsequently, reasonable experiences have been reported from several centers that indicate this to be as equally acceptable as open cholecystectomy before the third trimester ([Barone, 1999](#); [Cosenza, 1999](#); [Glasgow, 1998](#), and their colleagues). [Graham and co-workers \(1998\)](#) reviewed 105 cases reported through 1997 and added six of their own. They concluded that laparoscopic cholecystectomy was safe throughout pregnancy.

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY. Treatment during pregnancy of biliary duct obstruction by gallstones has been greatly facilitated by their removal with endoscopic retrograde cholangiopancreatography (ERCP) ([Nesbitt and co-workers, 1996](#)). Because these patients have more morbidity and mortality, especially with associated biliary pancreatitis, it has become commonplace to perform endoscopic sphincterotomy and gallstone extraction to be followed in a few days with laparoscopic cholecystectomy. In most cases, it will also obviate the need for intraoperative cholangiography, which some feel is contraindicated in pregnancy ([Graham and colleagues, 1998](#)).

ASYMPTOMATIC GALLSTONES DURING PREGNANCY. Gallstones are relatively common in asymptomatic pregnant women. An incidence of ultrasonically visualized asymptomatic stones of 2.5 to 10 percent during pregnancy or the puerperium has been reported in over 1500 women ([Maringhini and colleagues, 1987](#); [Valdivieso and co-workers, 1993](#)). Cholecystectomy is not indicated for silent stones during pregnancy.

PANCREATITIS

Acute pancreatic inflammation is triggered by activation of pancreatic trypsinogen followed by autodigestion characterized by cellular membrane disruption and proteolysis, edema, hemorrhage, and necrosis. In nonpregnant patients, acute pancreatitis is most likely associated with gallstones (45 percent) and alcohol abuse (35 percent), but during pregnancy, cholelithiasis is almost always the predisposing condition. It also is encountered in the postoperative patient and is associated with trauma, drugs, certain metabolic conditions including acute fatty liver of pregnancy, familial hypertriglyceridemia, and some viral infections. More recently, pancreatitis has been linked to the more than 800 mutations of the cystic fibrosis transmembrane conductance regulator gene ([Durie, 1998](#)).

Clinically, acute pancreatitis is characterized by mild to incapacitating epigastric pain, nausea and vomiting, and abdominal distention. Patients are usually in distress and have low-grade fever and tachycardia; hypotension is common. Findings include abdominal tenderness, and up to 10 percent of patients have associated pulmonary findings. Serum amylase levels three times upper normal values are confirmatory, but there is no correlation with their degree of elevation and severity of disease. In fact, usually by 48 to 72 hours, serum amylase levels return to normal despite evidence for continuing pancreatitis. Measurement of serum lipase activity increases the diagnostic yield. There is usually leukocytosis, and 25 percent of patients have hypocalcemia. Serum bilirubin and aspartate aminotransferase levels are usually somewhat elevated.

A number of prognostic factors may be used to predict severity of the disease. These include respiratory failure, shock, need for massive colloid replacement, hypocalcemia of less than 8 mg/dL, or dark hemorrhagic fluid on paracentesis. If three of the first four features are documented, survival is only 30 percent.

MANAGEMENT. Therapy is medical and includes analgesics for pain, intravenous hydration, and measures to decrease pancreatic secretion by ceasing oral intake. Nasogastric suction has not been shown to improve the outcome in mild to moderate disease. Antimicrobials have been shown to improve outcome in necrotizing pancreatitis ([Sainio and colleagues, 1995](#)). In most patients, acute pancreatitis is self-limited, and in 90 percent, inflammation subsides within 3 to 7 days after treatment. For patients with severe necrotizing pancreatitis, ERCP¹ and papillotomy is usually done and intensive supportive therapy is given. In some patients, laparotomy with debridement and drainage may be lifesaving.

PANCREATITIS DURING PREGNANCY. The predisposition of pregnancy toward gallstone formation may indirectly link pregnancy with pancreatitis. At Parkland Hospital, pancreatitis complicates about 1 in 3300 pregnancies ([Ramin and colleagues, 1995](#)). [Swisher and associates \(1994\)](#) reported an incidence of 1 in 1500 at UCLA Medical Center. [Legro and Laifer \(1995\)](#) found an incidence of 1 in 4000 at Magee Women's Hospital. In most of these women, cholelithiasis commonly coexists. In a small number of pregnant women with pancreatitis, there is an associated familial hyperlipidemic syndrome, usually hypertriglyceridemia ([Nies and Dreiss, 1990](#); [Sanderson and colleagues, 1991](#)). [Watts and associates \(1992\)](#) described two pregnant women with hypertriglyceridemia due to familial lipoprotein lipase deficiency.

DIAGNOSIS. Pancreatitis is diagnosed during pregnancy using the same criteria as in nonpregnant patients. [Legro and Laifer \(1995\)](#) reported 11 cases of pancreatitis complicating early pregnancy. Only a third were diagnosed correctly initially; another third were thought to have hyperemesis gravidarum. [Ramin and colleagues \(1995\)](#) reported that all but 1 of 43 pregnant women with pancreatitis had nausea, vomiting, and abdominal pain as presenting complaints. [Ordorica and](#)

[associates \(1991\)](#) confirmed earlier studies that serum amylase and lipase levels are not changed during pregnancy. Serial determinations of serum amylase and lipase activity remain the best methods to confirm the clinical diagnosis of pancreatitis. [Block and Kelley \(1989\)](#) reported that in all 21 pregnant women, serum amylase values exceeded 1500 IU/L. As shown in [Table 48-10](#), the mean amylase value in 43 pregnant women with pancreatitis was about 1400 IU/L, and the mean lipase value, about 7000 IU/L. Amylase values do not correlate with the severity of disease.

MANAGEMENT. Therapy is the same as for nonpregnant patients described earlier. In pregnant women, mild inflammation usually subsides in response to conservative therapy. In the Parkland Hospital series, all 43 women responded to conservative treatment and were hospitalized for a mean of 8.5 days ([Ramin and colleagues, 1995](#)). In 30 women described by [Swisher and associates \(1994\)](#), three women with associated gallstones underwent laparotomy for diagnostic uncertainty or unrelenting pain. In women with severe disease, fetal loss is high because of associated hypovolemia, hypoxia, and acidosis. Because more than half of cases are associated with gallstone disease, [ERCP¹](#) for common duct stones will likely be helpful ([Nesbitt and colleagues, 1996](#)). Cholecystectomy should be considered after inflammation subsides (see p. 1296).

PANCREATIC TRANSPLANTATION

According to the United Network for Organ Sharing (UNOS), the 3-year graft survival for pancreatic transplantation is almost 70 percent ([Lin and associates, 1998](#)). Because there is improved survival when a combined pancreas and kidney are grafted, most operations include both organs. Diabetes accounts for about a fourth of cases of renal failure leading to kidney transplantation.

[Tyden and colleagues \(1989\)](#) described four women in whom pancreatic-kidney transplantation was followed in 1 to 2 years by pregnancy. Because of pelvic placement of the pancreatic graft, there was concern that the enlarging uterus or labor might cause pancreatitis, but this did not occur. Moreover, glucose homeostasis was well-maintained throughout pregnancy. Of concern is the one woman who suffered acute pancreatic graft rejection postpartum. Successful vaginal deliveries have been described by [Allenby and colleagues \(1998\)](#). Notification of the National Transplantation Pregnancy Registry is encouraged by [Armenti and co-workers \(1997\)](#). At least two successful pregnancies have followed pancreatic islet autotransplantation ([Teuscher and colleagues, 1994](#); [Wahoff and associates, 1995](#)).

OBESITY

Excessive weight has become one of the major health problems in the United States as well as other "advanced" societies. Its etiology is multifactorial, and although it certainly is not simply a gastrointestinal disorder, it is considered here. In the National Health and Nutrition Examination Surveys from 1960 to 1991, an alarming increase was found in the prevalence of excessive weight among adults over the past decade ([Kuczmarski and colleagues, 1994](#)). It was estimated at that time that approximately a third of all adults in the United States were overweight. Indeed, [Allison and co-workers \(1999\)](#) attributed around 300,000 excessive deaths to obesity in this country in 1991. Because of this, a stated national health care goal of Healthy People 2000 was to reduce the prevalence of obesity to 20 percent or less ([Public Health Service, 1990](#)). Unfortunately, this was not achieved, and at the beginning of 2000, over half of the of the population was now overweight (see also [Chap. 1, p. 11](#)).

RISKS OF OBESITY. Individuals who are overweight are at increased risk for diabetes, hypertension, dyslipidemia, cardiovascular disease, stroke, liver and gallbladder disease, sleep apnea, osteoarthritis, colon cancer, as well as a number of obstetrical complications ([Must and colleagues, 1999](#)). Although the exact contribution of excessive weight and excess mortality has been controversial, in their prospective study, [Calle and associates \(1999\)](#) found that the mortality risk increased along with increasing body mass index ([Fig. 48-8](#)).

DEFINITION OF OBESITY. A variety of classifications have been used to define obesity. The most commonly used method is the body mass index (BMI) shown in [Figure 48-9](#). It is calculated as weight in kilograms divided by height in meters squared (kg/m^2). This is also known as *Quetelet's index*. The 1985 National Institutes of Health Consensus Panel on Obesity defined obesity as a 20 percent increase in body weight or a body mass index greater than the 85th percentile, which is 27.3 for women between 20 and 29 years old ([Burton and Foster, 1985](#)). Using this definition, nearly 40 percent of young adult women in the United States are obese.

EFFECTS OF OBESITY ON PREGNANCY

Marked obesity is unequivocally a hazard to the pregnant woman and her fetus. Because there have been no standardized definitions of obesity, in the past investigators have used a variety of classifications. For example, [Garbaciak and associates \(1985\)](#) defined morbid obesity as greater than 150 percent of ideal weight. They reported that chronic hypertension was increased about tenfold and gestational diabetes was found in about 10 percent of these women. [Johnson and colleagues \(1987\)](#) described the pregnancy outcomes of 588 women who weighed more than 250 pounds. Hypertension, diabetes, and postterm pregnancy were more frequent when compared with a group of control women who weighed less than 200 pounds. [Cunningham and associates \(1986\)](#) described obesity as a common co-factor along with hypertension in causing peripartum heart failure.

[Isaacs and associates \(1994\)](#) compared pregnancy outcomes in 103 women weighing more than 300 pounds with 69 control women whose weight averaged 160 pounds. Obese women had an increased incidence of chronic hypertension and diabetes. The primary cesarean delivery rate was increased threefold, and postpartum complications were also increased in obese women. Finally, infants were larger in obese women, and 10 percent weighed more than 4000 g. [Bianco and colleagues \(1998\)](#) reported similar findings in over 600 morbidly obese women as shown in [Table 48-11](#).

Fetal and neonatal complications are increased in obese women. [Wolfe and colleagues \(1990\)](#) reported difficulty in sonographic fetal visualization in women whose body mass index was greater than the 90th percentile. Several investigators then reported that obese women had a two- to threefold risk for neural-tube defects as well as other anomalies ([Mikhail, 1996](#); [Waller, 1994](#); [Werler, 1996](#), and their collaborators). Subsequently, [Shaw and colleagues \(1996, 2000\)](#) found a significant twofold increased incidence of neural-tube defects in women whose body mass index was 30 or higher.

MANAGEMENT. Management of obesity during pregnancy is a challenge. The usual net caloric increase during normal pregnancy ranges from 20,000 to 40,000 kcal and about 3.6 kg of gained weight is fat ([Kliegman and Gross, 1985](#)). A program of weight reduction is probably unrealistic, but if such a regimen is chosen, it is mandatory that the quality of the diet be monitored closely and that ketosis be avoided.

SURGICAL PROCEDURES FOR OBESITY. Various means to surgically decrease gastric volume have been devised to treat morbid obesity ([Yanovski and Yanovski, 1999](#)). A number of women have had pregnancies following such therapy. *Gastroplasty* creates a narrow channel through the stomach by using stapling devices. [Bilenka and colleagues \(1995\)](#) described 14 pregnancies in nine women who had undergone *vertical banded gastroplasty*. These women lost a mean of about 80 pounds and had fewer complications in subsequent pregnancies. [Martin and co-workers \(2000\)](#) described 23 pregnancies in women after *adjustable gastric banding*. For three women with excessive nausea and vomiting, band adjustment to decrease obstruction was successful.

Gastric bypass excludes the lower 90 percent of stomach by creating an upper gastrojejunostomy. [Printen and Scott \(1982\)](#) described their experiences with 51 pregnancies in 45 women who underwent gastric bypass surgery because of morbid obesity. Of the 46 infants delivered, fetal growth restriction was not a problem. [Richards and colleagues \(1987\)](#) reported similar experiences from 57 pregnancies cared for at the University of Utah. These women weighed an average of 194 pounds before and 147 pounds after surgery. Using pregnancies before gastric bypass as controls, they reported that the mean birthweight decreased from 3600 to 3200 g. Only 16 percent of the women had large-for-gestational-age infants compared with 37 percent before surgery. Impressively, the incidence of hypertension complicating pregnancy fell from 46 to 9 percent in women who had lost weight. [Wittgrove and co-workers \(1998\)](#) reported similar findings in 43 women.

Jejunioileal bypass has been followed by significant long-term morbidity and mortality, and the operation has been abandoned by most. [Knudsen and Kallen \(1986\)](#) reported results from the Danish-Swedish registry concerning 77 pregnancies after intestinal bypass. They described a lower mean birthweight, shorter gestations, and more small-for-gestational-age infants in these women when compared with nonobese control women. Of the 10 or so pregnant women with a jejunioileal bypass cared for at Parkland Hospital, most did well. They were given supplemental iron, folic acid, vitamin B₁₂, and a commercially available prenatal vitamin-mineral preparation. All but one infant were appropriately grown and in good health.

TABLE 48-2. Some Differentiating Characteristics of Ulcerative Colitis and Crohn Disease

Characteristic	Ulcerative Colitis	Crohn Disease
Prevalence	70-150/100,000	20-40/100,000 (increasing)
Peak incidence	20-40 years	15-30 years
Genetic factors		
Twin concordance	~50% (monozygous)	High
Family history	~25%	~25%
HLA association	HLA-Bw35, HLA-B27	HLA-A2, HLA-B27
Natural history		
Bowel involvement	Large bowel mucosa and submucosa	Small and large bowel mucosa and deeper layers; transmural involvement common
Colonoscopy	Continuous involvement beginning at rectum (40% ulcerative proctitis only) Mucosal granularity and friability with superficial ulceration	Small or large bowel only, or both; segmental involvement Patchy involvement
Symptoms	Rectal involvement Bloody diarrhea	Perianal disease Cramping abdominal pain and watery diarrhea
Clinical course	Tenesmus Exacerbations and remission (60-75% acute intermittent; 15-20% continuous chronic unremitting)	Vomiting, malnutrition, weight loss Exacerbations and remission; surgery commonly required
Extraintestinal manifestations	Arthritis, pyoderma, erythema nodosum (about 10%)	Same
Complications	Toxic megacolon (2%) Reactive arthritis Sclerosing cholangitis Cancer (3-5%)	Fistula formation Reactive arthritis Toxic megacolon Cancer risk less
Management	Medical Proctocolectomy curative	Medical Segmental resection if indicated

From Farmer (1994), Glickman (1998), and Kodner and colleagues (1999).

49. Hematological Disorders

Pregnancy induces physiological changes that often confuse the diagnosis of several hematological disorders and the assessment of their treatment. This is especially true for anemia. A number of marked pregnancy-induced hematological changes are discussed in detail in [Chapter 8 \(p. 177\)](#). One of the most significant changes is that of blood volume expansion with a disproportionate plasma volume increase, resulting in normally decreased hematocrit.

Pregnant women are susceptible to any of a variety of hematological abnormalities that may affect any woman of childbearing age. These include chronic disorders diagnosed before pregnancy such as hereditary anemias, immunological thrombocytopenia, and even malignancies to include leukemias and lymphomas. In other cases disorders arise during pregnancy because of pregnancy-induced demands such as iron-deficiency anemia and megaloblastic anemia of folate deficiency. In yet other cases pregnancy may unmask underlying hematological disorders such as compensated hemolytic anemias caused by hemoglobinopathies or red cell membrane defects. Finally, any hematological disease may first arise during pregnancy such as autoimmune hemolysis or aplastic anemia.

ANEMIAS

A precise definition of anemia in women is complicated by normal differences in the concentrations of hemoglobin between women and men, between white and black women, between women who are pregnant and those who are not, and between pregnant women who receive iron supplements and those who do not.

Extensive hematological measurements have been made in healthy nonpregnant women, none of whom were iron deficient because each had histochemically proven iron stores, and none were folate deficient because marrow erythropoiesis remained normoblastic. On the basis of data presented in [Table 49-1](#), anemia in nonpregnant women is defined as hemoglobin concentration less than 12 g/dL and less than 10 g/dL during pregnancy or the puerperium. The hemoglobin concentration is lower in midpregnancy, as shown in [Figure 49-1](#). Early in pregnancy and again near term, the hemoglobin level of most healthy women with iron stores is 11 g/dL or higher. For these reasons, the [Centers for Disease Control \(1990\)](#) defined anemia as less than 11 g/dL in the first and third trimesters, and less than 10.5 g/dL in the second trimester.

The modest fall in hemoglobin levels observed during pregnancy in healthy women not deficient in iron or folate is caused by a relatively greater expansion of plasma volume compared with the increase in hemoglobin mass and red cell volume. The disproportion between the rates at which plasma and erythrocytes are added to the maternal circulation is normally greatest during the second trimester. The long-used term **physiological anemia** to describe this process is an oxymoron and should be discarded. Late in pregnancy, plasma expansion essentially ceases while hemoglobin mass continues to increase ([Chap. 8, p. 177](#)).

During the puerperium, in the absence of excessive blood loss, hemoglobin concentration is not appreciably less than predelivery. After delivery the hemoglobin level typically fluctuates to a modest degree around the predelivery value for a few days and then rises to the higher nonpregnant level. The rate and magnitude of increase early in the puerperium are the result of the amount of hemoglobin added during pregnancy and the amount lost by blood loss at delivery and modified by a puerperal decrease in plasma volume.

FREQUENCY OF ANEMIA. Although anemia is somewhat more common among indigent pregnant women, it is by no means restricted to them. The frequency of anemia during pregnancy varies considerably, depending primarily upon whether supplemental iron is taken during pregnancy. For example, [Taylor and associates \(1982\)](#) reported that hemoglobin levels at term averaged 12.7 g/dL among women who took supplemental iron compared with 11.2 g/dL for women who did not.

ETIOLOGY OF ANEMIA. Any disorder causing anemia encountered in childbearing-age women may complicate pregnancy. A classification based primarily on etiology and including most of the common causes of anemia in pregnant women is shown in [Table 49-2](#).

EFFECTS OF ANEMIA ON PREGNANCY. The etiology of anemia is important when evaluating its effects on pregnancy outcome. For example, maternal and perinatal outcomes are altered markedly in women with sickle-cell anemia. Currently, there is no evidence that adverse outcomes are related to the anemia itself but rather to the vascular complications of sickling. According to [Bennett and colleagues \(1998\)](#), anemia per se, was seldom a cause for pregnancy-associated hospitalizations in the 1991-1992 National Hospital Discharge Data.

Most studies of the effects of anemia on pregnancy, such as those discussed in [Chapter 10 \(p. 235\)](#), describe large populations, and at least ostensibly deal with nutritional anemias, specifically those due to iron deficiency. [Klebanoff and co-workers \(1991\)](#) studied nearly 27,000 women and found a slightly increased risk of preterm birth with midtrimester anemia. [Lieberman and collaborators \(1987\)](#) found a positive association with low hematocrit and preterm birth in black women, and suggested that anemia was a marker for nutritional deficiencies. Anemia may be associated with fetal growth restriction. According to [Barker and colleagues \(1990\)](#), this may lead to adult cardiovascular disease ([Chap. 29, p. 757](#)). [Kadyrov and co-workers \(1998\)](#) have provided evidence that maternal anemia influences placental vascularization by altering angiogenesis during early pregnancy.

According to the World Health Organization, anemia has been implicated as contributory in up to 40 percent of maternal deaths in third-world countries ([Viteri, 1994](#)). Ironically, in otherwise healthy women, higher hemoglobin concentrations are more likely associated with adverse pregnancy outcome. In these cases, the normal blood volume expansion of pregnancy appears to have been curtailed. [Murphy and colleagues \(1986\)](#) reported findings from the Cardiff Birth Survey of over 54,000 singleton pregnancies and described excessive perinatal mortality with *high* hemoglobin concentrations. Specifically, women whose hemoglobin concentration exceeded 13.2 g/dL at 13 to 18 weeks had excessive perinatal mortality, low-birthweight infants, and preterm delivery, as well as preeclampsia in nulliparas. [Scanlon and associates \(2000\)](#) studied the relationship between maternal hemoglobin and preterm or growth-restricted infants in 173,031 pregnancies. Low hemoglobin (< 3 SD) at 12 weeks was associated with a 1.7-fold risk for preterm birth whereas high hemoglobin (> 3 SD) at 12 or 18 weeks had 1.3- to 1.8-fold increases in fetal growth restriction.

IRON-DEFICIENCY ANEMIA

The two most common causes of anemia during pregnancy and the puerperium are iron deficiency and acute blood loss. Not infrequently, the two are intimately related, because excessive blood loss with its concomitant loss of hemoglobin iron and exhaustion of iron stores in one pregnancy can be an important cause of iron-deficiency anemia in the next pregnancy.

Iron deficiency is common in women, and the [Centers for Disease Control and Prevention \(1989\)](#) estimate that about 8 million American women of childbearing age are iron deficient. Poor nutritional status frequently is associated with iron-deficiency anemia ([Scholl, 1998](#)). In a typical gestation with a single fetus, the maternal need for iron induced by pregnancy averages close to 800 mg; about 300 mg for the fetus and placenta and about 500 mg, if available, for maternal hemoglobin mass expansion. Approximately 200 mg more are shed through the gut, urine, and skin. This total amount—1000 mg—considerably exceeds the iron stores of most women. Unless the difference between the amount of stored iron available to the mother and the iron requirements of normal pregnancy cited is compensated for by absorption of iron from the gastrointestinal tract, iron-deficiency anemia develops.

With the rather rapid expansion of blood volume during the second trimester, iron lack is often manifested by an appreciable drop in hemoglobin concentration. Although the rate of expansion of blood volume is not so great in the third trimester, the need for iron is still increased because augmentation of maternal hemoglobin mass continues, and considerable iron is now transported to the fetus. Because the amount of iron diverted to the fetus from an iron-deficient mother is not much different from the amount normally transferred, the newborn infant of a severely anemic mother does not suffer from iron-deficiency anemia. Neonatal iron stores are related to maternal iron status ([Blot and co-workers, 1999](#)). They are also influenced by when and how the cord is clamped ([Chap. 13, p. 319](#)).

DIAGNOSIS. Classical morphological evidence of iron-deficiency anemia—erythrocyte hypochromia and microcytosis—is less prominent in the pregnant woman compared with the nonpregnant woman with the same hemoglobin concentration. Moderate iron-deficiency anemia during pregnancy—for example, a hemoglobin concentration of 9 g/dL—usually is not accompanied by obvious morphological changes in erythrocytes. With this degree of anemia from iron deficiency, however, serum ferritin levels are lower than normal, and there is no stainable bone marrow iron. The serum iron-binding capacity is elevated, but by itself this is of little diagnostic value because it also is elevated during normal pregnancy in the absence of iron deficiency. Moderate normoblastic hyperplasia of the bone marrow also is found to be similar to that in normal pregnancy. **Thus, iron-deficiency anemia during pregnancy is the consequence primarily of expansion of plasma volume without normal expansion of maternal hemoglobin mass.**

The initial evaluation of a pregnant woman with moderate anemia should include measurements of hemoglobin, hematocrit, and red cell indices; careful examination of a peripheral blood smear; a sickle-cell preparation if the woman is of African origin; and measurement of serum iron concentration or ferritin, or both. Serum ferritin

levels normally decline during pregnancy ([Goldenberg and colleagues, 1996](#)). Levels less than 15 ug/L confirm iron-deficiency anemia ([Centers for Disease Control and Prevention, 1989](#)). Alternatively, [van den Broek and colleagues \(1998\)](#) provided evidence that a cutoff point of 30 ug/L has an 85 percent positive-predictive value and a 90 percent negative-predictive value. Pragmatically, the diagnosis of iron deficiency in moderately anemic pregnant women usually is presumptive and based largely on the exclusion of other causes of anemia.

When the pregnant woman with moderate iron-deficiency anemia is given adequate iron therapy, a hematological response is detected by an elevated reticulocyte count. The rate of increase of hemoglobin concentration or hematocrit varies considerably, but usually it is slower than in nonpregnant women. The reason is related largely to the differences in blood volumes, and during the latter half of pregnancy, newly formed hemoglobin is added to the characteristically much larger volume.

TREATMENT. The objectives of treatment are correction of the deficit in hemoglobin mass and eventually restitution of iron stores. Both of these objectives can be accomplished with orally administered, simple iron compounds—ferrous sulfate, fumarate, or gluconate—that provide a daily dose of about 200 mg of **elemental iron**. If the woman cannot or will not take oral iron preparations, then parenteral therapy is given ([Andrews, 1999](#); [Hallak and associates, 1997](#)). To replenish iron stores, oral therapy should be continued for 3 months or so after the anemia has been corrected.

Transfusions of red cells or whole blood seldom are indicated for the treatment of iron-deficiency anemia unless hypovolemia from blood loss coexists or an emergency operative procedure must be performed on a *severely* anemic woman.

ANEMIA FROM ACUTE BLOOD LOSS

Anemia resulting from recent hemorrhage is more likely to be evident during the puerperium. Both abruptio placentae and placenta previa may be sources of serious blood loss and of anemia before as well as after delivery. Earlier in pregnancy, anemia caused by acute blood loss is common in instances of abortion, ectopic pregnancy, and hydatidiform mole. Massive hemorrhage demands immediate treatment to restore and maintain perfusion of vital organs ([Chap. 25, p. 635](#)). Even though the amount of blood replaced commonly does not completely repair the hemoglobin deficit created by the hemorrhage, in general, once dangerous hypovolemia has been overcome and hemostasis has been achieved, the residual anemia should be treated with iron. For the moderately anemic woman whose hemoglobin is more than 7 g/dL, whose condition is stable, who no longer faces the likelihood of further serious hemorrhage, who can ambulate without adverse symptoms, and who is not febrile, iron therapy for at least 3 months rather than blood transfusions is the best treatment.

ANEMIA ASSOCIATED WITH CHRONIC DISEASE

Weakness, weight loss, and pallor have been recognized since antiquity as characteristics of chronic disease. A wide variety of disorders—chronic infections and neoplasms, especially—result in moderate and sometimes severe anemia, usually with slightly hypochromic and microcytic erythrocytes. In the past, infections—especially tuberculosis, endocarditis, or osteomyelitis—were common causes, but antimicrobial therapy has decreased their incidences significantly. Today, chronic renal failure, cancer and chemotherapy, human immunodeficiency virus (HIV) infection, and chronic inflammation are the most common causes of this form of anemia. The common denominator is increased production of cytokines that mediate the immune or inflammatory response ([Means, 1999](#)).

In nonpregnant patients with chronic inflammatory diseases, the hemoglobin concentration is rarely less than 7 g/dL. Typically, bone marrow cellular morphology is not altered markedly. Serum iron concentration is decreased, and serum iron-binding capacity, while lower than in normal pregnancy, is not much below the normal nonpregnant range. Serum ferritin levels usually are elevated. Thus, although slightly different from each other mechanistically, these anemias share similar features which include varying degrees and combinations of alterations in reticuloendothelial function, iron metabolism, and decreased erythropoiesis ([Andrews, 1999](#)).

During pregnancy, a number of chronic diseases may cause anemia. Some of these are chronic renal disease, suppuration, inflammatory bowel disease, systemic lupus erythematosus, granulomatous infections, malignant neoplasms, and rheumatoid arthritis. Anemia is typically intensified as plasma volume expands out of proportion to red cell mass expansion. Women with severe **acute pyelonephritis** often develop overt anemia. This appears to result from increased red cell destruction but with normal erythropoietin production ([Cavenee and colleagues, 1994](#)).

CHRONIC RENAL DISEASE. Any type of chronic renal insufficiency can be accompanied by anemia of variable severity, usually due to erythropoietin deficiency. There is also an element of anemia of chronic disease. During pregnancy, red cell mass is augmented in some of these women, but less so than in normal pregnancy ([Cunningham and associates, 1990](#)). The degree of red cell mass expansion corresponds to the degree of renal impairment, and because total blood volume expansion usually is normal in these women, preexisting anemia is intensified.

TREATMENT. Anemia of chronic disorders responds to treatment with **recombinant erythropoietin**. It has been used successfully to treat anemia associated with chronic renal insufficiency, chronic inflammation, and malignancy ([Goodnough and associates, 1997](#)). From their review, [Vora and Gruslin \(1998\)](#) found only a few reports of its use during pregnancy. [Braga and colleagues \(1996\)](#) treated five women with severe anemia from chronic renal insufficiency. We have treated only a few pregnant women whose anemia was due to chronic renal insufficiency. While red cell mass usually increased over several weeks, a worrisome side effect is hypertension, which is already prevalent in these women ([Chap. 47, p. 1264](#)). In the study by [Braga and co-workers \(1996\)](#) cited earlier, one of five treated women developed placental abruption.

MEGALOBLASTIC ANEMIA

Megaloblastic anemias are a family of hematological disorders whose characteristic blood and bone marrow abnormalities are caused by impaired DNA synthesis. The prevalence of megaloblastic anemia during pregnancy varies considerably throughout the world, and it is now rare in the United States.

FOLIC ACID DEFICIENCY. In the United States, megaloblastic anemia beginning during pregnancy almost always results from folic acid deficiency, and in the past was referred to as **pernicious anemia of pregnancy**. It usually is found in women who do not consume fresh green leafy vegetables, legumes, or animal protein. Women with megaloblastic anemia may have developed troublesome nausea, vomiting, and anorexia during pregnancy. As the folate deficiency and anemia worsen, anorexia often becomes more intense, further aggravating the dietary deficiency. In some instances, excessive ethanol ingestion is either the cause or contributes to its development.

In normal nonpregnant women, the daily folic acid requirement is 50 to 100 ug/day. During pregnancy, requirements for folic acid are increased, and as discussed in [Chapter 10 \(p. 237\)](#), 400 ug/day is recommended. The earliest biochemical evidence is low folic acid activity in plasma. The earliest morphological evidence usually is hypersegmentation of neutrophils. As anemia develops, the newly formed erythrocytes are macrocytic. With preexisting iron deficiency, macrocytic erythrocytes cannot be detected by measurement of the mean corpuscular volume. Careful examination of a smear of peripheral blood, however, usually will demonstrate some macrocytes. As the anemia becomes more intense, an occasional nucleated erythrocyte appears in the peripheral blood. At the same time, examination of the bone marrow discloses megaloblastic erythropoiesis. Anemia may then become severe, and thrombocytopenia, leukopenia, or both also may develop.

The fetus and placenta extract folate from maternal circulation so effectively that the fetus is not anemic even when the mother is severely anemic from folate deficiency. Cases have been recorded in which newborn hemoglobin levels were 18 g/dL or more, while maternal values were as low as 3.6 g/dL ([Pritchard and Scott, 1970](#)).

TREATMENT. The treatment of pregnancy-induced megaloblastic anemia should include folic acid, a nutritious diet, and iron. As little as 1 mg of folic acid administered orally once daily produces a striking hematological response. By 4 to 7 days after beginning treatment, the reticulocyte count is increased appreciably, and leukopenia and thrombocytopenia are corrected promptly. Sometimes the rate of increase in hemoglobin concentration or hematocrit is disappointing, especially when compared with the usual exuberant reticulocytosis that starts soon after therapy has been initiated.

PREVENTION. A diet sufficient in folic acid prevents megaloblastic anemia. A great deal of attention has been devoted to the role of folate deficiency in the genesis of neural-tube defects ([Chap. 10, p. 237](#); [Chap. 36, p. 958](#)). These findings led the [Centers for Disease Control \(1992\)](#) and the [American College of Obstetricians and Gynecologists \(1996\)](#) to recommend that all childbearing-age women consume at least 0.4 mg of folic acid daily. Additional folic acid is given in circumstances where folate requirements are unusually excessive, as in multifetal pregnancy or hemolytic anemia, such as sickle-cell disease. Other indications include Crohn disease, alcoholism, and some inflammatory skin disorders. There is evidence that women who previously have had infants with neural-tube defects have a lower recurrence rate if folic acid, 4 mg daily, is given prior to and through early pregnancy.

VITAMIN B₁₂ DEFICIENCY. Megaloblastic anemia caused by lack of vitamin B₁₂ during pregnancy is exceedingly rare. **Addisonian pernicious anemia** is characterized by the failure to absorb vitamin B₁₂ because of lack of intrinsic factor. It is an extremely uncommon autoimmune disease in women of reproductive age,

and typically has its onset in women over 40. Moreover, unless women with this disease are treated with vitamin B₁₂, infertility may be a complication. In our limited experience, vitamin B₁₂ deficiency in pregnant women is more likely encountered following partial or total gastric resection. Other causes are Crohn disease, ileal resection, and bacterial overgrowth in the small bowel.

Serum vitamin B₁₂ levels are measured by radioimmunoassay. During pregnancy, these normally are lower than nonpregnant values because of decreased serum concentrations of B₁₂-carrier proteins, the **transcobalamins** ([Zamorano and colleagues, 1985](#)). Women who have had a total gastrectomy should be given 1000 mg of cyanocobalamin (vitamin B₁₂) intramuscularly at monthly intervals. Those with a partial gastrectomy usually do not need such therapy, but vitamin B₁₂ levels during pregnancy should be measured. There is little reason for withholding folic acid during pregnancy simply out of fear of jeopardizing the neurological integrity of women who might be pregnant and simultaneously have unrecognized, and therefore untreated, Addisonian pernicious anemia.

ACQUIRED HEMOLYTIC ANEMIAS

AUTOIMMUNE HEMOLYTIC ANEMIA. This is an uncommon condition and the cause for aberrant antibody production is unknown. Anemias caused by these factors may be due to warm-active autoantibodies (80 to 90 percent), cold-active antibodies, or a combination. These syndromes also may be classified as primary or idiopathic, and half are secondary to underlying diseases or other factors. Examples of the latter include lymphomas and leukemias, connective-tissue diseases, some infections, chronic inflammatory diseases, or drug-induced factors ([Provan and Weatherall, 2000](#)). In some cases classified initially as idiopathic, careful follow-up may allow detection of an underlying disease.

With autoimmune hemolytic anemia, typically both the direct and indirect antiglobulin (Coombs) tests are positive. Hemolysis and the positive antiglobulin tests may be the consequence of either IgM or IgG antierythrocyte antibodies. Spherocytosis and reticulocytosis are characteristic of the peripheral blood smear. **Cold-agglutinin disease** may be induced by *Mycoplasma pneumoniae* or infectious mononucleosis.

Women with autoimmune hemolytic anemia sometimes demonstrate marked acceleration of hemolysis during pregnancy. Glucocorticoids usually are effective as in the nonpregnant state, and treatment is with prednisone, 1 mg/kg per day, or its equivalent. Coincidental thrombocytopenia usually is corrected by therapy.

IgM antibodies do not cross the placenta and thus fetal red cells are not affected; however, IgG antibodies, especially subclasses IgG₁ and IgG₃, do cross. The most common example of adverse fetal effects from maternally produced IgG antibodies is maternal D isoimmunization with hemolytic disease in the fetus and neonate ([Chap. 39, p. 1057](#)). Transfusion of red cells for the mother with severe autoimmune hemolytic disease is complicated by the presence of circulating antierythrocyte antibodies. Warming the donor cells to body temperature decreases their destruction by cold agglutinins.

DRUG-INDUCED HEMOLYTIC ANEMIA. Drug-induced hemolysis encountered during pregnancy must be differentiated from other forms of autoimmune hemolytic anemia. Hemolysis typically is mild; it resolves upon withdrawing the drug, and it can be prevented by avoidance of the drug. Mechanisms of actions differ, but generally they are mechanisms of drug-mediated immunological injury to red cells. The drug acts as a high-affinity hapten with a red cell protein to which antidrug antibodies attach, for example IgM antipenicillin antibodies. It may act as a low-affinity hapten and adhere to cell membrane proteins. Some drugs that may induce antierythrocyte antibodies that might be used during pregnancy are shown in [Table 49-3](#).

The severity of symptoms depends on the degree of hemolysis. Usually there is mild to moderate chronic hemolysis, but some drugs that act as low-affinity haptens may precipitate severe acute hemolysis. [Garratty and associates \(1999\)](#) recently described seven cases of severe hemolytic anemia caused by cefotetan prophylaxis for obstetrical procedures. The direct antiglobulin test is positive; there is spherocytosis and reticulocytosis; and there may be thrombocytopenia and leukopenia. In most cases, withdrawing the offending drug results in reversal of symptoms. Corticosteroids are of questionable efficacy, and transfusions are given only if there is severe anemia. Especially in African-American women, drug-induced hemolysis is much more often related to a congenital erythrocyte enzymatic defect, such as severe **glucose-6-phosphate dehydrogenase (G6PD) deficiency** (p. 1314).

PREGNANCY-INDUCED HEMOLYTIC ANEMIA. Unexplained hemolytic anemia during pregnancy is a rare but apparently distinct entity in which severe hemolysis develops early in pregnancy and resolves within months after delivery. It is characterized by no evidence for an immune mechanism or for any intraerythrocytic or extraerythrocytic defects ([Starksen and associates, 1983](#)). Because the fetus-infant also may demonstrate transient hemolysis, an immunological cause is suspected. Maternal corticosteroid treatment usually is effective. We have observed one woman with recurrent hemolysis during several pregnancies, and in each instance, intense severe hemolytic anemia was controlled by prednisone given until delivery. Her children appear to be normal.

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA. Although commonly regarded as a hemolytic anemia, this is a hemopoietic stem cell disorder characterized by formation of defective platelets, granulocytes, and erythrocytes. Paroxysmal nocturnal hemoglobinuria is acquired and arises from one abnormal clone of cells, much like a neoplasm ([Packham, 1998](#)). One mutated X-linked gene responsible for this condition is termed **PIG-A** for phosphatidylinositol glycan protein A. Resultant abnormal anchor proteins of erythrocyte and granulocyte membrane makes them unusually susceptible to lysis by complement ([Provan and Weatherall, 2000](#)).

Its clinical manifestation is that of acquired hemolytic anemia that has an insidious onset and a chronic course. Hemoglobinuria develops at irregular intervals and is not necessarily nocturnal. Hemolysis may be initiated by transfusions, infections, or surgery. The severity of disease ranges from mild to lethal. Complications include those from chronic anemia, which is exacerbated by iron deficiency from urinary loss of iron. Almost 40 percent of patients suffer venous thromboses, and the Budd-Chiari syndrome caused by hepatic vein thrombosis has been observed. Renal abnormalities and hypertension also are common. Median survival after diagnosis is 10 years but 15 percent undergo spontaneous long-term remission ([Hillmen and colleagues, 1995](#)). Except possibly for marrow transplantation, no definitive treatment exists.

EFFECTS ON PREGNANCY. Paroxysmal nocturnal hemoglobinuria is a serious and unpredictable disease and pregnancy may be dangerous. [Greene and colleagues \(1983\)](#) reviewed 31 cases in pregnancy and found that complications developed in over three fourths. Maternal mortality was 10 percent and almost half of the women had postpartum venous thrombosis, including Budd-Chiari syndrome or cerebral vein thrombosis. [Solal-Celigny and co-workers \(1988\)](#) reported eight pregnancies of which only half resulted in surviving infants. In a multicenter study, [De Gramont and colleagues \(1987\)](#) reported complications during two thirds of 38 pregnancies. Although they observed no maternal deaths, life-threatening complications were common, especially from hemolysis and hemorrhage.

OTHER ACQUIRED ANEMIAS. As described by [Pritchard and associates \(1976\)](#), overt fragmentation (microangiopathic) hemolysis with visible hemoglobinemia infrequently complicates **preeclampsia-eclampsia**. This commonly is referred to as **HELLP syndrome**, from Hemolysis, **E**levated liver enzymes, and **L**ow Platelets ([Chap. 24, p. 579](#)). The most fulminant acquired hemolytic anemia encountered during pregnancy is caused by the exotoxin of *Clostridium perfringens* ([Chap. 33, p. 877](#)) or that of group A β -hemolytic streptococcus ([Chap. 26, p. 678](#)). Finally, Gram-negative bacterial endotoxin, or lipopolysaccharide, especially with severe acute pyelonephritis, may be accompanied by evidence of hemolysis and mild to moderate anemia ([Cox and colleagues, 1991](#)).

HEMOLYTIC ANEMIAS CAUSED BY INHERITED ERYTHROCYTE DEFECTS

The normal erythrocyte is shaped like a biconcave disc, and there is a redundancy of membrane surface area relative to volume. This allows numerous cycles of reversible deformations as the erythrocyte withstands shearing forces created in arteries and negotiates through splenic slits a fraction of its cross-sectional diameter. A number of inherited red cell membrane defects or enzyme deficiencies result in destabilization of the membrane lipid bilayer. Subsequent loss of lipids from the erythrocyte membrane, surface area deficiency, and poorly deformable cells that undergo hemolysis results in varying degrees of anemia. Some of these inherited membrane defects that will cause accelerated destruction are hereditary spherocytosis, pyropoikilocytosis, and ovalocytosis.

HEREDITARY SPHEROCYTOSIS. There are several inherited erythrocyte membrane protein deficiencies that give rise to the syndrome of hereditary spherocytosis. Although most are due to autosomally dominant variably penetrant **spectrin** deficiency, others are autosomally recessive and may be caused by **ankyrin** or **protein 4.2** deficiency or combinations thereof ([Rosse and Bunn, 1994](#)). These disorders are characterized clinically by varying degrees of anemia and jaundice as the consequence of hemolysis of microspherocytic red cells ([Fig. 49-2](#)). Confirmation of diagnosis is by documentation of spherocytes on peripheral smear, reticulocytosis, and increased osmotic fragility.

Hemolysis with corresponding anemia is dependent upon an intact spleen, which is usually enlarged. Splenectomy, although not correcting the membrane defect, spherocytosis, or increased osmotic fragility, does greatly reduce hemolysis, anemia, and jaundice. So-called **crisis**, characterized by severe anemia from accelerated red cell destruction or more likely failure of production, or both, may develop in the woman with a functioning spleen. Infection must be detected and vigorously treated.

PREGNANCY. In general, women with hereditary spherocytosis do well during pregnancy. Folic acid supplementation is recommended. [Maberry and associates](#)

(1992) reported our experiences from Parkland Hospital with 50 pregnancies in 23 women with spherocytosis. In late pregnancy, hematocrits varied from 23 to 41 percent (mean 31) and reticulocyte counts ranged from 1 to 23 percent. There was minimal maternal morbidity. There were eight abortions, and four of 42 infants were born preterm but none were growth retarded. Infection in four women intensified hemolysis and three required transfusions. Similar results were reported by [Pajor and colleagues \(1993\)](#) in 19 pregnancies in eight Hungarian women.

The newborn infant who has inherited hereditary spherocytosis may or may not demonstrate hyperbilirubinemia and anemia during the neonatal period. We observed the hemoglobin level to fall to as low as 5.0 g/dL by 5 weeks of age in the daughter of a woman with hereditary spherocytosis.

RED CELL ENZYME DEFICIENCIES. A number of erythrocyte enzymes are necessary for its anaerobic utilization of glucose. A deficiency of many but certainly not all of these enzymes may cause **hereditary nonspherocytic anemia**. Most of are inherited as autosomal recessive traits. **Glucose-6-phosphate dehydrogenase deficiency**, by far the most commonly identified enzyme deficiency, is a well-known exception that is X-linked. There are over 400 variants of this enzyme ([Beutler, 1991](#)). In the A variant, inherited by about 2 percent of African-American women, erythrocytes are markedly deficient in normal enzyme activity. In this, the deficient or homozygous state, both X chromosomes are affected. The heterozygous state, with one deficient and one normal X chromosome, is identified in 10 to 15 percent of African-American women. The defect probably confers some degree of protection against malarial infection. Random X-chromosome inactivation results in a variable deficiency of enzyme activity. Infections or several oxidant drugs may induce hemolysis in some heterozygous as well as homozygous women. Thus, anemia is episodic, although some variants induce chronic nonspherocytic hemolysis. Because young erythrocytes contain more enzyme activity than do older erythrocytes, in the absence of bone marrow depression, anemia ultimately stabilizes and is corrected soon after the drug is discontinued.

Pyruvate kinase deficiency, although unusual, is probably the next most common enzyme deficiency. It is inherited as an autosomal recessive trait. [Ghidini and Korker \(1998\)](#) described conservative management without transfusions in a woman whose hemoglobin reached a nadir of 6.8 g/dL at midpregnancy. [Gilsanz and colleagues \(1993\)](#) described recurrent hydrops fetalis, due to homozygously affected fetuses. In a fourth pregnancy, they diagnosed fetal anemia and lack of pyruvate kinase deficiency using funipuncture.

There are a number of other very rare enzyme abnormalities that may cause hemolysis, and some that do not. Although the degree of chronic hemolysis varies, most episodes of severe anemia with all of these enzyme deficiencies are induced by drugs or infections as previously discussed. During pregnancy, iron and folic acid are given. Oxidant drugs are avoided, and bacterial infections are treated promptly. Transfusions with red cells are given only if the hematocrit falls below 20, unless there is evidence for heart failure or hypoxia.

APLASTIC AND HYPOPLASTIC ANEMIA

Although rarely encountered during pregnancy, aplastic anemia is a grave complication. The diagnosis is made when anemia, usually with thrombocytopenia, leukopenia, and markedly hypocellular bone marrow, is demonstrated ([Marsh and colleagues, 1999](#)). In about a third of cases, anemia is induced by drugs and other chemicals, infection, irradiation, leukemia, and immunological disorders. *Fanconi anemia* and *Diamond-Blackfan syndrome* are inherited. In the other two thirds of cases, a cause cannot be determined ([Provan and Weatherall, 2000](#)). The basic functional defect appears to be a marked decrease in committed marrow stem cells. There is considerable evidence that the condition is immunologically mediated ([Young and Maciejewski, 1997](#)). With severe disease, defined as bone marrow hypocellularity of less than 25 percent, the 1-year survival rate is only 20 percent.

APLASTIC ANEMIA DURING PREGNANCY. In most cases, aplastic anemia and pregnancy appear to have been a chance association. Because about a third of women improved following termination of pregnancy, it has been postulated that pregnancy induces erythroid hypoplasia in some way ([Aitchison and colleagues, 1989](#)). Certainly, in a few women, hypoplastic anemia has been identified first during a pregnancy and then improved or even resolved when the pregnancy terminated, only to recur with a subsequent pregnancy ([Bourantas and associates, 1997](#); [Snyder and colleagues, 1991](#)).

[Rijhsinghani and Wiechert \(1994\)](#) described two pregnancies in a woman with *Diamond-Blackfan anemia*. This rare form of pure red cell aplasia may be inherited as autosomally recessive. Some patients respond to glucocorticoid therapy, but most are transfusion-dependent. Our experiences with two such women are similar. *Gaucher disease* is an autosomally recessive lysosomal enzyme deficiency that has multisystem involvement. Anemia and thrombocytopenia are worsened by pregnancy ([Granovsky-Grisaru and associates, 1995](#)). Subsequently, this same Israeli group showed that *αglucerase* enzyme replacement improved pregnancy outcomes in six women ([Elstein and colleagues, 1997](#)).

The two great risks to the pregnant woman with aplastic anemia are hemorrhage and infection ([Ascarelli and co-workers, 1998](#)). In cases reported since 1960, mortality during or after pregnancy has been 50 percent, and almost invariably, mortality is due to bleeding or sepsis. *Fanconi anemia* appears to be associated with a better prognosis. [Alter and colleagues \(1991\)](#) reviewed the literature and concluded that women who become pregnant had less severe disease.

MANAGEMENT. None of the erythropoietic agents that predictably produce remission in other anemias are effective. The treatment for severe aplastic anemia that is most likely to be effective is **bone-marrow or stem-cell transplantation**. For patients with less severe disease, or those for whom a donor cannot be found, **antithymocyte globulin** is the best available therapy ([Marsh and associates, 1999](#)). Immunosuppressive therapy with cyclosporine improves the response to antithymocyte globulin. Corticosteroids are possibly of value, as are large doses of testosterone or other androgenic steroids. Treated women almost certainly become virilized. The female fetus may develop the stigmata of androgen excess (pseudohermaphroditism), depending upon the compound, dose, and capacity of the placenta to aromatize the androgen ([Chap. 7, p. 121](#)).

A continuous search for infection should be made, and when found, specific antimicrobial therapy should be started promptly. Granulocyte transfusions are given only during actual infection. Red cell transfusions are given for symptomatic anemia, and we transfuse routinely to maintain the hematocrit at about 20. If the platelet count is very low, platelet transfusions may be needed to control hemorrhage. Vaginal delivery performed so as to minimize incisions and lacerations will lessen blood loss if the uterus is stimulated to contract vigorously after delivery. Even when thrombocytopenia is intense, the risk of severe hemorrhage can be minimized by vaginal delivery performed to avoid lacerations and an extensive episiotomy.

BONE MARROW TRANSPLANTATION. This requires immunosuppressive therapy for some months after transplantation. Previous blood transfusions, and even pregnancy, enhance the risk of graft rejection. For patients who are disease free at 2 years, survival rates of 90 percent accrue with transplantation ([Deeg and colleagues, 1998](#)). Acute and chronic graft-versus-host disease is the most common serious complication and causes two thirds of deaths within the first two years ([Socie and co-workers, 1999](#)). This same group reported that half of 95 women patients subsequently became pregnant.

There have been a number of case reports of successful pregnancies in women who previously had undergone bone marrow transplantation ([Borgna-Pignatti and associates, 1996](#); [Eliyahu and Shalev, 1994](#)). We have followed only two women with prior marrow transplantation, and both demonstrated a normal pregnancy-induced hematological response to pregnancy and had uneventful courses. [Sanders and colleagues \(1996\)](#) reviewed outcomes in 41 women with 72 pregnancies following bone marrow transplantation. Excluding 20 early pregnancy losses and terminations, the remaining 52 were productive of live-born infants. Almost half of these pregnancies were complicated—25 percent of the total had preterm delivery and 15 percent had hypertension.

HEMOGLOBINOPATHIES

SICKLE-CELL HEMOGLOBINOPATHIES

Sickle hemoglobin (hemoglobin S) results from a single β-chain substitution of glutamic acid by valine because of an A for T substitution at codon 6 of the β-globin gene. Sickle-cell anemia (SS disease), sickle cell-hemoglobin C disease (SC disease), and sickle cell-β-thalassemia disease (S-β-thalassemia disease) are the most common of the sickle hemoglobinopathies. Maternal morbidity and mortality, abortion, and perinatal mortality are all increased with these hemoglobinopathies.

PATHOPHYSIOLOGY. Red cells with [hemoglobin S¹](#) undergo sickling when they are deoxygenated and the hemoglobin aggregates. Constant sickling and de-sickling causes membrane damage, and the cell may become irreversibly sickled. Clinically, the hallmark of sickling episodes are periods during which there is ischemia and infarction within various organs. These changes produce clinical symptoms, predominately pain, and are called "sickle crisis." There often is severe pain with sickle-cell disease, and there may be aplastic, megaloblastic, sequestration, and hemolytic crises. In a study of 392 infants with sickle-cell disease diagnosed before 6 months, [Miller and associates \(2000\)](#) reported that 18 percent had severe morbidity when followed for a mean of 10 years.

Chronic and acute changes from sickling include bony abnormalities such as osteonecrosis of femoral and humeral heads, renal medullary damage, autosplenectomy in homozygous SS patients and splenomegaly in other variants, hepatomegaly, ventricular hypertrophy, pulmonary infarctions, cerebrovascular accidents, leg ulcers, and a propensity to infection and sepsis with Gram-positive as well as Gram-negative organisms ([Serjeant, 1997](#); [Weatherall and Provan, 2000](#)). The median age at

death is 42 years for men and 48 years for women ([Platt and associates, 1994](#)).

INHERITANCE OF SICKLING SYNDROMES. The inheritance of the gene for S hemoglobin from each parent results in sickle-cell anemia (SS disease). In the United States, 1 of 12 African Americans has the sickle-cell trait, which results from inheritance of one gene for the production of S hemoglobin and one for normal hemoglobin A. The theoretical incidence of sickle-cell anemia among African Americans is 1 in 576 ($1/12 \times 1/12 \times 1/4 = 576$), but the disease is less common during pregnancy because of earlier mortality, especially during early childhood.

About 1 in 40 African Americans has the gene for hemoglobin C. Therefore, the probability of [hemoglobin S](#)¹ and C traits in a black couple is about 1 in 500 ($1/40 \times 1/12$), and the probability of their child co-inheriting the gene for hemoglobin S and an allelic gene for hemoglobin C is 1 in 4. As the consequence of these genetic frequencies, about 1 of 2000 ($1/12 \times 1/40 \times 1/4$) pregnant African-American women is expected to have SC disease.

The inheritance of the gene for [hemoglobin S](#)¹ from one parent and the allelic gene for β -thalassemia from the other results in sickle cell- β -thalassemia disease. Because the incidence of β -thalassemia minor is about 1 in 40 to 50, S- β -thalassemia occurs about 1 in 2000 ($1/12 \times 1/40 \times 1/4$).

PREGNANCY AND SICKLE-CELL SYNDROME. Pregnancy is a serious burden to women with sickle hemoglobinopathies, especially hemoglobin SS disease. Ischemic necrosis of multiple organs, but especially bone marrow causes severe pain—so-called **sickle-cell crisis**—usually becoming more frequent, and infections and pulmonary complications are more common. [Powars and colleagues \(1986\)](#), in an extensive review, compared maternal and perinatal outcomes from before and after 1972. They reported that maternal mortality fell from 6 to 1 percent in these two periods. [Poddar and colleagues \(1986\)](#) reported a maternal mortality rate of 7 per 644 (1.1 percent) in pregnant women with hemoglobin SS disease. In some Nigerian studies, maternal mortality rates ranged from 2 to 9 percent.

As shown in [Table 49-4](#), in addition to excessive maternal mortality, more than a third of pregnancies in women with sickle syndromes terminated in abortion, stillbirth, or neonatal death. [Smith and associates \(1996\)](#) provided data from the National Institutes of Health Cooperative Study of Sickle Cell Disease. Of 155 women with SS disease, there were 320 pregnancies. A third were terminated either by elective or spontaneous abortions, the stillbirth rate was 9 per 1000, and 63 percent of infants were born alive.

HEMOGLOBIN SC. In nonpregnant women, morbidity and mortality from sickle cell-hemoglobin C disease are appreciably lower than from sickle-cell anemia. Indeed, fewer than half of women with SC disease have ever been symptomatic prior to pregnancy. During pregnancy and the puerperium, however, attacks of severe bone pain and episodes of pulmonary infarction and embolization become more common ([Cunningham and associates, 1983](#)). A particularly worrisome pulmonary complication is related to embolization of necrotic bone marrow, both fat and cellular, and acute respiratory insufficiency may develop ([Fig. 49-3](#)). In an 18-year anterospective study at Parkland Hospital, the maternal mortality rate for women with hemoglobin SC disease was close to 2 percent ([Pritchard and co-workers, 1973](#)). As shown in [Table 49-4](#), maternal deaths with hemoglobin SC disease were as common as with SS disease. The perinatal mortality rate is somewhat greater than that of the general population but nowhere as great as with sickle-cell anemia. In 39 women with SC hemoglobin who had 77 pregnancies, [Smith and colleagues \(1996\)](#) reported no maternal or fetal deaths.

MANAGEMENT OF SICKLING SYNDROMES. Adequate management of pregnant women with sickle-cell anemia or other sickle-cell hemoglobinopathies necessitates close observation with careful evaluation of all symptoms, physical findings, and laboratory studies. In the absence of infection or nutritional deficiency, the hemoglobin concentration usually does not fall below 7 g/dL. Because these women maintain their hemoglobin concentration by intense hemopoiesis to compensate for the markedly shortened erythrocyte life span, any factor that impairs erythropoiesis or increases red cell destruction, or both, aggravates the anemia. The folic acid requirements during pregnancy complicated by sickle-cell anemia are considerable and supplementary folic acid of 1 mg/day is given.

One rather common danger is that the symptomatic woman may categorically be considered to be suffering from a sickle-cell crisis. As a result, ectopic pregnancy, placental abruption, pyelonephritis, appendicitis, cholecystitis, or other serious obstetrical or medical problems that cause pain, anemia, or both may be overlooked. **The term "sickle-cell crisis" should be applied only after all other possible causes of pain or fever or reduction in hemoglobin concentration have been excluded.**

The cause of pain is intense sequestration of sickled erythrocytes with infarction in various organs. These episodes may develop acutely, especially late in pregnancy, during labor and delivery, and early in the puerperium. Acute infarction is usually accompanied by severe pain, and because the bone marrow is frequently involved, intense bone pain is common. Relief of pain from intravascular sickling is not afforded by heparinization or dextran. To maintain blood volume, intravenous hydration is given, along with meperidine or morphine administered parenterally for severe pain. Many of these women frequently are dehydrated due to diminished oral intake secondary to pain and they often have fever, which exacerbates hypovolemia. Oxygen given via nasal cannula may increase oxygen tension and decrease the intensity of sickling at the capillary level. We have found that red cell transfusions after the onset of severe pain do not dramatically improve the intensity of the pain and may not shorten its duration. Conversely, as discussed later, prophylactic red cell transfusions almost always eliminate pain episodes by preventing vaso-occlusive episodes.

There are special circumstances during pregnancy that increase appreciably the morbidity of these women. Covert bacteriuria and acute pyelonephritis are increased substantively, and careful surveillance for bacteriuria and its eradication is important to prevent most urinary symptomatic infections. If pyelonephritis develops, these erythrocytes are extremely susceptible to endotoxin, which can cause dramatic and rapid red cell destruction while simultaneously suppressing erythropoiesis. As described in [Chapter 56 \(p. 1466\)](#), parvovirus B19 can destroy erythrocyte precursors and cause reversible hypoplastic anemia ([Weatherall and Provan, 2000](#)). Pneumonia, especially due to *Streptococcus pneumoniae*, is common. The [Advisory Committee on Immunization Practices \(1997\)](#) recommends polyvalent pneumococcal vaccine for these women. Influenza vaccine should be given annually. In addition, vaccination against *Haemophilus influenzae* type B is recommended by some for asplenic states ([Association of Professors of Gynecology and Obstetrics, 1999](#)).

As many as 40 percent of patients suffer from a serious and frequent complication known as **acute chest syndrome** ([Vichinsky and colleagues, 2000](#)). It is characterized by pleuritic chest pain, fever, cough, lung infiltrates, and hypoxia. There is a spectrum of pathology that includes infection, infarction, pulmonary sequestration, and fat embolization. Recurrent episodes may lead to restrictive chronic lung disease associated with arteriolar vasculopathy ([Powars and co-workers, 1988](#)). [Van Erk and associates \(1992\)](#) reported a maternal death in a woman with sickle-cell disease thought to be a result of pulmonary hypertension secondary to vasculopathy.

Women with sickle-cell anemia rarely die of heart disease, but almost all of these women eventually have some degree of **cardiac dysfunction**. In most cases, ventricular dysfunction from hypertrophy is compensated by increased preload and decreased afterload with a normal ejection fraction and a high cardiac output. Chronic hypertension will worsen this ([Gandhi and colleagues, 2000](#)). During pregnancy, the basal hemodynamic state characterized by high cardiac output and increased blood volume is further aggravated ([Veille and Hanson, 1994](#)). Although most of these women tolerate changes of pregnancy without problems, when complications such as severe preeclampsia or serious infections develop, ventricular failure may ensue ([Cunningham and associates, 1986](#)).

ASSESSMENT OF FETAL HEALTH. Because of the high incidence of fetal growth restriction and perinatal mortality, serial fetal assessment is necessary. The [American College of Obstetricians and Gynecologists \(1999\)](#) recommends weekly antepartum fetal surveillance beginning at 32 to 34 weeks. Serial ultrasonography is usually done to monitor fetal growth and amniotic fluid volume. [Anyaegbunam and colleagues \(1991\)](#) reported observations of fetal well-being obtained during 39 sickling crisis in 24 women. In almost 60 percent, they demonstrated reversible nonreactive stress tests, and all had an increased uterine artery systolic-diastolic (S/D) ratio. They found no changes in the umbilical artery S/D^2 ratios, however, suggesting that transient effects of sickle-cell crisis do not compromise umbilical and hence fetal blood flow. At Parkland Hospital, we serially assess these women with ultrasound to determine amniotic fluid volume and follow fetal growth. Nonstress or contraction stress tests are not done routinely unless fetal movement is reported to be diminished or other significant complications develop that prompt admission.

DELIVERY. Labor and delivery in women with hemoglobin SS disease should be managed the same way as for women with cardiac disease ([Chap. 44, p. 1185](#)). The woman should be kept comfortable but not oversedated. Epidural analgesia is ideally suited for labor and delivery. Compatible blood should be available. If a difficult vaginal or cesarean delivery is contemplated, and the hematocrit is less than 20 percent, the hemoglobin concentration should be increased by packed erythrocyte transfusions. At the same time, care must be taken to prevent circulatory overload from ventricular failure and pulmonary edema.

PROPHYLACTIC RED CELL TRANSFUSIONS. In a number of conditions, prophylactic transfusions decrease morbidity in sickle-cell syndromes. An example is perioperative transfusion. Another is transfusions to prevent strokes in high-risk children ([Adams and co-workers, 1998](#)). There currently is controversy over the use of prophylactic transfusions during pregnancy for women with sickle-cell syndromes ([American College of Obstetricians and Gynecologists, 2000d](#)). The most dramatic impact of prophylactic transfusion has been on maternal morbidity. In a 10-year study at Parkland Hospital, we offered prophylactic transfusions to all pregnant women with sickle-cell syndromes. Red cell transfusions were given throughout pregnancy to maintain the hematocrit above 25 percent and [hemoglobin S](#)¹ at no greater than 60 percent ([Cunningham and associates, 1979](#)). There was minimal maternal morbidity such as pain, fever, and suppression of erythropoiesis. In a later

study, we compared these and additional women with historical controls not given blood ([Cunningham and associates, 1983](#)). When pregnancy outcomes were compared with historical controls not routinely transfused, there was a significant reduction in maternal morbidity and hospitalizations. A comparative study by [Howard and colleagues \(1995\)](#) showed similar data.

In a multicenter study, [Koshy and colleagues \(1988\)](#) randomized 72 pregnant women with sickle-cell disease to be given either prophylactic transfusions or to be transfused only if indicated. They reported that the incidence of painful sickle-cell crises was decreased significantly in women transfused prophylactically, but there were no differences in perinatal outcomes. They observed a nonsignificant decrease in cumulative complications in women given prophylactic transfusions compared with controls (19 versus 42 percent). Because they did not find any improvement in survival of the mother or fetus, coupled with risks inherent in blood transfusions, they concluded that prophylactic red cell transfusions were not necessary.

Current consensus is that either management plan may be appropriate for a particular woman. Thus, management is individualized, and some choose prophylactic transfusions in women with a history of multiple vaso-occlusive episodes and poor obstetrical outcomes. Unfortunately, these are not always predictive of complications for the current pregnancy, especially in women with SC hemoglobin ([Cunningham and colleagues, 1983](#)).

COMPLICATIONS. Hazards of multiple transfusions are not insignificant, and morbidity from transfusions has proved troublesome. Delayed hemolytic transfusion reactions occur in as many as 10 percent of patients ([Garratty, 1997](#)). Hepatitis and red cell isoimmunization are major problems. At Parkland Hospital, the incidence of isoimmunization per unit of blood transfused was 3 percent in patients with sickle-cell disease ([Cox and associates, 1988](#)). In 12 studies, a mean of 25 percent of chronically transfused sickle-cell patients were isoimmunized ([Garratty, 1997](#)). Finally, although the spectre of iron overload and transfusion hemochromatosis is worrisome, we found no evidence of this in liver biopsies performed in 40 such women transfused during pregnancy ([Yeomans and co-workers, 1990](#)). There also was no evidence of acute or chronic hepatitis in these biopsy specimens.

EXPERIMENTAL THERAPY. Increasing the production of [hemoglobin S¹](#) may be harmful to patients with sickle-cell anemia because blood viscosity increases with hematocrit. Conversely, induction of hemoglobin F by stimulating gamma-chain synthesis appears to be a promising form of chronic treatment for sickling and some thalassemia syndromes. Gamma chains of hemoglobin F inhibit polymerization of hemoglobin S and therefore inhibit sickling. Combined regimens of **hydroxyurea** and **5-azacytidine** as well as **recombinant erythropoietin** and **hydroxyurea** increase fetal hemoglobin production with less sickling ([Schechter and Rodgers, 1995](#)). In addition, hydroxyurea reduces sickle erythrocyte adherence to endothelium ([Steinberg, 1999](#)). While the drug decreases yearly sickle-cell crises by about half, its long-term safety is unknown ([Charache and associates, 1995](#)). Experience with hydroxyurea in pregnancy is limited, but it is teratogenic in animals ([Briggs and colleagues, 1998](#)). [Perrine and colleagues \(1993\)](#) have given **butyric acid** as a means of increasing hemoglobin F.

A promising treatment for severe symptomatic sickle-cell anemia is **bone marrow transplantation** as discussed on page 1315. Because there is a basic defect in bone marrow stem cells in hemoglobinopathies, introduction of normal hemoglobin A erythrocyte precursors may be curative ([Walters and associates, 1996](#)). According to [Steinberg \(1999\)](#), about 100 sickle-cell patients—mostly children—have undergone transplantation. Mortality is 10 percent and most survivors were symptom free.

Prenatal diagnosis of sickle-cell disease may allow for in utero **stem cell therapy** with normal hemoglobin A stem cells ([Eddleman, 1998](#); [Shaaban and Flake, 1999](#)). The immunological immaturity of the second-trimester fetus may dampen rejection of foreign cells and thus allow a higher success rate for transplantation.

Finally, transgenic "knock-out" mice that make only human globin chains have been developed ([Paszty and colleagues, 1997](#); [Ryan and co-workers, 1997](#)). A sickle-cell mouse has also been developed, and although not a perfect human model, a more thorough understanding of the disease should evolve ([Nagel, 1998](#)).

CONTRACEPTION AND STERILIZATION. Because of chronic debility, the further complications caused by pregnancy, and the predictably shortened life span of women with sickle-cell anemia, contraception and possibly sterilization are important considerations. According to the [American College of Obstetricians and Gynecologists \(2000b\)](#), estrogen-progesterone oral contraceptives have not been assessed well in women with sickle hemoglobinopathies. Many authors, however, do not recommend their use because of potential adverse vascular and thrombotic effects ([Chap. 58, p. 1525](#)). Progesterone has been long known to prevent painful sickle-cell crises. Thus, low-dose oral progesterone or progesterone implants may be used, although some investigators feel that the safety issue is unclear. Conversely, [de Abood and associates \(1997\)](#) reported significantly fewer as well as less intense pain crises in women given depot medroxyprogesterone intramuscularly. Intrauterine devices probably are contraindicated in women with sickle-cell anemia because of increased risk of infection. The safest contraceptives for these women are unfortunately those with the highest failure rates—condoms/foam and diaphragms. Permanent sterilization is obviously an option for women with sickle-cell hemoglobinopathies.

SICKLE-CELL TRAIT. The inheritance of the gene for [hemoglobin S¹](#) from one parent and for hemoglobin A from the other results in sickle-cell trait. The amount of S hemoglobin is distinctly less than the amount of A hemoglobin. The frequency of red cell sickling among African Americans is reported to be about 8 percent. We tested almost 50,000 black women attending Parkland Maternal Health and Family Planning Clinics and also determined that 8 percent had sickle trait.

Extensive studies of the effect, or lack of effect, of sickle-cell trait on pregnancy have been reported ([Pritchard and associates, 1973](#); [Tuck and co-workers, 1983](#)). Sickle-cell trait did not influence unfavorably the frequency of abortion, perinatal mortality, low birthweight, or pregnancy-induced hypertension. Urinary infection, however, was about twice as common in the group with sickle-cell trait. Subsequent investigations disclosed that twice as many pregnant women with sickle-cell trait had asymptomatic bacteriuria as did black women whose erythrocytes did not sickle ([Whalley, 1967](#)). [Tollin and Seely \(1994\)](#) have described a woman with hypopituitarism who they speculate suffered an intrapartum pituitary infarction related to sickle-cell trait.

Sickle-cell trait should not be considered a deterrent to pregnancy on the basis of increased risks to the mother. The probability, however, for a serious sickle-cell hemoglobinopathy in her offspring is 1 in 4 whenever the father carries a gene for an abnormal hemoglobin or for β -thalassemia. Prenatal diagnosis of sickle-cell disease through amniocentesis or chorionic villus sampling is now available ([Chap. 37, p. 989](#)). [Xu and colleagues \(1999\)](#) recently described single-blastomere DNA analysis and successful in-vitro fertilization of a couple with sickle-cell trait. The ethics associated with prenatal screening for hemoglobinopathies have been summarized by [Bowman \(1991\)](#).

OTHER HEMOGLOBINOPATHIES

HEMOGLOBIN C AND C- β -THALASSEMIA. Hemoglobin C results from a single β -chain substitution of glutamic acid by lysine at position 6. It is quite common in West Africa, but only about 2 percent of African Americans have the mutant gene for hemoglobin C. Hemoglobin C trait does not cause anemia, nor does it predispose to adverse pregnancy outcomes. When co-inherited with sickle-cell trait, the resultant hemoglobin SC causes the problems previously discussed.

Pregnancy and homozygous hemoglobin C disease or hemoglobin C- β -thalassemia appear to be relatively benign associations. [Maberry and colleagues \(1990\)](#) reported our experiences with 72 pregnancies complicated by C-hemoglobinopathies. The degree of anemia was usually mild to moderate, and the mean third-trimester hematocrit was 27 percent (range 21 to 33) for 49 pregnancies complicated by hemoglobin CC disease and 30 percent (range 28 to 33) for 23 pregnancies complicated by C- β -thalassemia. Blood volume expansion in these women averaged about 35 percent compared with their nonpregnant volumes.

Pregnancy outcomes ([Table 49-5](#)) were not different in women with C hemoglobin syndromes compared with the general obstetrical population. When severe anemia is identified, iron or folic acid deficiency or some other superimposed cause should be suspected. Supplementation with folic acid and iron, unless blood is transfused, is likely to prove of value in pregnant women with any hemoglobinopathy.

HEMOGLOBIN E. Hemoglobin E is the second most common hemoglobin variant worldwide. Hemoglobin E results from a single β -chain substitution of lysine for glutamic acid at codon 26. The hemoglobin is susceptible particularly to oxidative stress. The prevalence of hemoglobin E trait is common in Southeast Asia and is very close to that for [hemoglobin S¹](#) in the United States. Homozygous inheritance gives rise to **hemoglobin E disease**. This hemoglobinopathy has become more prevalent in the United States since the influx of a large number of Southeast Asians after 1970. [Hurst and co-workers \(1983\)](#) identified homozygous hemoglobin E, hemoglobin E plus α -thalassemia, or hemoglobin E trait in 36 percent of Cambodian children and 25 percent of Laotians, but in only 1 percent of Vietnamese. Alpha- and β -thalassemia traits were prevalent in all groups.

The homozygous state for hemoglobin E is associated with little or no anemia, hypochromia, marked microcytosis, and erythrocyte targeting. In our limited experience, pregnancies in women homozygous for hemoglobin E do not appear to be at increased risk. Iron-deficiency anemia as the consequence of intestinal parasites, repeated pregnancies, or both, may co-exist with E hemoglobinopathy.

Hemoglobin E- β -thalassemia is a common cause of childhood anemia in Southeast Asia ([Fucharoen and Winichagoon, 2000](#)). It has been reported to cause severe

anemia that may require transfusion during pregnancy ([Hsia, 1991](#)). Hemoglobin SE is usually considered benign, but [Eichhorn and colleagues \(1999\)](#) reported a sickle-like crisis in a patient that was precipitated by B19 parvovirus infection. It is not clear if hemoglobin SE disease is as ominous during pregnancy as hemoglobin SC or S- β -thalassemia disease ([Ramahi and colleagues, 1988](#)).

HEMOGLOBINOPATHY IN THE NEWBORN. Infants with sickle-cell anemia, sickle cell-hemoglobin C disease, and homozygous hemoglobin C disease can be identified accurately at birth by electrophoresis performed on hemoglobin obtained from uncontaminated cord blood. The [Agency for Health Care Policy and Research \(1993\)](#) of the United States Public Health Service has recommended that all newborn babies be tested for sickle-cell disease regardless of their race or ethnic background. In most states, such screening is performed routinely on blood submitted for phenylketonuria and hypothyroidism testing. The Texas Department of Health performs hemoglobin electrophoresis using a specific technique called **isoelectric focusing**. The benefit of screening for sickle hemoglobinopathies is that there is clearly decreased mortality in children with sickle-cell disease who are recognized at birth and given monthly prophylactic injections of penicillin G and assessed closely for risk factors for strokes ([Adams and colleagues, 1998](#); [Centers for Disease Control and Prevention, 2000](#)).

PRENATAL DIAGNOSIS. Using polymerase chain reaction (PCR), prenatal diagnosis of sickle-cell anemia is currently relatively simple, accurate, and rapid ([Chap. 36, p. 966](#)). The DNA used can be obtained by either amniocentesis or chorionic villus sampling. Hemoglobin C and most instances of β -thalassemia can be identified by analysis of DNA polymorphism or by identifying in vitro the kinds of globin chains synthesized by fetal red cells obtained from the fetus or placenta.

THALASSEMIAS

The genetically determined hemoglobinopathies termed thalassemias are characterized by impaired production of one or more of the normal globin peptide chains. Abnormal synthesis rates may result in ineffective erythropoiesis, hemolysis, and varying degrees of anemia. The different forms of thalassemia are classified according to the globin chain that is deficient in amount compared with its partner chain. Several hundred thalassemia syndromes have been described. The two major forms involve either impaired production of α -peptide chains causing α -thalassemia, or of β -chains to cause β -thalassemia. The incidence of these traits during pregnancy for all races is probably 1 in 300 to 500 ([Gehlbach and Morgenstern, 1988](#)).

ALPHA-THALASSEMIA. Because there are two α -globin genes, the inheritance of α -thalassemia is more complicated than for β -thalassemia. Four clinical syndromes, the consequence of impaired α -globin chain synthesis, have been identified. For each syndrome, a close correlation has been established between clinical severity and the degree of impairment of synthesis of α -globin chains. In most populations, the α -globin chain "cluster" or gene loci are duplicated on chromosome 16. Thus, the normal genotype for diploid cells can be expressed as $\alpha\alpha/\alpha\alpha$. There are two main groups of α -thalassemia determinants: α^0 -thalassemia is characterized by the deletion of both loci from one chromosome ($-/\alpha\alpha$), whereas α^+ -thalassemia is characterized by the loss of a single locus from one chromosome ($-a/\alpha\alpha$ heterozygote) or both ($-a/-a$, homozygote).

There are two major phenotypes. The deletion of all four α -globin chain genes ($-/-$) characterizes **homozygous α -thalassemia**. Because α -chains make up fetal hemoglobin, the fetus is affected. Without α -globin chains, hemoglobin Bart (γ_4) and hemoglobin H (β_4) are formed as abnormal tetramers. Hemoglobin Bart has an appreciably increased affinity for oxygen. The fetus dies either in utero or very soon after birth, and demonstrates the typical clinical features of nonimmune hydrops fetalis shown in [Figure 49-4](#) (see also [Chap. 39, p. 1068](#)). [Lam and associates \(1999\)](#) found that sonography at 12 to 13 weeks was 100 percent sensitive and specific for identifying affected fetuses by measuring the cardiothoracic ratio. [Carr and colleagues \(1995\)](#) transfused a fetus with α -thalassemia at 25, 26, and 32 weeks and reversed its ascites. The transfusion dependent infant was delivered at 34 weeks. **Hemoglobin Bart disease** is a common cause of stillbirths in Southeast Asia. [Hsieh and associates \(1989\)](#) studied 20 such hydropic fetuses by funipuncture at 17 to 35 weeks and reported that blood contained 65 to 98 percent Bart hemoglobin.

The compound heterozygous state for α^0 - and α^+ -thalassemia results in the deletion of three of four genes ($-/-a$), leaving only one functional α -globin gene per diploid genome. This is referred to as **hemoglobin H disease** (β_4), and it is compatible with extrauterine life. The abnormal red cells at birth contain a mixture of hemoglobin Bart (γ_4), hemoglobin H (β_4), and hemoglobin A. The neonate appears well at birth, but after early infancy, hemolytic anemia develops. Most, if not all, of the 20 to 40 percent of hemoglobin Bart present at birth is replaced postnatally by hemoglobin H. In the adult, 7 to 16 percent of hemoglobin is H ([Chen and colleagues, 2000](#)). The disease is characterized by hemolytic anemia of varying severity and, in some patients, disease severity is similar to β -thalassemia major. Anemia in these women usually is worsened during pregnancy.

A deletion of two genes results clinically in **athalassemia minor**, which is characterized by minimal to moderate hypochromic microcytic anemia. These may be due to α^0 - or α^+ -thalassemia traits. Thus, genotypes may be $-a/-a$ or $-/\alpha\alpha$. Differentiation is only by DNA analysis ([Weatherall and Provan, 2000](#)). Because there is no associated clinical abnormality with α -thalassemia minor, it often goes unrecognized. Hemoglobin Bart is present at birth, but as it dissipates, it is not replaced by hemoglobin H. Red cells are hypochromic and microcytic, and the hemoglobin concentration is normal to slightly depressed. Women with α -thalassemia minor appear to tolerate pregnancy quite well.

The single gene deletion ($-a/\alpha\alpha$) is the **silent carrier state**. No clinical abnormality is evident in the individual with a single gene deletion.

FREQUENCY. The relative frequency of α -thalassemia minor, hemoglobin H disease, and hemoglobin Bart disease varies remarkably among racial groups. All of these variants are encountered in Asians. In individuals of African descent, however, even though α -thalassemia minor is demonstrated in about 2 percent, hemoglobin H disease is extremely rare and hemoglobin Bart disease is unreported. The reason for the discrepancy is that Asians usually have a α^0 -thalassemia minor with both gene deletions typically from the same chromosome ($-/\alpha\alpha$), whereas in blacks with a α^+ -thalassemia minor, one gene is deleted from each chromosome ($-a/-a$). The α -thalassemia syndromes appear sporadically in other racial and ethnic groups. Diagnosis of α -thalassemia minor, as well as α -thalassemia major in the fetus, can be accomplished by DNA analysis using molecular techniques ([American College of Obstetricians and Gynecologists, 2000c](#)).

BETA-THALASSEMIA. The β -thalassemias are the consequence of impaired production of β -globin chains, and the molecular pathology for the defective production is quite complex. Over 150 point mutations in the β -globin gene have been described ([Weatherall, 2000](#)). Most are single nucleotide substitutions that produce transcription defects, RNA splicing or modification, translation, or highly unstable hemoglobins. Thus, deletional and nondeletional mutations affect the transcription, processing, or translation of β -globin RNA. The $d\beta$ -gene "cluster" is on chromosome 11.

With β -thalassemia there is decreased β -chain production and excess α -chains precipitate to cause cell membrane damage. These basic defects lead to the panorama of pathology that characterizes homozygous β -thalassemia, so-called β -thalassemia major or **Cooley anemia**. With heterozygous β -thalassemia minor, hypochromia, microcytosis, and slight to moderate anemia develop without the intense hemolysis that characterizes the homozygous state. The hallmark of the common β -thalassemias is an elevated hemoglobin A_2 level.

In the typical case of **thalassemia major**, the neonate is healthy at birth, but as the hemoglobin F level falls, the infant becomes severely anemic and fails to thrive. If children are entered into an adequate transfusion program, they develop normally until the end of the first decade when effects of iron loading become apparent. Prognosis is improved by iron-chelation therapy with deferoxamine ([Olivieri and associates, 1998](#)). Females who survive beyond childhood usually are sterile, and life expectancy even with transfusion therapy is shortened. [Lucarelli and associates \(1993\)](#) reported a 3-year survival rate of 94 percent with bone marrow transplantation for 151 patients.

In the past, pregnancy in women with severe thalassemia was rare. As therapy with iron-chelation and transfusions has become standardized, a number of centers have reported encouraging pregnancy outcomes. In two studies from Athens, [Aessopos \(1999\)](#) and [Daskalakis \(1998\)](#) and their colleagues reported a total of 31 pregnancies without severe complications. [Kumar and associates \(1997\)](#) from Manipur, India, described 32 women who had successful pregnancies. All of these investigators stress that underlying cardiomyopathy should be excluded and that intensive surveillance is needed throughout pregnancy.

With **β -thalassemia minor**, A_2 hemoglobin—composed of two α - and two δ -globin chains—is increased to more than 3.5 percent. Simultaneously, hemoglobin F, composed of two α - and two γ -globin chains, is usually increased to more than 2 percent. The red cells are hypochromic and microcytic but anemia is mild. The hemoglobin concentration typically is 8 to 10 g/dL late in the second trimester, with an increase to between 9 and 11 g/dL near term, compared with a hemoglobin level of 10 to 12 g/dL in the nonpregnant state. There is usually pregnancy-induced augmentation of erythropoiesis and, using ^{51}Cr -tagged erythrocytes, we have documented normal blood volume expansion with slightly subnormal red cell mass expansion.

There is no specific therapy for β -thalassemia minor during pregnancy. Most often, the outcomes for the mother and fetus are satisfactory ([Jensen and colleagues, 1995](#)). Blood transfusions are seldom indicated except for hemorrhage. Prophylactic iron and folic acid in daily doses of about 60 mg and 1 mg, respectively, are given.

The potential exists for the fetus to inherit β -thalassemia major or sickle cell— β -thalassemia. Prenatal diagnosis of β -thalassemia using chorionic villus sampling can be carried out at 9 to 13 weeks ([Weatherall and Provan, 2000](#)). This may be difficult and is not always successful. Techniques include a combination of site-specific restriction endonuclease analysis, restriction fragment polymorphism linkage analysis, polymerase chain reaction, and oligonucleotide probes ([Monni and co-workers, 1993](#)). [Galvani \(2000\)](#) and [Kanavakis \(1999\)](#) and their associates have described preimplantation blastomere biopsy to select unaffected embryos for in vitro fertilization.

POLYCYTHEMIA

Erythrocytosis during pregnancy is usually of the secondary type related to chronic hypoxia, most often from congenital cardiac disease or a pulmonary disorder ([Chap. 44, p. 1193](#)). Occasionally it follows heavy cigarette smoking. We have encountered otherwise healthy young pregnant women who were heavy smokers with chronic bronchitis and a hematocrit of 55 to 60 percent! If polycythemia is severe, the probability of a successful pregnancy outcome is remote.

[Brewer and colleagues \(1992\)](#) described a woman with persistent erythrocytosis associated with a placental site tumor. The hematocrit remained around 55 to 60 percent until hysterectomy was done. Serum erythropoietin concentration was normal.

Polycythemia vera is a myeloproliferative hemopoietic stem cell disorder characterized by excessive proliferation of erythroid, myeloid, and megakaryocytic precursors. It likely is an acquired genetic disorder of stem cells ([Provan and Weatherall, 2000](#)). Symptoms are related to increased blood viscosity, and thrombotic complications are common. It is a condition of older patients and rarely co-exists with pregnancy. [Ruch and Klein \(1964\)](#) described a woman whose nonpregnant hematocrit was as high as 63. During each of two pregnancies, however, her hematocrit ranged from a low of 35 during the second trimester to 44 at term. Fetal loss seems to be high in women with polycythemia vera.

Measurement of serum erythropoietin by radioimmunoassay will differentiate polycythemia vera (low values) from secondary polycythemia (high values). There is evidence that erythroid precursors in this disorder will respond to erythropoietin and may even be hypersensitive.

THROMBOCYTOPENIAS

Low platelet counts in pregnancy may appear clinically to be idiopathic or, more often, to be associated with one of the following disorders: acquired hemolytic anemia, severe preeclampsia or eclampsia, severe obstetrical hemorrhage with blood transfusions, consumptive coagulopathy from placental abruption or similar hypofibrinogenemic states, septicemia, lupus erythematosus, antiphospholipid antibodies, megaloblastic anemia caused by severe folate deficiency, drugs, viral infections, allergies, aplastic anemia, or excessive irradiation. Some forms are inherited ([George, 2000](#)). An enormous number of drugs and naturally occurring foods can cause platelet dysfunction ([George and Shattil, 1991](#)). Aspirin is a prototype. [Kain and associates \(1995\)](#) observed that cocaine use was associated with a 6 percent incidence of thrombocytopenia in pregnant women.

GESTATIONAL THROMBOCYTOPENIA

Normal pregnancy may be accompanied by a physiological drop in platelet concentration, usually evident in the third trimester. There is no evidence that platelet lifespan is decreased or that platelet activation occurs in normal pregnancy ([Baker and Cunningham, 1999](#); [Star and colleagues, 1997](#)). Thus, it is thought that decreased platelet counts occur from hemodilution as well as platelet trapping. Gestational thrombocytopenia is a diagnosis of exclusion. In addition to the usual secondary causes of thrombocytopenia, a number of platelet alterations are commonly associated with preeclampsia-eclampsia. These are discussed in [Chapter 24 \(p. 576\)](#) and include mild to very severe thrombocytopenia as well as increased platelet activation, adherence, and platelet dysfunction.

The definition used for thrombocytopenia is important. From their review, [Rouse and associates \(1998\)](#) cite an incidence of gestational thrombocytopenia—defined as less than 150,000/uL—of 4 to 7 percent. [Burrows and Kelton \(1993a\)](#) reported that 6.6 percent of 15,471 pregnant women had a platelet count of less than 150,000/uL, but in only 1.2 percent was it less than 100,000/uL. Almost three fourths of 1027 women whose platelet counts were less than 150,000/uL were healthy and found to have incidental thrombocytopenia. The other fourth had either a hypertensive disorder of pregnancy (21 percent) or an immunological disorder (4 percent). [Boehlen and associates \(2000\)](#) found that 11.6 percent of 6770 pregnant women had platelet counts of less than 150,000/uL, and that 116,000/uL was 2.5 standard deviations below the mean.

INHERITED THROMBOCYTOPENIAS

The **Bernard-Soulier syndrome** is characterized by lack of platelet membrane glycoprotein (GPIb/IX) and severe dysfunction. Maternal antibodies against fetal GPIb/IX antigen can cause isoimmune fetal thrombocytopenia. [Peng and colleagues \(1991\)](#) described an affected woman who during four pregnancies had episodes of postpartum hemorrhage, gastrointestinal hemorrhage, and fetal thrombocytopenia. [Fujimori and associates \(1999\)](#) described a similarly affected woman whose neonate died from intracranial hemorrhage from thrombocytopenia.

[Chatwani and associates \(1992\)](#) described a woman with autosomally dominant **May-Hegglin anomaly**. Because fetal inheritance could not be excluded, they performed cesarean section at term. The infant was not affected. [Urato and Repke \(1998\)](#) described a woman diagnosed 2 years before pregnancy. Vaginal delivery was allowed, and despite a platelet count of 16,000/uL, she did not bleed excessively. The neonate inherited the anomaly, but also had no bleeding despite a platelet count of 35,000/uL.

IMMUNE THROMBOCYTOPENIC PURPURA

The entity long referred to as **idiopathic thrombocytopenic purpura (ITP)** is usually the consequence of an immune process in which antibodies are directed against platelets. Antibody-coated platelets are destroyed prematurely in the reticuloendothelial system, especially the spleen. The mechanism of production of these platelet-associated immunoglobulins—PAIgG, PAIgM, and PAIgA—is not known, but most investigators consider them to be autoantibodies.

The American Society of Hematology convened a panel to develop clinical practice guidelines for diagnosis and management of immune thrombocytopenic purpura ([George and colleagues, 1996](#)). Acute ITP³ is most often a childhood disease that follows a viral infection. Most cases resolve spontaneously, although perhaps 10 percent become chronic. Conversely, in adults ITP is primarily a chronic disease of young women and rarely resolves spontaneously. Secondary forms of chronic thrombocytopenia must be ruled out to include systemic lupus erythematosus, lymphomas, leukemias, or a number of systemic diseases. For example, up to 10 percent of HIV-positive patients have associated thrombocytopenia ([Glantz and Roberts, 1994](#)). About 2 percent have positive serological tests for lupus, and some cases are associated with high titers of anticardiolipin antibodies.

Outcomes for adults with primary ITP⁴ are shown in [Table 49-6](#). A small number recover spontaneously, and for those who do not, platelet counts usually range from 10,000 to 100,000/uL. In those whose platelet counts remain less than 30,000/uL, or those with significant bleeding at higher levels, treatment with prednisone, 1 to 2 mg/kg, will raise the platelet count in about two thirds, but relapse is exceedingly common ([George and associates, 1996](#)). Glucocorticoids exert their action by suppressing phagocytic activity of the splenic monocyte-macrophage system.

For patients with no response to corticosteroid therapy in 2 to 3 weeks, those in whom massive doses are needed to sustain remission, or those with frequent recurrences, splenectomy is indicated. In about 60 percent, there is substantive improvement as the consequence of decreased removal of platelets by the spleen and reduced antibody production. Massive doses—400 mg/kg—of gamma globulin given intravenously over 5 days results in satisfactory platelet count elevation in two thirds of patients. Such therapy may be useful in patients with life-threatening thrombocytopenia refractive to other therapy, or preoperatively before splenectomy.

Therapy is problematic for the 30 percent of adults who do not respond to corticosteroids or splenectomy. Immunosuppressive drugs, including azathioprine, cyclophosphamide, and cyclosporine, have been used with some success. Danazol, vinca alkaloids, plasma exchange, and high-dose dexamethasone pulse therapy have been described.

IMMUNE THROMBOCYTOPENIA AND PREGNANCY. There is no evidence that pregnancy increases the risk of relapse in women with previously diagnosed immune thrombocytopenia. Nor does it make the condition worse in women with active disease. It is certainly not unusual for women who have been in clinical remission for several years to have recurrent thrombocytopenia during pregnancy; however, this may be because of closer surveillance. Hyperestrogenemia has also been suggested as a cause.

Treatment is considered if the platelet count is less than 50,000/uL ([George and associates, 1996](#)). Corticosteroids in a dose of 1 mg/kg per day may be required for improvement, and most likely treatment will have to be continued throughout pregnancy. Corticosteroid therapy usually produces amelioration, but in refractory disease, high-dose immunoglobulin is given intravenously. [Clark and Gall \(1997\)](#) reviewed 16 case reports of 21 pregnancies in which ITP⁵ was treated with immunoglobulin. All but four responded with post-treatment platelet counts of over 50,000/uL; in 11 of these, it exceeded 100,000/uL. Such therapy is expensive, and in 2000, hospital costs for a 5-day course of treatment ranged from \$5500 to \$8000 for a 70-kg person. Also, shortages of immunoglobulin for high-dose infusion are not uncommon ([Centers for Disease Control and Prevention, 1999](#)).

In women with no response to steroid or immunoglobulin therapy, splenectomy may be effective. Late in pregnancy, the procedure technically is more difficult and cesarean delivery may be necessary to improve exposure.

FETAL AND NEONATAL EFFECTS. Platelet-associated IgG antibodies can cross the placenta and cause thrombocytopenia in the fetus-neonate. The severely thrombocytopenic fetus is at increased risk for intracranial hemorrhage as the consequence of labor and delivery. This fortunately is unusual. [Payne and colleagues \(1997\)](#) reviewed studies of maternal ITP⁶ published since 1973 and added their experiences with 55 cases. Of a total of 601 newborns, 12 percent had severe thrombocytopenia (< 50,000/uL). Only six infants had intracranial hemorrhage, and in three of these the initial platelet count was 50,000/uL or greater.

Considerable attention has been directed at identifying the fetus with potentially dangerous thrombocytopenia. All investigators have concurred that there is not a strong correlation between fetal and maternal platelet counts ([Fig. 49-5](#)) ([George and associates, 1996](#); [Payne and co-workers, 1997](#)). Because of this, several investigators have attempted to quantify the relationship between maternal IgG circulating platelet antibody, platelet-associated antibody, and fetal platelet count. Unfortunately, there is little concurrence. [Kaplan and associates \(1990\)](#) and [Samuels and colleagues \(1990\)](#) reported conflicting results in using indirect platelet immunoglobulin for identification of high-risk neonates. In both studies, however, historical information was useful. Specifically, a history of ITP⁷ remote from pregnancy increased the likelihood of neonatal thrombocytopenia.

[Burrows and Kelton \(1993a\)](#) detected neonatal thrombocytopenia (cord platelets < 50,000/uL) in 19 of 15,932 newborns (0.12 percent). Only 1 of 756 mothers with gestational thrombocytopenia had an affected infant. Of 1414 hypertensive women with thrombocytopenia, five infants had thrombocytopenia. Conversely, of 46 mothers with immune thrombocytopenic purpura, four infants had thrombocytopenia. Importantly, isoimmune thrombocytopenia was associated with profound thrombocytopenia, with cord platelet counts less than 20,000/uL, and there was one fetal death and two other cases of intracranial hemorrhage (see later discussion). In a similar population study, [Boehlen and associates \(1999\)](#) determined antiplatelet antibodies in pregnant women whose platelet counts were less than 150,000/uL. This included 12 percent of almost 6800 women. Of 430 thrombocytopenic women, 9 percent had antibodies detected, but these were of no predictive value. [Sainio and co-workers \(2000\)](#) performed cord platelet counts in almost 4500 neonates. About 2 percent were less than 150,000/uL but only 0.2 percent (1 in 410) were less than 50,000/uL. All cases with bleeding were due to isoimmune thrombocytopenia.

DETECTION OF FETAL THROMBOCYTOPENIA. [Scott and co-workers \(1983\)](#) concluded earlier that no clinical characteristic or laboratory test would accurately predict fetal platelet count. They recommended intrapartum platelet determinations made on blood obtained from the fetal scalp once the cervix was 2 to 3 cm dilated and the membranes ruptured. Whenever the platelet count in scalp blood was identified to be less than 50,000/uL, they performed immediate cesarean delivery. [Daffos and colleagues \(1985\)](#) subsequently reported percutaneous umbilical cord blood sampling for platelet quantification in fetuses whose mothers had immune thrombocytopenia ([Chap. 37, p. 991](#)). This was associated with a high complication rate. [Berry and associates \(1997\)](#) reported no complications but found only a high negative-predictive value. [Payne and colleagues \(1997\)](#) summarized six such studies reported since 1988. Of 195 cases, severe neonatal thrombocytopenia (< 50,000/uL) was found in 7 percent; however, the serious complication rate of cordocentesis was 4.6 percent.

Because of the low incidence of severe neonatal thrombocytopenia and morbidity, [Burrows and Kelton \(1993b\)](#), as well as [Silver and colleagues \(1995\)](#) concluded that fetal platelet determinations and cesarean delivery are not necessary. [Payne and associates \(1997\)](#) as well as the American Society of Hematology ([George and co-workers, 1996](#)) concur. [Peleg and Hunter \(1999\)](#) recently surveyed members of the Society of Maternal-Fetal Medicine and received a 60 percent response. Only a third recommended fetal testing with chronic ITP⁸, and a fourth would do fetal testing in women with new-onset ITP during pregnancy.

ISOIMMUNE THROMBOCYTOPENIA. Platelet isoimmunization can develop in a manner identical to erythrocyte antigen isoimmunization. Its incidence may be as high as 1 in 2000 to 3000 births. If fetal platelet antigens for which maternal platelets are negative gain access to her circulation, the mother then may produce antibodies in subsequent pregnancies that will destroy fetal platelets that have this antigen. The most common antibody is against PL^{A1} platelet-specific antigen. About 2 percent of Caucasians are homozygous for PL^{B1} antigen ([Jaegtvik and associates, 2000](#)). The first pregnancy is affected in about half of cases. This disorder is discussed in [Chapter 39 \(p. 1072\)](#).

THROMBOCYTOSIS

Thrombocytosis, or thrombocythemia, generally is defined as platelets persisting in numbers greater than 450,000/uL. Common causes of **secondary or reactive thrombocytosis** are malignant tumors, iron deficiency, hemorrhage, inflammatory diseases, and connective-tissue disorders. Platelet counts seldom exceed 800,000/uL in these secondary disorders, and prognosis depends on the underlying disease. On the other hand, **essential thrombocytosis** is a myeloproliferative disorder that accounts for most cases in which platelet counts exceed 1 million/uL. Thrombocytosis usually is asymptomatic, but arterial and venous thromboses may develop. [Cortelazzo and colleagues \(1995\)](#) reported that myelosuppression with hydroxyurea for nonpregnant patients with essential thrombocytosis decreased thrombotic episodes from 24 to 4 percent compared with untreated controls.

PREGNANCY. While case reports indicate that pregnancies associated with thrombocytosis have excessive spontaneous abortions, placental infarctions, and preterm delivery, this likely is not the case. [Beard and co-workers \(1991\)](#) described nine pregnancies in six women whose mean platelet count was 1.25 million/uL. One woman aborted and eight pregnancies were delivered at term. [Randi and colleagues \(1994\)](#) reported that six pregnancies in five women with essential thrombocytosis (mean platelets 1.5 million/uL) were normal. Treatment that has been suggested during pregnancy includes aspirin, dipyridamole, heparin, plateletpheresis, or combinations thereof. [Delage and co-workers \(1996\)](#) reviewed 11 cases in which interferon- α was given with successful outcomes. They also described a woman at midpregnancy who had platelets of 2.3 million/uL and had transient blindness. Thrombocytapheresis was performed and interferon- α was used to keep the platelets at around 1 million/uL until delivery.

THROMBOTIC MICROANGIOPATHIES

The original description in 1925 by Moschowitz of **thrombotic thrombocytopenic purpura** was characterized by the pentad of thrombocytopenia, fever, neurological abnormalities, renal impairment, and hemolytic anemia. In 1955, [Gasser and colleagues](#) described the **hemolytic uremic syndrome**, which was similar to thrombotic thrombocytopenic purpura but with more profound renal involvement and fewer neurological aberrations. In 1968, [Robson and co-workers](#) described **postpartum renal failure** characterized by uremia associated with microangiopathic hemolytic anemia and thrombocytopenia ([Chap. 47, p. 1268](#)).

Although it is likely that there are different etiologies to account for the variable findings within these syndromes, they are clinically indistinguishable in adults ([Moake, 1998](#)). There is, however, a pure form of the hemolytic uremic syndrome in children, incited by viral or bacterial infection. [Kincaid-Smith and co-workers \(1988\)](#) reported an association between the lupus anticoagulant and thrombotic microangiopathy. There is no evidence that postpartum renal failure differs remarkably from the hemolytic uremic syndrome except that the woman recently had been pregnant. It seems likely that these syndromes account for the occasional case of severe preeclampsia accompanied by hemolysis and thrombocytopenia that does not respond to delivery ([Kahra and associates, 1998](#); [Magann and colleagues, 1994](#)).

PATHOGENESIS. Microthrombi, consisting of hyaline material made up of platelets and small amounts of fibrin, develop within arterioles and capillaries. These aggregates produce ischemia or infarctions in various organs. The general consensus is that intravascular platelet aggregation stimulates the cascade of events leading to end-organ failure, and although there is evidence for endothelial damage, it is unknown whether this is a consequence or a cause. For over 20 years, unusually large multimers of von Willebrand factor have been identified with active disease. Recently, it was shown that the metalloprotease responsible for cleaving von Willebrand factor secreted by endothelial cells is neutralized by antibodies during an acute episode ([Furlan and colleagues, 1998](#); [Tsai and associates, 1998](#)). Because these resulting large multimers bind platelets and cause aggregation, they likely are the inciting agents of thrombotic thrombocytopenic purpura, but not hemolytic uremic syndrome ([Moake, 1998](#)).

CLINICAL PRESENTATION. Thrombotic microangiopathies are characterized by thrombocytopenia, fragmentation hemolysis, and variable organ dysfunction. A viral prodrome may precede up to 40 percent of cases. Neurological symptoms are present or develop in up to 90 percent of patients and include headache, altered consciousness, convulsions, or stroke. Because renal involvement is common, the two syndromes are difficult to separate ([Moake, 1998](#)). Renal failure is thought to be more severe with the hemolytic uremic syndrome, and in half of the cases, dialysis is required.

HEMATOLOGICAL ABNORMALITIES. Thrombocytopenia is usually severe. Fortunately, even with very low platelet counts, spontaneous severe hemorrhage is uncommon. Microangiopathic hemolysis is associated with moderate to marked anemia, and transfusions are frequently necessary. The blood smear is characterized by erythrocyte fragmentation with schizocytosis. The reticulocyte count is high, and nucleated red blood cells are numerous. Consumptive coagulopathy, although common, is usually subtle and clinically insignificant.

TREATMENT. Plasmapheresis and exchange transfusion with normal plasma has remarkably improved the outcome for these formerly commonly fatal diseases. Transfusions with red blood cells are imperative for life-threatening anemia. [Rock and colleagues \(1991\)](#) found plasma exchange to be superior to plasma infusion in nonpregnant patients; however, overall mortality was still 30 percent. [Bell and co-workers \(1991\)](#) reported their experiences with 108 patients treated at Johns Hopkins Hospital; 10 percent of these patients were pregnant. Those with minimal neurological symptoms were given prednisone, 200 mg daily, but if there were neurological abnormalities or rapid clinical deterioration, plasmapheresis and plasma exchange were performed daily. About a fourth of patients with mild disease responded to prednisone alone. Of those requiring plasmapheresis, relapses were common but overall survival was 91 percent. As emphasized by [Hayward \(1994\)](#) and [Shumak \(1995\)](#) and their associates, relapses (20 to 30 percent) are common and include long-term sequelae such as renal impairment.

PREGNANCY AND THROMBOTIC MICROANGIOPATHY. Evidence is lacking that pregnancy predisposes women to develop thrombotic microangiopathies. Over a 25-year period, [Dashe and co-workers \(1998\)](#) encountered 11 pregnancies complicated by these syndromes or their presumed variants among nearly 275,000 women from our well-defined catchment area who were delivered at Parkland Hospital. This frequency of 1 in 25,000 is not greater than that in our general hospital population.

It is not surprising that severe preeclampsia and eclampsia complicated further by thrombocytopenia and overt hemolysis have been confused with thrombotic thrombocytopenic purpura and vice versa ([Hsu and colleagues, 1995](#); [Magann and co-workers, 1994](#)). Differentiating between preeclampsia, especially atypical preeclampsia, and these syndromes can be difficult, especially at the outset. One constant feature of thrombotic microangiopathies is hemolytic anemia, which is rarely severe with preeclampsia, even when the syndrome of [hemolysis, elevated liver enzymes, and low platelets \(HELLP\)](#)⁹ is present. While deposition of hyaline microthrombi within the liver is seen with thrombotic microangiopathy, hepatocellular necrosis characteristic of preeclampsia has not been described. Whereas delivery leads to resolution of preeclampsia with HELLP syndrome, there is no evidence that thrombotic microangiopathy is improved by delivery ([Letsky, 2000](#)). Importantly, seven of 11 women described by [Dashe and colleagues \(1998\)](#) had recurrent disease either when not pregnant or within the first trimester of a subsequent pregnancy.

Unless the diagnosis is unequivocally one of these thrombotic microangiopathies, rather than severe preeclampsia or eclampsia, the response to pregnancy termination should be evaluated before resorting to plasmapheresis and exchange transfusion, massive-dose glucocorticoid therapy, or other therapy.

Plasmapheresis is not indicated for preeclampsia-eclampsia complicated by hemolysis and thrombocytopenia.

In the past, maternal and fetal outcomes in reported cases have been dismal. [Weiner \(1987\)](#) reviewed 65 cases in which he tried carefully to exclude women with preeclampsia. Perinatal mortality was 80 percent. With plasma therapy, maternal salvage was excellent, but without such therapy, mortality was 68 percent. [Egerman and co-workers \(1996\)](#) described 11 women whom they treated with plasmapheresis from 1988 through 1996. There were two maternal and three fetal deaths. In our experiences from Parkland Hospital, five of eight women treated by plasmapheresis had a dramatic salutary response ([Dashe and associates, 1998](#)).

LONG-TERM PROGNOSIS. Recent observations indicate that pregnant women with thrombotic microangiopathy have a number of long-term complications. In the Parkland study by [Dashe and associates \(1998\)](#), 9-year follow-up disclosed multiple recurrences; renal disease requiring dialysis and/or transplantation; severe hypertension; and blood-borne infectious diseases. Two women died remote from pregnancy—one from dialysis complications and one from acquired immunodeficiency syndrome (AIDS) transmitted by blood therapy. [Egerman and colleagues \(1996\)](#) reported similar observations. Although it is not possible to ascertain if the guarded prognosis in these women is different from the natural history, clearly, development of thrombotic microangiopathy during pregnancy has severe immediate and long-term mortality.

INHERITED COAGULATION DEFECTS

Obstetrical hemorrhage, a common event, is rarely the consequence of an inherited defect in the coagulation mechanism. There are a number of syndromes, however, that are particularly important.

HEMOPHILIAS. Hemophilia A is an X-linked recessively transmitted disease characterized by a marked deficiency of *small component* antihemophilic factor (factor VIII:C). The heterozygous state is responsible for the disease. It is rare among women compared with men. With few exceptions, the homozygous state that results from the inheritance of two abnormal X chromosomes is the requisite for hemophilia A in women. In a few instances, it appears in women spontaneously, as a newly mutant gene.

The genetic and clinical features of severe deficiency of factor IX—Christmas disease or hemophilia B—are quite similar to those for hemophilia A. [Guy and associates \(1992\)](#) reviewed five cases in pregnancy, all with a favorable outcome. They recommended administration of factor IX where levels are below 10 percent.

The degree of risk is influenced markedly by the level of circulating factor VIII:C or factor IX. If the level is at or very close to zero, the risk is major. In female carriers, activity is expected to average 50 percent, but there is a range due to lyonization ([Letsky, 2000](#)). If levels fall below 10 to 20 percent, hemorrhage may occur. These clotting factors increase appreciably during normal pregnancy and in carriers of hemophilia A and B. Desmopressin may also stimulate factor VIII:C release. The risk of hemorrhage is reduced by avoiding lacerations, minimizing episiotomy, and maximizing postpartum myometrial contractions and retraction. [Kadir and co-workers \(1997\)](#) reported that 20 percent of carriers had postpartum hemorrhage; in two it was massive.

Affected male fetuses may develop hematomas with either vaginal or cesarean delivery ([Kadir and associates, 1997](#)). After delivery the risk of hemorrhage in the neonate increases, especially if circumcision is attempted.

Whenever the mother has hemophilia A or B, all of her sons will have the disease, and all of her daughters will be carriers. If she is a carrier, half of her sons will inherit the disease and half of her daughters will be carriers. Prenatal diagnosis of hemophilia is possible in some families using chorionic villus biopsy ([Chap. 37, p. 989](#)). The confirmation of a male fetus also identifies a 50 percent risk of inheriting hemophilia.

FACTOR VIII INHIBITOR. Rarely, antibodies directed against factor VIII are acquired and may lead to life-threatening hemorrhage. This phenomenon has been identified in women during the puerperium. The prominent clinical feature is severe, protracted, repetitive hemorrhage from the reproductive tract starting a week or so after an apparently uncomplicated delivery ([Reece and associates, 1988](#)). The activated partial thromboplastin time is markedly prolonged. Treatment has included multiple transfusions of whole blood and plasma, huge doses of cryoprecipitate, large volumes of an admixture of activated coagulation factors including porcine factor VIII, immunosuppressive therapy, and attempts at various surgical procedures, especially curettage and hysterectomy.

VON WILLEBRAND DISEASE. Clinically, von Willebrand disease is a heterogeneous group of about 20 functional disorders involving aberrations of factor VIII complex and platelet dysfunction. These abnormalities are the most commonly inherited bleeding disorders, and their prevalence is about 1 percent ([Mannucci, 1998](#)). Most of the variants of von Willebrand disease are inherited as autosomal dominant traits. Examples are types I and II disease which are the most common variants. Type III, which is the most severe, is phenotypically recessive.

The **von Willebrand factor** (vWF) is a large, multimeric glycoprotein that forms part of the factor VIII complex. It is essential for normal platelet adhesion to subendothelial collagen and formation of a primary hemostatic plug at the site of blood vessel injury. It also plays a major role in the stabilization of the coagulant properties of factor VIII. The procoagulant component is the antihemophilic factor or factor VIII:C, which is a glycoprotein synthesized by the liver. Conversely, von Willebrand factor, which is present in platelets as well as plasma, is synthesized by endothelium and megakaryocytes under the control of autosomal genes on chromosome 12. The von Willebrand factor antigen (vWF:Ag) is the antigenic determinant measured by immunoassays.

CLINICAL PRESENTATION. Symptomatic patients usually present with evidence of a platelet defect. The possibility of von Willebrand disease is usually considered in women with bleeding suggestive of a chronic disorder of coagulation. The classical autosomal dominant form usually is symptomatic in the heterozygous state. The less common but clinically more severe autosomal recessive form is manifest when inherited from both parents, both of whom demonstrate little or no disease. Type I, which accounts for 75 percent of variants of von Willebrand disease, is characterized clinically by easy bruising, epistaxis, mucosal hemorrhage, and excessive bleeding with trauma, including surgery. Its laboratory features are usually a prolonged bleeding time, prolonged partial thromboplastin time, decreased von Willebrand factor antigen, decreased factor VIII immunological as well as coagulation-promoting activity, and inability of platelets in plasma from an affected person to

react to a variety of stimuli.

EFFECT OF PREGNANCY. During pregnancy, women with von Willebrand disease often develop normal levels of factor VIII coagulant activity as well as von Willebrand factor antigen, although the bleeding time still may be prolonged. These levels may double or triple by term. If factor VIII activity is very low, or if there is bleeding, then treatment is recommended. With significant bleeding, 15 or 20 units of cryoprecipitate are given every 12 hours. Alternatively, factor VIII concentrates may be given that contain high-molecular-weight vWF¹⁰ multimers (Koate-HS, Hemate-P). These concentrates are highly purified and are heat treated to destroy human immunodeficiency virus. [Lubetsky and associates \(1999\)](#) have described continuous infusion with Hemate-P during nine surgical procedures and one vaginal delivery.

There have been a number of studies describing pregnancy outcomes in women with von Willebrand disease. [Conti and associates \(1986\)](#) summarized 38 cases, and in a fourth bleeding was reported with abortion, delivery, or the puerperium. Similarly, [Greer and colleagues \(1991\)](#) reported that eight of 14 pregnancies were complicated by postpartum hemorrhage. [Kadir and co-workers \(1998\)](#) reported their experiences from the Royal Free Hospital in London with 84 pregnancies in women with von Willebrand disease. There was a 20 percent incidence of primary postpartum hemorrhage and another 20 percent had late hemorrhage. Most cases were associated with low vWF¹¹ levels in untreated women. No woman given prophylactic peripartum treatment had hemorrhage.

INTERITANCE. Although most patients with von Willebrand disease are heterozygous variants with a mild bleeding disorder, the disease can be severe. Certainly when both parents have the disorder, their homozygous offspring will develop a serious bleeding disorder. [Mullaart and colleagues \(1991\)](#) documented evidence for periventricular hemorrhage in a 32-week fetus who inherited type IIa von Willebrand disease from her father. [Sherer and associates \(1998\)](#) reviewed these and other predisposing causes of fetal intracranial hemorrhage. Chorionic villus biopsy with DNA analysis to detect the missing genes has been accomplished ([Chap. 37, p. 989](#)). Some authorities recommend cesarean delivery to avoid trauma to a possibly affected fetus if the mother has had severe disease.

OTHER INHERITED COAGULATION FACTOR DEFICIENCIES. A number of rare coagulopathies may result in a manner similar to the hemophilias. **Factor VII deficiency** is a rare autosomal recessive disorder, the gene for which is on chromosome 13. Normally, factor VII increases during pregnancy, but it may do so only mildly in factor VII-deficient patients ([Fadel and Krauss, 1989](#)).

Factor X or Stuart-Prower factor deficiency is extremely rare and is inherited as an autosomal recessive trait. Factor X levels typically rise during normal pregnancy by 50 percent. [Konje and colleagues \(1994\)](#) described a woman with 2 percent activity who was given prophylactic treatment with plasma-derived factor X, which raised plasma levels to 37 percent; however, she suffered an intrapartum placental abruption. [Bofill and co-workers \(1996\)](#) gave intrapartum fresh-frozen plasma to a woman with less than 1 percent factor X activity, and she delivered spontaneously without incident.

Factor XI (plasma thromboplastin antecedent) deficiency probably is the consequence of an autosomal trait that is manifest as severe disease in the homozygous individuals but a minor defect in the heterozygote. This deficiency state is most prevalent in Ashkenazi Jews, and it seldom is encountered in pregnancy. [Musclow and colleagues \(1987\)](#) described 41 deliveries in 17 women with factor XI deficiency, and in none were transfusions required. They also described a 37-week pregnant woman who developed a spontaneous hemarthrosis. [Kadir and associates \(1998\)](#) described 29 pregnancies in 11 women. In none of these did factor XI levels increase; 15 percent had primary postpartum hemorrhage, and 25 percent had delayed hemorrhage. Peripartum treatment with factor XI concentrate at the time of delivery prevents hemorrhage ([Letsky, 2000](#)).

Factor XII deficiency is another autosomal recessive disorder that rarely complicates pregnancy. An increased incidence of thromboembolism is encountered in nonpregnant patients with this deficiency. [Lao and colleagues \(1991\)](#) reported an affected pregnant woman in whom placental abruption developed at 26 weeks.

Factor XIII deficiency is autosomal recessive and it may be associated with maternal intracranial hemorrhage ([Letsky, 2000](#)). Treatment is given with fresh-frozen plasma.

Autosomally inherited abnormalities of fibrinogen usually involve the formation of a functionally defective fibrinogen, commonly referred to as **dysfibrinogenemia** ([Edwards and Rijhsinghani, 2000](#)). Familial **hypofibrinogenemia**—sometimes **afibrinogenemia**—are infrequent recessive disorders. Our experiences suggest that hypofibrinogenemia represents a heterozygous autosomal dominant state with 50 percent of the offspring affected. Typically, thrombin-clottable protein has ranged from 80 to 110 mg/dL when nonpregnant, and this increases by 40 or 50 percent in normal pregnancy. Those pregnancy complications that give rise to acquired hypofibrinogenemia, that is, placental abruption, are more common in fibrinogen deficiency, but the existence of such conditions provided the impetus for study. [Goodwin \(1989\)](#) reviewed the literature and reported a high incidence of placental abruption and postpartum hemorrhage. [Trehan and Fergusson \(1991\)](#) and [Funai and associates \(1997\)](#) described successful outcomes in two women in whom fibrinogen or plasma infusions were given weekly or biweekly throughout pregnancy.

THROMBOPHILIAS

A number of important regulatory proteins inhibit clotting. There are physiological antithrombotic proteins that act as inhibitors at strategic sites in the coagulation cascade to maintain blood fluidity under normal circumstances. Examples include **antithrombin III** and **protein C** and its co-factor, **protein S**. Inherited deficiencies of these inhibitory proteins are caused by mutations of genes influencing their control. Because they may be associated with recurrent thromboembolism, they are collectively referred to as *thrombophilias*. Other inherited coagulopathies arise from mutations that include **activated protein C resistance** from factor V single-gene mutations of which the most common is the factor V Leiden mutation. There is also a function-enhancing mutation in the **prothrombin gene (G20210A)** and also **hyperhomocystinemia**.

Taken in toto, these mutations are common. For each syndrome there are many different single-gene point mutations that may be responsible (see discussion that follows). The aggregate prevalence of the six aforementioned coagulants is nearly 20 percent. Their inheritance is usually associated in nonpregnant patients with increased risk of deep-vein thrombosis and pulmonary embolism, sagittal sinus thrombosis, and portal vein thrombosis. [Heijboer and colleagues \(1990\)](#) studied the prevalence of isolated abnormal coagulation-inhibiting proteins in 277 nonpregnant patients with venographically proven deep-vein thrombosis. Their incidence combined was 8.3 percent compared with 2.2 percent for normal controls. In some of these patients, environmental provocation such as surgery or oral contraceptive use will enhance the likelihood of thromboembolism.

Pregnancy is also an inciting factor in many of these thrombophilias. Pregnancy-related complications include, in addition to thromboembolism, increased risk for severe early-onset preeclampsia, placental infarction and abruption, fetal growth restriction, and stillbirths. Some of these are listed in [Table 49-7](#). [De Stefano and co-workers \(1994\)](#) cited pregnancy as a common triggering event for thrombosis in 238 patients with inherited thrombophilia.

In general, venous thrombosis and pulmonary embolism are treated as for any case ([Chap. 46, p. 1237](#)). Patients with prior episodes are given heparin prophylaxis. Routine screening for thrombophilia is not warranted in asymptomatic women with no history of thrombosis ([American College of Obstetricians and Gynecologists, 2000a](#); [Lockwood, 1999](#)). It is uncertain if prophylaxis is necessary in women without prior adverse outcomes but who are incidentally found to have thrombophilia.

ANTITHROMBIN III DEFICIENCY. These are rare mutations but the most thrombogenic ([Table 49-7](#)). Most are point mutations ([Lockwood, 1999](#)). [Conard and co-workers \(1990\)](#) reported that half of 63 pregnancies with antithrombin III deficiency were complicated by thrombosis either antepartum or postpartum. From their review, [Swain and Gilstrap \(1999\)](#) cite a risk of 45 to 70 percent of thromboembolism during pregnancy. [Seguin and colleagues \(1994\)](#) reviewed 23 cases of neonatal antithrombin III deficiency. There were 11 cases of thrombosis and 10 deaths. Heparin therapy is indicated throughout pregnancy ([Togliola and Weg, 1996](#)).

PROTEIN C DEFICIENCY. This deficiency is autosomal dominant, and there are a number of mutations. They are characterized by various combinations of reduced immunological and functional protein C levels ([Lockwood, 1999](#)). The heterozygous trait for protein C results in plasma levels of 55 to 65 percent of normal, and has an incidence of about 1 in 300 ([Allaart and associates, 1993](#)). Diagnosis during pregnancy has been problematic because some investigators have reported that pregnancy changes circulating levels. In a prospective cross-sectional study, however, [Faught and colleagues \(1995\)](#) reported that protein C levels were unchanged during pregnancy. Most authorities recommend that the diagnosis be established in the nonpregnant state.

About half of heterozygotes will suffer venous thrombotic episodes by adulthood. Homozygotes, or double heterozygotes, have severe deficiency usually manifest as *purpura fulminans* in the neonate. [Conard and colleagues \(1990\)](#) reported that 25 percent of 93 pregnancies complicated by protein C deficiency had deep-vein thrombosis. Puerperal thromboembolism is twice as common as antepartum occurrence. [Ruos and co-workers \(1990\)](#) described a woman with functional protein C deficiency who suffered a sagittal sinus thrombosis 10 days postpartum.

PROTEIN S DEFICIENCY. This is a cofactor for protein C activity, and its deficiency is caused by one of several autosomal dominant mutations. There are three types depending on free, functional, and total antigenically determined levels ([Lefkowitz and colleagues, 1996](#)). According to [Comp and colleagues \(1986\)](#), total protein S

plasma concentrations, as well as functional protein S activity, are diminished substantively during normal pregnancy. [Faught and associates \(1995\)](#) observed that while total protein S concentration did not differ across pregnancy, there was a significant fall in free protein S levels after early pregnancy. [Lefkowitz and co-workers \(1996\)](#) reported a striking decline in protein S functional levels; thus diagnosis during pregnancy is difficult.

The lifetime risk of thromboembolism in patients with protein S deficiency is about 50 percent ([Allaart and colleagues, 1993](#)). [Conard and associates \(1990\)](#) described thrombosis in five of 29 pregnancies with this deficiency. One woman had a cerebral vein thrombosis. While the incidence of antepartum thromboembolism is increased, thrombosis is even more likely in the puerperium in a manner similar to protein C ([Lockwood, 1999](#)). Because of this, most authorities recommend that anticoagulation with heparin be given during pregnancy. Likely because many of these women already are receiving warfarin when they conceive, the disorder is associated with several fetal anomalies ([Chap. 38, p. 1014](#)).

ACTIVATED PROTEIN C RESISTANCE. This currently is the most prevalent thrombophilic syndrome. It is characterized by resistance of plasma to the anticoagulant effect of activated protein C. It is much more common than protein S, C, and antithrombin III deficiencies combined, with a frequency in the normal population of 3 to 7 percent ([Svensson and Dahlback, 1994](#)). The most common mutation is *factor V Leiden*, which is a G → A substitution in nucleotide 1691 that results in substitution of glutamine for arginine at position 506. This single missense gene mutation is autosomal dominant. Inheritance causes a thromboembolic risk because the Arg506 cleavage site is now resistant to the naturally occurring anticoagulant, activated protein C. Factor V Leiden is extremely common in Europeans (5 to 9 percent), intermediate in Hispanic Americans (2 percent), and rare in African Americans and Asians ([Fassett and colleagues, 2000](#); [Rees and co-workers, 1995](#)).

As discussed earlier, functional protein S levels normally decline during pregnancy. This causes resistance to activated protein C which is amplified by normal increased factor VIII levels during pregnancy. The combination appears to exacerbate the prothrombotic effects of the factor V Leiden mutation ([Walker and co-workers, 1997](#)). As shown in [Table 49-7](#), the risk for thromboembolism during pregnancy is increased 50-fold and is as high as 30 percent ([Dizon-Townson and colleagues, 1997](#)). Pregnancy wastage is only slightly increased, and the risk for preeclampsia is increased from two- to eightfold. Importantly, 10 percent of affected pregnancies have placental infarctions on the fetal side ([Dizon-Townson and associates, 1996](#)). The risk for abruptio placentae is increased up to eightfold ([Wiener-Megnagi and co-workers, 1998](#)). It also appears that fetuses heterozygous for factor V Leiden mutation can suffer cerebrovascular infarctions with resultant cerebral palsy ([Thorarensen and colleagues, 1997](#)).

HYPERHOMOCYSTEINEMIA. A number of enzymes can affect plasma levels of homocysteine. When these are deficient, hyperhomocystinemia develops and increases the risk for atherosclerosis, thromboembolism, fetal neural-tube defects, and recurrent miscarriage ([Lockwood, 1999](#)). The most common cause is the C667T thermolabile mutation of 5,10-methylene tetrahydrofolate reductase (MTHFR). This is autosomal recessive, and [Kupferminc and associates \(1999\)](#) found a prevalence of 8 percent of homozygotes in women with normal pregnancies.

Fortunately, because it is so common, complications are uncommon even with MTHFR¹² homozygosity. [Lockwood \(1999\)](#) cites a 10 percent lifetime incidence of thromboembolism, which is increased only 2.5-fold over normal. Thromboembolism is probably also more likely in pregnancy, as are other adverse pregnancy outcomes ([Table 49-7](#)). [Laivuori and associates \(2000\)](#) did not find an excessive incidence of preeclampsia. In a number of placentas examined because of bad perinatal outcomes, [Khong and Hague \(1999\)](#) found acute atherosclerosis, intraluminal endovascular trophoblast, and infarctions. None of these was specific.

PROTHROMBIN G20210A MUTATION. This mutant gene is found in about 2 to 3 percent of the population and is associated with a three- to fourfold lifetime risk of thromboembolism ([Margaglione and associates, 1998](#)). As shown in [Table 49-7](#), the risk of thromboembolism in pregnancy is increased 15-fold ([Gerhardt and collaborators, 2000](#)). It is also associated with an increased incidence of abruptio placentae and fetal growth restriction ([Kupferminc and co-workers, 1999](#)).

TABLE 49-1. Hemoglobin Concentrations in 85 Healthy Women with Proven Iron Stores

Hemoglo (g/dL)	Nonpregnant	Midpregnancy	Late Pregnancy
Mean	13.7	11.5	12.3
Less than 12.0	1%	72%	36%
Less than 11.0	None	29%	6%
Less than 10.0	None	4%	1%
Lowest	11.7	9.7	9.8
