20. Induction and Augmentation of Labor

According to the National Center for Death Statistics, of the 3.9 million deliveries in the United States in 1995, 34 percent involved labor induction or augmentation ([Ventura and colleagues, 1997](#)). At Parkland Hospital, approximately 30 percent of labors are induced or augmented using oxytocin. At the University of Alabama at Birmingham Hospital, from 1996 through 1999, in over 17,000 deliveries, 20 percent of women were given oxytocin for labor induction and 35 percent for augmentation. Common indications for induction include membrane rupture without spontaneous onset of labor, maternal hypertension, nonreassuring fetal status, and postterm gestation. The purpose of this chapter is to describe techniques available in the United States to effect cervical ripening and for the induction or augmentation of labor.

GENERAL CONCEPTS

The concept of elective induction for either convenience of the practitioner and/or the patient is not recommended by us, or by the [American College of Obstetricians and Gynecologists \(1999a\)](#). This practice is associated with an increase in cesarean births, especially in nulliparas ([Bland and colleagues, 2000](#); [Maslow and Sweeny, 2000](#); [Prysak and Castronova, 1998](#); [Yeast and associates, 1999](#)). Induction is indicated when the benefits to either the mother or fetus outweigh those of continuing the pregnancy. The spectrum of valid indications for induction includes emergent conditions such as ruptured membranes with chorioamnionitis or severe preeclampsia. There also are several relative indications that may approximate an elective induction. Some examples include women at term with a history of rapid labor and/or who reside an appreciable distance from the obstetrical facility. Such situations may be further aggravated by geographical (mountainous) and/or climatological (winter conditions) circumstances. Although less urgent, these situations present valid indications for induction at term.

Another general concept is the recognition that induction is associated with increased complications as compared with spontaneous labor. Complications include an increased incidence of chorioamnionitis and increased cesarean delivery. The latter may simply be due to the uterus being poorly prepared for labor; examples include an "unripe cervix" or a myometrium unable to achieve effective synchronous contractions. It is also likely that the increase in cesarean deliveries associated with labor induction is influenced by individual physician preferences regarding the duration of attempt at induction, especially in the circumstance of an "unripe cervix." For example, attempted labor induction with intravenous oxytocin for only 4 to 6 hours in a postterm nulliparous woman with an unripe cervix would not be expected to be successful ([Rouse and colleagues, 2000](#)).

Thus, the duration for either induction or augmentation, with the expectation of a successful progression of labor, has received too little attention. More precise data are needed considering the wide range of individual practitioner management.

CONTRAINDICATIONS

A number of uterine, fetal, or maternal conditions present contraindications to labor induction. Most of these are similar to those that would preclude spontaneous labor and delivery. **Uterine contraindications** primarily relate to a prior disruption such as a classical incision or uterine surgery. Placenta previa would also preclude labor. Fetal contraindications include appreciable macrosomia, some fetal anomalies such as hydrocephalus, malpresentations, or nonreassuring fetal status. **Maternal contraindications** are related to maternal size, pelvic anatomy, and selected medical conditions such as active genital herpes.

PREINDUCTION CERVICAL RIPENING

The condition or "favorability" of the cervix is important to labor induction. In many cases, the induction technique chosen depends upon the perceived ease of its anticipated success. Physical characteristics of the cervix and lower uterine segment are most important. The level of the presenting part, or station, is also important. One quantifiable method that is predictive of a successful labor induction is that described by [Bishop \(1964\)](#). Elements of the **Bishop score** include dilatation, effacement, station, consistency, and position of the cervix ([Table 20-1](#)). Induction to active labor is usually successful with a score of 9 or greater and is less successful with lower scores. Most practitioners would consider a woman whose cervix is 2 cm dilated, 80 percent effaced, soft and midposition, and with the fetal occiput at -1 station as likely to have a successful labor induction. In these circumstances, initiation of labor with a dilute intravenous oxytocin solution is usually successful.

Unfortunately, women too frequently have an indication for induction of labor but with various degrees of an unripe cervix. As the Bishop score decreases, there is an increasingly unsuccessful induction rate. Thus, considerable research has been directed toward various techniques to "ripen" the cervix prior to the stimulation of uterine contractions.

PHARMACOLOGICAL TECHNIQUES

PROSTAGLANDIN E₂. Local application of prostaglandin E₂ gel (dinoprostone) is widely used for cervical ripening ([American College of Obstetricians and Gynecologists, 1999a, 1999b](#)). Histological changes include a dissolution of collagen bundles and an increase in submucosal water content ([Rayburn and colleagues, 1994](#)). These changes in cervical connective tissue at term are similar to those observed in early labor.

[Rayburn \(1989\)](#) reviewed cumulative experiences with intracervical or intravaginal prostaglandin E₂ preparations in over 5000 pregnancies comprising over 70 prospective clinical trials. He concluded that prostaglandin E₂ was superior to placebo in enhancing cervical effacement and dilation. The prostaglandin-induced cervical ripening process often included initiation of labor. Moreover, with the latter, labor is similar to that of normal spontaneous labor. Use of low-dose prostaglandin E₂ increases the chances of successful induction, decreases the incidence of prolonged labor, and reduces total and maximal oxytocin doses ([Brindley and Sokol, 1988](#)). Approximately half of treated women enter labor and deliver within 24 hours ([Rayburn, 1989](#)). The reported effects of prostaglandin on overall cesarean delivery rates, however, have been inconsistent. While some studies have shown a reduction, most have not shown a significant decrease ([Bernstein, 1991](#); [Brindley and Sokol, 1988](#); [Keirse, 1993](#)).

Early trials included various dosages of intracervical (0.3 to 0.5 mg) or intravaginal (3 to 5 mg) prostaglandin E₂, which were compared with untreated controls. In a meta-analysis of 18 such studies encompassing 1811 women, [Owen and co-workers \(1991\)](#) found that prostaglandin E₂ significantly improved Bishop scores and induction-to-delivery times. They found no benefit regarding the cesarean delivery rate.

In 1992, the Food and Drug Administration approved prostaglandin E₂ gel (Prepidil) for cervical ripening in women at or near term who have an indication for induction. The gel is available in a 2.5-mL syringe that contains 0.5 mg of dinoprostone. The intracervical route offers the advantages of prompting less uterine activity and greater efficacy in women with a very unripe cervix ([Ekman and co-workers, 1983](#)).

A 10-mg dinoprostone vaginal insert (Cervidil) also was approved in 1995 for cervical ripening. The insert provides slower release of medication (0.3 mg/hr) than the gel. Most trials with the insert have compared this formulation with intracervical gel ([Chyu and Strassner, 1997](#); [Rayburn and colleagues, 1992](#)). Similar to results with dinoprostone gel, clinical trials demonstrate that these vaginal inserts shorten the interval from induction-to-delivery. One advantage is that the insert can be removed should hyperstimulation occur.

PATIENT SELECTION. A Bishop score of 4 or less ([Table 20-1](#)) is considered as identifying an unfavorable cervix and thus an indication for prostaglandin E₂ cervical ripening.

ADMINISTRATION. It is recommended that these preparations be administered either at or near the delivery suite, where continuous uterine activity and fetal heart rate monitoring can be performed ([American College of Obstetricians and Gynecologists, 1995b](#)). The woman remains recumbent for at least 30 minutes following application. An observation period ranging from 30 minutes to 2 hours may be prudent. If there is no change in uterine activity or fetal heart rate after this period, she then may be transferred or discharged. When contractions occur, they are usually apparent in the first hour and show peak activity in the first 4 hours ([Bernstein, 1991](#); [Miller and colleagues, 1991](#)). If regular contractions persist, fetal heart rate monitoring should be continued and vital signs recorded.

A minimum safe time interval between prostaglandin E₂ administration and the initiation of oxytocin has not been established. According to manufacturer guidelines, oxytocin induction should be delayed for 6 to 12 hours.

SIDE EFFECTS. Reported rates of uterine hyperstimulation—defined as six or more contractions in 10 minutes for a total of 20 minutes—are 1 percent for

intracervical gel (0.5-mg dose) and 5 percent for intravaginal gel (2- to 5-mg dose) ([Brindley and Sokol, 1988](#); [Rayburn, 1989](#)). Because serious hyperstimulation or further fetal compromise can occur when prostaglandin is used with preexisting labor, such use is not generally accepted. When hyperstimulation occurs, it usually begins within 1 hour after the gel or insert is applied. Removing the insert by pulling on the tail of the net surrounding it will usually reverse this effect. Irrigation of the cervix and vagina to remove the gel has not been found to be helpful.

Systemic effects, including fever, vomiting, and diarrhea from low-dose prostaglandin E₂, are negligible. The manufacturers recommend caution when using any prostaglandin E₂ product in patients with glaucoma, severe hepatic or renal impairment, or asthma. This is despite that prostaglandin E₂ is a bronchodilator, and that neither bronchoconstriction nor significant blood pressure changes have been reported with low-dose gel.

Neonatal outcomes compare favorably with those achieved by oxytocin induction. The likelihood of a low Apgar score, need for resuscitation, admission to an intensive care nursery, or perinatal death is not increased with prostaglandin E₂ ([Keirse, 1993](#)).

PROSTAGLANDIN E₁. Misoprostol (Cytotec) is a synthetic prostaglandin E₁, and currently available as a 100-ug tablet for prevention of peptic ulcers. It has been used "off label" for preinduction cervical ripening and labor induction. Misoprostol is inexpensive with a cost less than \$1 per 100-ug tablet compared with \$75 for 0.5 mg of dinoprostone gel. It is stable at room temperature and easily administered orally or placed into the vagina, but not the cervix. In October, 2000, G. D. Searle & Company has notified physicians that misoprostol is not approved for labor induction or abortion. The [American College of Obstetricians and Gynecologists \(1999b, 2000\)](#) states that intravaginal administration of 25 ug not more frequently than every 3 to 6 h is effective in women with an unfavorable cervix.

VAGINAL MISOPROSTOL. Initial studies suggested that misoprostol tablets placed into the vagina were either superior to or equivalent in efficacy compared with intracervical prostaglandin E₂ gel ([Chuck and Huffaker, 1995](#); [Varaklis and colleagues, 1995](#); [Wing and co-workers, 1995a, 1995b](#)). The [American College of Obstetricians and Gynecologists \(1999b\)](#) reviewed 19 prospective randomized trials in which more than 1900 women were given misoprostol in intravaginal dosages ranging from 25 to 200 ug. The committee recommends the use of intravaginal misoprostol in an approximate 25-ug dose (a quarter of a 100-ug tablet). Such usage is considered to decrease the need for oxytocin, achieve higher rates of vaginal delivery within 24 hours of induction, and significantly reduce induction-to-delivery intervals ([Sanchez-Ramos and colleagues, 1997](#)). [Hofmeyr and associates \(1999\)](#) reviewed data from the United Kingdom Cochrane Centre, and support these recommendations but cautioned that increased uterine hyperstimulation with fetal heart rate changes was of concern.

The 50-ug dose results in significantly increased tachysystole, meconium passage, and meconium aspiration compared with prostaglandin E₂ gel ([Farah and colleagues, 1997](#); [Wing and co-workers, 1995a, 1995b](#)). There is also an increased incidence of cesarean delivery due to uterine hyperstimulation when compared with dinoprostone ([Buser and collaborators, 1997](#)). The 25-ug dose every 3 hours was associated with significantly fewer adverse effects than the 50-ug dose. Reports of uterine rupture in women with prior uterine surgery currently preclude the use of misoprostol in these women ([Bennet, 1997](#); [Sciscione and associates, 1998](#); [Wing and colleagues, 1998](#)). In one report, [Plaut and associates \(1999\)](#) described uterine rupture in 5 of 89 (6 percent) women with a previous cesarean delivery who were induced with misoprostol compared with only 1 of 423 such women not given misoprostol ($P = .0001$).

ORAL MISOPROSTOL. [Windrim and associates \(1997\)](#) reported that orally administered misoprostol was of similar efficacy for cervical ripening and labor induction as intravaginal administration. [Bennett and colleagues \(1998\)](#) and [Topozada and co-workers \(1997\)](#) found a shorter interval-to-delivery with the vaginal application, but more frequent fetal heart rate abnormalities. [Adair and colleagues \(1998\)](#) concluded that oral and vaginal applications were of similar efficacy but that an oral dosage of 200 ug was associated with more frequent abnormal uterine contractility. [Wing and collaborators \(1999\)](#) reported that 50-ug oral misoprostol was less effective than 25 ug administered vaginally for cervical ripening and labor induction. These investigators ([Wing and colleagues, 2000](#)) subsequently reported that a 100-ug oral dose was as effective as the 25-ug intravaginal dose. Clearly, more information is needed regarding an optimum dosage and route of administration of misoprostol. Kinetics of oral absorption as well as vaginal absorption in regard to vaginal pH should also be studied ([Karim and colleagues, 1989](#); [Zieman and associates, 1997](#)).

MECHANICAL TECHNIQUES

Cervical dilatation with a balloon catheter was first attributed to Barnes by [Woodman \(1863\)](#). Several variations of this method are used currently. One method shown in [Figure 20-1](#) includes the infusion of extra-amnionic normal saline and is referred to by some as **EASI**. [Sherman and colleagues \(1996\)](#) summarized the results of 13 trials with balloon catheters and concluded that, with or without saline infusion, the method resulted in rapid improvement in Bishop scores and shorter labors. In these 13 trials, the incidence of cesarean births ranged from 4 to 46 percent.

A number of comparative trials has been done. [Schreyer and colleagues \(1989\)](#) found that extra-amnionic saline infusion resulted in a greater increase in Bishop score in less time than vaginal prostaglandin E₂. [Vengalil and colleagues \(1998\)](#) reported similar outcomes with cesarean delivery rates and induction-to-delivery times with catheter infusion compared with 50-ug misoprostol administered vaginally every 4 hours. Studies by [Hemlin and Moller \(1998\)](#) and [Sciscione and associates \(1999\)](#) reported catheter infusion to be more efficacious for cervical ripening than 0.5 mg of intracervical prostaglandin E₂. [Goldman and Wigton \(1999\)](#) reported a significantly higher Bishop score at 6 and 12 hours with catheter infusion compared with intracervical dinoprostone. [Abramovici and co-workers \(1999\)](#) also found superior efficacy with catheter induction compared with 50-ug oral misoprostol every 4 hours in nulliparas with a Bishop score of 5 or less. Almost 85 percent of those induced by catheter delivered within 24 hours compared with nearly 55 percent of these given misoprostol. Misoprostol and catheter/oxytocin had equivalent success rates.

[Guinn and colleagues \(2000\)](#) randomized women to intracervical prostaglandin E₂, laminaria plus intravenous oxytocin, or catheter infusion plus oxytocin. Cesarean delivery was similar with all three interventions. The randomization-to-delivery time of 18 hours with catheter infusion was significantly less than the 21.5 hours with laminaria plus oxytocin or 24.8 hours with prostaglandin E₂ gel. [Buccellato and associates \(2000\)](#) reported similar outcomes with 50-ug misoprostol compared with extra-amnionic saline.

HYGROSCOPIC CERVICAL DILATORS. Initiation of cervical dilatation with hygroscopic osmotic cervical dilators has long been accepted as efficacious prior to pregnancy termination ([Hale and Pion, 1972](#); [Chap. 33, p. 871](#)). For labor induction with a viable pregnancy, less information is available regarding hygroscopic dilators to improve an "unripe cervix."

[Krammer and colleagues \(1995a, 1995b\)](#) and [Gilson and associates \(1996\)](#) reported that hygroscopic dilators resulted in rapid improvement of cervical status. Importantly, however, there was no beneficial effect on the cesarean delivery rate or randomization-to-delivery intervals. In the randomized study cited earlier, [Guinn and co-workers \(2000\)](#) reported that cervical ripening with cervical dilators plus oxytocin induction were similar in efficacy to either catheter infusion or prostaglandin E₂ cervical gel.

The attraction of these dilators is their low cost, ease of placement, and their ability to be quickly removed. Most recently, [Guinn and colleagues \(2000\)](#) at the University of Alabama compared cervical prostaglandin gel, cervical dilators, and **EASI**¹ in women induced at term. Despite similar cesarean delivery rates, women randomized to cervical dilators had a significantly longer interval-to-delivery time compared with women assigned to EASI. The use of hygroscopic dilators appears to be safe, although anaphylaxis has followed laminaria insertion ([Cole and Bruck, 2000](#); [Nguyen and Hoffman, 1995](#)). It is of some benefit for initiation of cervical dilation in women with an indication for induction of labor.

MEMBRANE STRIPPING. Induction of labor by membrane "stripping" or "sweeping" is a relatively common practice. In a randomized study of 180 women, [McColgin and colleagues \(1990a, 1990b\)](#) reported that membrane stripping was safe and associated with a decreased incidence of postterm gestation. These investigators observed significantly increased levels of plasma prostaglandins with membrane stripping ([McColgin and co-authors, 1993](#)). [Allott and Palmer \(1993\)](#) randomized 195 women with normal pregnancies beyond 40 weeks to digital cervical examination either with or without membrane stripping. Stripping was performed by inserting the index finger as far through the internal os as possible and rotating twice through 360 degrees to separate the membranes from the lower segment. Two thirds of those who underwent stripping entered spontaneous labor within 72 hours compared with a third of the other group. Ruptured membranes, infection, and bleeding were not increased, and induction for post-term pregnancy was significantly decreased with stripping.

[Boulvain and colleagues \(1999\)](#) reviewed 13 reports of sweeping of membranes to induce labor and prevent postterm pregnancy in almost 2000 women. Membrane stripping at term was considered to be safe in that maternal and neonatal infection and membrane rupture were similar in the intervention versus control groups. The cesarean delivery rate was also similar in both groups. Membrane stripping was considered beneficial because these women were significantly more likely to deliver within 48 hours, within 1 week, or before 41 weeks. Finally, significantly fewer women in the membrane-stripping group required labor induction.

SUMMARY OF PREINDUCTION CERVICAL RIPENING

Induction of labor in the presence of an "unripe" cervix is frequently indicated. Initial pharmacological efforts to effect cervical ripening targeted cervical or vaginal prostaglandin E₂ preparations (dinoprostone). Subsequently developed pharmacological methods include either oral or vaginal prostaglandin E₁ (misoprostol). These pharmacological techniques have been compared in a few studies to mechanical techniques such as extra-amniotic saline infusion ([EASI](#)¹) through a transcervical 30-mL balloon Foley catheter or to insertion of hygroscopic cervical dilators. It is likely that all of the described techniques have some benefit when compared with no attempt at cervical ripening. Unfortunately, benefits are limited to either differences in an improved Bishop score and/or times to either active labor and/or delivery. There is little evidence and no consensus that any of these techniques have resulted in a significant reduction in cesarean births or in lower maternal or neonatal morbidity compared with untreated controls.

LABOR INDUCTION AND AUGMENTATION WITH OXYTOCIN

Synthetic oxytocin is one of the most commonly used medications in the United States. Oxytocin was the first polypeptide hormone synthesized, and the 1955 Nobel Prize in chemistry was awarded for this ([DuVigneaud and co-workers, 1953](#)). Virtually every parturient receives oxytocin following delivery and many also receive it to induce or augment labor. According to the National Center for Health Statistics, in 1995 more than 1.3 million American women were given oxytocin to stimulate labor ([Ventura and colleagues, 1997](#)).

In many cases, there is only a semantical difference between labor induction and augmentation. Induction of labor implies stimulation of contractions before the spontaneous onset of labor, with or without ruptured membranes. Augmentation refers to stimulation of spontaneous contractions that are considered inadequate because of failure of progressive dilatation and descent. Some practitioners consider augmentation to include stimulation of contractions following spontaneously ruptured membranes without labor. While some physicians use different oxytocin infusion regimens for each of these, we use the same technique that is described subsequently.

There are a myriad of obstetrical, medical, and fetal indications for labor induction. These are described throughout this book. The diagnosis of inadequate labor is discussed in detail in [Chapter 18](#). The use of oxytocin given by intravenous infusion to augment inadequate labor—uterine dysfunction—is appropriate only after assessment to exclude fetopelvic disproportion. With oxytocin induction or augmentation, it is mandatory that the fetal heart rate and contraction pattern be observed closely. The [American College of Obstetricians and Gynecologists \(1999a\)](#) recommends fetal heart rate and uterine contraction monitoring similar to that for any high-risk pregnancy. This is done either by palpation of contraction frequency and relaxation or by electronic means of recording uterine activity ([Chap. 14, p. 354](#)). Uterine contraction pressures cannot be accurately quantified by palpation ([Arrabal and Nagey, 1996](#)).

TECHNIQUE FOR ADMINISTRATION OF INTRAVENOUS OXYTOCIN

A variety of methods for stimulation of uterine contractions with oxytocin has been employed. The woman should have direct nursing supervision while oxytocin is being infused. The goal is to effect uterine activity that is sufficient to produce cervical change and fetal descent while avoiding uterine hyperstimulation and/or development of a nonreassuring fetal status. Contractions must be evaluated continually and oxytocin discontinued if they persist as greater than five in a 10-minute period or seven in a 15-minute period; if they last longer than 60 to 90 seconds; or if the fetal heart rate pattern becomes nonreassuring. With hyperstimulation, immediate discontinuation of oxytocin nearly always rapidly decreases the frequency of contractions. When oxytocin is stopped, its concentration in plasma rapidly falls because the mean half-life is approximately 5 minutes.

[Seitchik and co-workers \(1984\)](#) studied the pharmacokinetics of intravenously infused oxytocin and found that a uterine response occurs within 3 to 5 minutes of beginning infusion and that a plasma steady state is reached in 40 minutes. Response depends on preexisting uterine activity, sensitivity, and cervical status, which are related to pregnancy duration and to individual biological differences. [Caldeyro-Barcia and Poseiro \(1960\)](#) reported that uterine response to oxytocin increases from 20 to 30 weeks, but is unchanged from 34 weeks until term, at which time sensitivity rapidly increases ([Chap. 14, p. 355](#)). [Satin and co-workers \(1992b\)](#) studied factors affecting the oxytocin dosage required for adequate labor stimulation in 1773 pregnancies. Important predictors of oxytocin dosage included cervical dilatation, parity, and gestational age.

Synthetic oxytocin is usually diluted into 1000 mL of a balanced salt solution that is administered by infusion pump. Administration by any other route is not recommended for labor stimulation. To avoid bolus administration, the infusion should be inserted into the main intravenous line close to the venipuncture site. A typical oxytocin infusate consists of 10 to 20 units—equivalent to 10,000 to 20,000 mU—mixed into 1000 mL of lactated Ringer solution, resulting in an oxytocin concentration of 10 or 20 mU/mL, respectively.

At Parkland Hospital from 1996 through 1999, over 15,000 women were given oxytocin to induce or augment labor. Bedside attendance is provided by trained nursing personnel and continuous electronic monitoring of the fetal heart rate and uterine activity is conducted. Oxytocin is avoided generally in cases of abnormal fetal presentations and of marked uterine overdistention such as pathological hydramnios, an excessively large fetus, or multiple fetuses. Women of high parity (6 or more) are generally not given oxytocin because uterine rupture occurs more readily ([Chap. 25, p. 646](#)). At Parkland, oxytocin is usually withheld from women with a previous uterine scar and a live fetus ([Chap. 25, p. 648](#)). Conversely, a prior cesarean delivery is not a contraindication to induction or augmentation at the University of Alabama or the University of Texas at Houston. The fetal condition must be reassuring, as determined by heart rate and lack of thick meconium in amniotic fluid. A dead fetus is not a contraindication to oxytocin usage unless there is overt fetopelvic disproportion.

OXYTOCIN DOSAGE. According to [American College of Obstetricians and Gynecologists \(1999a\)](#), any of a number of oxytocin regimens are appropriate for labor stimulation. Some are shown in [Table 20-2](#). Until relatively recently, only variations of the low-dose protocol were used in the United States. In [1984, O'Driscoll and colleagues](#) described a protocol for the active management of labor that called for oxytocin at a starting dose of 6 mU/min and advanced in 6-mU/min increments. Following this, various trials during the 1990s compared high-dose (4 to 6 mU/min) versus conventional low-dose (0.5 to 1.5 mU/min) regimens both for labor induction and augmentation.

At Parkland Hospital, [Satin and colleagues \(1992a\)](#) tested an oxytocin regimen of 1 mU/min compared with 6 mU/min. With the low-dose regimens, increases of 1 mU/min were given as needed at 20-minute intervals. With the high-dose protocol, increases of 6 mU/min were given as needed at 20-minute intervals to a maximum of 42 mU/min. The protocol allowed reduction of the dosage by 3 mU/min in the presence of uterine hyperstimulation. This flexible high-dose protocol was evaluated in nearly 5000 pregnancies and found to be more effective than the low-dose infusion. Specifically, of 1112 women with labor induction, the high-dose regimen had a significantly shorter mean admission-to-delivery time, fewer failed inductions, and there were no cases of neonatal sepsis. Of 1676 women who had labor augmentation, those who received the high-dose regimen had a significantly shorter duration-to-delivery time, fewer forceps deliveries, fewer cesarean deliveries for dystocia, less intrapartum chorioamnionitis, and less neonatal sepsis.

In this report by [Satin and colleagues \(1992a\)](#), hyperstimulation was identified in approximately half of women with the high-dose regimen. This was managed by oxytocin discontinuation followed by resumption when indicated but with only half the stopping dosage. Thereafter the dosage was increased at 3 mU/min when appropriate compared with 6 mU/min for women without hyperstimulation. Women who received the 6-mU/min regimen for labor augmentation underwent cesarean delivery for "fetal distress" in 6 compared with 3 percent of those in the low-dose group. No adverse neonatal effects were observed in either group.

[Xenakis and colleagues \(1995\)](#) reported benefits for a high-dose regimen starting at 4 mU/min with 4-mU/min incremental increases. [Merrill and Zlatnik \(1999\)](#) randomized 1307 women for labor induction (816) or augmentation (491) to either low-dose oxytocin given at 1.5 mU/min with incremental increases of 1.5 mU/min or to a higher-dose infusion begun at 4.5 mU/min and increased by 4.5-mU/min increments. Women randomized to the higher-dose regimen had a significantly decreased duration from induction-to-second-stage labor and from induction-to-delivery time. Nulliparas in the high-dose group had a trend toward a lower cesarean delivery rate for disproportion compared with those in the low-dose group (5.9 versus 11.9 percent, $P = .06$). In women whose labor was augmented, those randomized to the higher-dose regimen also had significantly shorter labors but a similar cesarean delivery rate.

The benefits favor the higher-dose regimens. In 1990, routine usage of the 6-mU/min oxytocin regimen was incorporated at Parkland Hospital. At the University of Alabama, the 2-mU/min oxytocin regimen is used. In both cases, these are used for either labor induction or augmentation, with graduated increased incremental dosages.

INCREASING DOSAGE INTERVALS. There are a number of suitable regimens with intervals to increase oxytocin dosage that vary from every 15 to 40 minutes ([Table 20-2](#)). [Satin and colleagues \(1994\)](#) compared a regimen beginning with 6 mU/min with incremental 6-mU/min increases over 20- versus 40-minute intervals. Women given the 20-minute interval regimen for labor augmentation had a significant reduction in cesarean delivery for dystocia compared with the 40-minute interval regimen (8 versus 12 percent). In women with labor induction, uterine hyperstimulation was significantly more frequent with the 20-minute compared with the 40-minute regimen (40 versus 31 percent). This, however, was not observed in those undergoing labor augmentation (31 versus 28 percent). Because of the concern

for hyperstimulation, the current Parkland protocol is to initiate oxytocin at 6 mU/min, with incremental increases every 40 minutes, but employing a flexible dosing schedule based on hyperstimulation.

Others report successful high-dose regimens escalated at more frequent intervals. [Frigoletto and associates \(1995\)](#) and [Xenakis and co-workers \(1995\)](#) began oxytocin at 4 mU/min with increases as needed every 15 minutes. [Merrill and Zlatnik \(1999\)](#) started with 4.5 mU/min with increases every 30 minutes. [Lopez-Zeno and colleagues \(1992\)](#) began at 6 mU/min with increases every 15 minutes. Other variations are acceptable; for example, at the University of Alabama at Birmingham, intravenous oxytocin for labor induction or augmentation is begun at 2 mU/min and is increased as needed every 15 minutes to 4, 8, 12, 16, 20, 25, and 30 mU/min.

RISKS VERSUS BENEFITS. Oxytocin is a powerful drug, but previously described disasters of killed or maimed mothers and babies because of **uterine rupture** are uncommon today. This is because of several well-done studies to codify its administration and to quantify its efficacy and safety. As shown in [Table 20-3](#), uterine rupture associated with oxytocin is rare even in parous women, unless the uterus is scarred.

Oxytocin has amino-acid homology similar to arginine vasopressin. Thus, when infused at high doses, it has significant antidiuretic action. Whenever 20 mU/min or more is infused, renal free water clearance decreases markedly. If aqueous fluids are infused in appreciable amounts along with oxytocin, **water intoxication** can lead to convulsions, coma, and even death.

UTERINE CONTRACTION PRESSURES WITH OXYTOCIN STIMULATION. Uterine contraction forces calculated in spontaneously laboring women range from 90 to 390 Montevideo units ([Fig. 20-2](#)). [Caldeyro-Barcia and associates \(1950\)](#) and [Seitchik and colleagues \(1984\)](#) found that the mean or median spontaneous uterine contraction pattern resulting in a progression to a vaginal delivery was between 140 and 150 Montevideo units ([Chap. 14, p. 355](#)).

In the management of arrest of active-phase labor, and with no contraindication to intravenous oxytocin, decisions are made knowing the safe upper range of uterine activity with spontaneous labor. [Hauth and co-workers \(1986\)](#) described an effective and safe protocol for labor augmentation with which over 90 percent of women achieved an average of 200 to 225 Montevideo units. [Hauth and associates \(1991\)](#) later reported that nearly all women whose arrest of labor persisted despite oxytocin were able to generate over 200 Montevideo units. Importantly, despite no labor progression, there were no adverse maternal or newborn effects following cesarean delivery.

The [American College of Obstetricians and Gynecologists \(1995a\)](#) recommends that prior to diagnosing an arrest of first-stage labor, the uterine contraction pattern should exceed 200 Montevideo units for 2 hours without cervical change. More data are needed regarding the precise safety and efficacy of contraction patterns in subgroups of women with a prior cesarean delivery, with twins, with an overdistended uterus, and in those with chorioamnionitis.

DURATION OF OXYTOCIN ADMINISTRATION. In 1989 the [American College of Obstetricians and Gynecologists](#) defined arrest in first-stage labor as a completed latent phase along with a uterine contraction pattern of more than 200 Montevideo units that has been present for over 2 hours without cervical change. There are only sparse data to support a more accurate recommendation for the duration of augmentation for active phase arrest. [Arulkumaran and associates \(1987\)](#) extended the limits of the 2 hours to define failed augmentation. Using a 4-hour limit, they reported a cesarean rate of only 1.3 percent in those who continued to have adequate contractions. For those without progress, another 4 hours were allowed, and a third of these were delivered vaginally.

[Rouse and colleagues \(1999\)](#) studied 542 women at term with active phase arrest who were managed within a prospective protocol. The protocol did not include the 2-hour rule, but rather included an intent to achieve a sustained pattern of over 200 Montevideo units for a minimum of 4 hours. This was increased up to 6 hours if activity of over 200 Montevideo units could not be sustained. Almost 92 percent of these women were delivered vaginally. Because women with a prior cesarean delivery, multifetal gestation, nonvertex presentations, or chorioamnionitis were excluded, these investigators recommended that further studies be performed.

These reports are suggestive that changes in management of labor may contribute to reducing the cesarean delivery rate. We anticipate increased attention to the duration of oxytocin augmentation in the active phase arrest disorders. If future studies confirm those of [Arulkumaran and colleagues \(1987\)](#) and [Rouse and co-workers \(1999\)](#) regarding the efficacy and safety of a longer duration of oxytocin augmentation, then this should be implemented.

AMNIOTOMY

Amniotomy or artificial rupture of the membranes, also referred to in Britain as surgical induction, is commonly used to induce or augment labor. The term amniorrhexis is used by some to signify either spontaneous or artificial membrane rupture, although this term and amniotomy erroneously imply rupture only of the amnion and not the chorion. Other common indications for amniotomy include internal electronic fetal heart rate monitoring when fetal jeopardy is anticipated and intrauterine assessment of contractions when labor has been unsatisfactory. Elective amniotomy to hasten spontaneous labor or detect meconium is also acceptable and commonly practiced.

Because amniotomy for these indications is so prevalent, it is difficult to find information on when during normal labor the fetal membranes would spontaneously rupture if left unperturbed. [Fraser and co-workers \(1991\)](#) studied elective amniotomy compared with no intervention in term pregnancies with spontaneous labor. Almost 60 percent of the nonintervention group reached 8 cm dilatation or more before the membranes ruptured spontaneously. It is likely that an even greater proportion of women would have entered second-stage labor with intact membranes because amniotomy for electronic internal monitoring or labor augmentation was performed in 38 percent.

Several precautions to minimize the risk of cord prolapse should be observed when membranes are ruptured artificially. Care should be taken to avoid dislodging the fetal head. An assistant applying fundal and suprapubic pressure may reduce the risk of cord prolapse. Some prefer to rupture membranes during a contraction. The fetal heart rate should be assessed prior to and immediately after the procedure.

ELECTIVE AMNIOTOMY. Artificial membrane rupture with the intention of accelerating labor is among the most commonly performed procedures in obstetrics. Whether this procedure confers more benefit than harm has been the focus of controversy. There have been three investigations addressing this controversy recently, and these are summarized in [Table 20-4](#). In all three studies, amniotomy at about 5 cm dilatation accelerated spontaneous labor 1 to 2 hours without increasing the overall rate of cesarean delivery or need for oxytocin stimulation. In the study by [Garite and associates \(1993\)](#), oxytocin use was decreased when early elective amniotomy was performed. Importantly, there were no adverse perinatal effects. These investigators, however, did identify increased mild and moderate umbilical cord compression patterns as a result of amniotomy. Despite this, severe decelerations were not increased and consequently cesarean delivery for fetal distress was unaffected.

AMNIOTOMY INDUCTION. Artificial rupture of the membranes can be used to induce labor, but it implies a firm commitment to delivery. The main disadvantage of amniotomy when used alone for labor induction is the unpredictable and occasionally long interval to the onset of contractions. Although this is widely practiced, there have been few investigations comparing amniotomy alone with other methods. In a randomized trial, [Bakos and Backstrom \(1987\)](#) found that amniotomy alone or combined with oxytocin was superior to oxytocin alone. [Mercer and colleagues \(1995\)](#) randomized 209 women undergoing oxytocin induction to amniotomy at 1 to 2 cm dilatation (early amniotomy) or at 5 cm (late amniotomy). Early amniotomy was associated with significantly shorter labor (approximately 4 hours), but there was an increased incidence of chorioamnionitis (23 percent) and cord compression monitoring patterns (12 percent).

AMNIOTOMY FOR AUGMENTATION. It is common practice to perform amniotomy when spontaneous labor is abnormally slow. Given the evidence that is available from trials in established spontaneous labor and from labor induction, it is likely that amniotomy would enhance progress in dysfunctional labor. [Rouse and co-workers \(1994\)](#) performed a randomized study and found that the addition of amniotomy to oxytocin augmentation of arrest of labor in the active phase shortened labor by 44 minutes. It also significantly increased the incidence of chorioamnionitis. Amniotomy, as an adjunct to oxytocin infusion, did not affect the route of delivery compared with oxytocin alone.

ACTIVE MANAGEMENT OF LABOR

This term describes a codified approach to diagnosis and management of labor. It is discussed in detail in [Chapter 18 \(p. 446\)](#).

Montevideo units are calculated by subtracting the baseline uterine pressure from the peak contraction pressure for each contraction in a 10-minute window and adding the pressures generated by each contraction. In the example shown, there are five contractions in 10 minutes, producing pressure changes of 52, 50, 47, 44, and 49 mm Hg, respectively. The sum of these five contractions is 242 Montevideo units (From the [American College of Obstetricians and Gynecologists, 1989](#), with permission).

SECTION VI - OPERATIVE OBSTETRICS

21. Forceps Delivery and Vacuum Extraction

Although there is periodic and vocal demand to delete assisted vaginal delivery, clinical experience provides recurring evidence that leaving all to natural forces or the scalpel will not accomplish this goal ([American College of Obstetricians and Gynecologists, 2000](#); [Robinson, 1994](#)). When criteria for outlet forceps are met, and there is a nonreassuring fetal heart rate pattern, there is no question that assisted or operative vaginal delivery is indicated. The same heart rate pattern, but with the fetus at +1 station and as an occiput transverse, is an entirely different operation and a source of legitimate debate concerning optimal delivery route and risk for mother and fetus. Lack of skill and experience or emergency conditions do change the conditions of the debate and may seriously limit available options.

FORCEPS DELIVERY

Obstetrical forceps are designed for extraction of the fetus. True forceps were first devised in the late 16th or beginning of the 17th century. The reader is referred to the 19th and earlier editions of *Williams Obstetrics* for the history of their design and development.

DESIGN OF FORCEPS

Forceps vary considerably in size and shape, but basically consist of two crossing branches. Each branch has four components: the blade, shank, lock, and handle. Each blade has two curves, the cephalic and pelvic. The cephalic curve conforms to the shape of the fetal head, and the pelvic curve with that of the birth canal. Some varieties are fenestrated rather than solid to permit a more firm hold on the fetal head.

The cephalic curve ([Fig. 21-1](#)) should be large enough to grasp the fetal head firmly without compression. The pelvic curve ([Fig. 21-1](#)) corresponds more or less to the axis of the birth canal, but varies considerably among different instruments. The blades are connected to the handles by the shanks, which give the requisite length to the instrument. The shanks are either parallel as in Simpson forceps or crossing as in Tucker-McLane forceps.

The kind of articulation, or forceps lock, varies among different instruments. The common method of articulation consists of a socket located on the shank at the junction with the handle, into which fits a socket similarly located on the opposite shank ([Figs. 21-1](#) and [21-2](#)). This form of articulation is commonly referred to as the English lock. A sliding lock is used in some forceps, such as Kielland forceps ([Fig. 21-3](#)) and allows the shanks to move forward and backward independently. In some cases, the operator chooses to use an axis-traction device to help maintain the appropriate vector for a necessary deliver ([Fig. 21-4](#)).

CLASSIFICATION OF FORCEPS DELIVERIES

The most appropriate and current classification for forceps operations is that proposed originally in 1988 and reaffirmed in 2000 by the American College of Obstetricians and Gynecologists ([Table 21-1](#)). This same classification is utilized for vacuum deliveries. This classification emphasizes the two most important discriminators of risk for both mother and infant: station and rotation. It is emphasized that station contemporaneously is measured in centimeters (0 to +5), rather than by dividing the lower pelvis into thirds. Deliveries are categorized as outlet, low, and midforceps procedures. High forceps operations are those in which instruments are applied before engagement and have no place in modern obstetrics. Rotations of greater than 45 degrees are usually more difficult than lesser degrees ([Hagadorn-Freathy and colleagues, 1991](#); [Pearl and associates, 1993](#)).

INCIDENCE OF FORCEPS DELIVERY

In any given institution, incidence will depend upon prevailing medical staff attitude, kinds of analgesia and anesthesia used for labor and delivery, and parity of the population. [Zahniser and colleagues \(1992\)](#) analyzed data from the National Hospital Discharge Survey to examine trends in the use of forceps, vacuum extraction, and cesarean section from 1980 to 1987. The rate of cesarean deliveries increased by 48 percent, while forceps procedures declined by 43 percent ([Fig. 21-5](#)). [Learman \(1998\)](#) reported data for the next 8 years, and as shown, operative vaginal delay remained at about 10 to 12 percent. By 1994, these were nearly evenly distributed between forceps and vacuum deliveries. [Curtin and Park \(1999\)](#) analyzed United States birth certificate data through 1997 and reported that forceps use was consistently declining as vacuum extraction deliveries consistently increased. More recently, [DiMarco and associates \(2000\)](#) have documented a decline in operative vaginal deliveries with parallel increase in cesarean deliveries.

The incidence varies geographically. [Notzon and associates \(1991\)](#) reported a decline in operative vaginal delivery rates in both the United States and Scotland, but a simultaneous increase in Norway. [Ruderman and colleagues \(1993\)](#) reported rates for Canadian family physicians and obstetricians, respectively, as follows: midforceps 10.1 and 13.5 percent; low forceps 5.3 and 10.5 percent; and vacuum 9.4 and 18.3 percent.

There is considerable regional difference in the United States on operative delivery ([Table 21-2](#)). The cesarean delivery rate declined but vacuum deliveries surpassed forceps deliveries in all but the southern United States. The frequency of operative delivery, including operative vaginal delivery, may also be related to maternal age. In a review of over 24,000 cases in women 40 years or older, [Gilbert and colleagues \(1999b\)](#) reported a higher rate of both cesarean delivery and operative vaginal delivery in women 40 or older compared with those aged 20 to 29 years. Most forceps and vacuum procedures are outlet or low pelvic procedures that pose very little risk to mother and fetus ([Carmona and colleagues, 1995](#); [Hagadorn-Freathy and associates, 1991](#)).

TRAINING

[Ramin and colleagues \(1993\)](#) surveyed 295 residency training programs in the United States and Canada, of which 203 responded. These represented a minimal total of 458,000 deliveries for 1990. Although two programs were not familiar with the revised 1998 classification of the American College of Obstetrics and Gynecologists, all but 20 percent of the remainder had incorporated these definitions. All responding programs utilized outlet and low forceps. Approximately half used outlet forceps for 5 percent or more of their deliveries, while about a third utilized low forceps for 5 percent or more of their deliveries. Midforceps operations were much less prevalent, and 15 percent of programs reported no use, while another 60 percent performed these operations for fewer than 1 percent of deliveries. Hospitals with high cesarean section rates did not perform fewer midforceps operations. With appropriate use and training, the "forceps cycle" described by [Yeomans and Hankins \(1992\)](#) can be avoided or broken.

EFFECTS OF REGIONAL ANALGESIA ON INSTRUMENTAL DELIVERY

Epidural analgesia is widely accepted as causative in failure of spontaneous rotation to occiput anterior position, as well as in slowing second-stage labor and decreasing maternal expulsive efforts. In some series its use has been associated with increases in forceps delivery from 4 percent to 31 percent and increased vacuum extraction rates of 0.7 to 3.5 percent ([Ploekinger and associates, 1995](#); [Sizer and Nirmal, 2000](#)).

In a randomized clinical trial conducted at Parkland Hospital, [Ramin and colleagues \(1995\)](#) compared segmental lumbar epidural analgesia with intermittent intravenous meperidine for pain relief during labor. As shown in [Table 21-3](#), first- and second-stage labor were significantly prolonged, and this paralleled an increase in low-forceps and cesarean delivery, but not outlet forceps. In a follow-up study from the same institution, [Sharma and colleagues \(1997\)](#) found no increase in operative vaginal delivery in women receiving epidural analgesia compared with patient-controlled intravenous meperidine during labor. In a recent meta-analysis of epidural versus opioid analgesia, [Halpern and colleagues \(1998\)](#) reported that women receiving epidural analgesia were twice as likely to have an instrumental delivery, but not for dystocia.

Epidural blockade increases the frequency of malposition of the fetal head, especially the occiput posterior position, and this in turn may increase the frequency of instrumental delivery. [Kaminski and associates \(1987\)](#) documented occiput posterior positions in 27 percent of women given epidural analgesia compared with only 8 percent of those not given epidural analgesia.

In an attempt to decrease the incidence of forceps delivery associated with epidural analgesia, [Saunders and colleagues \(1989\)](#) compared routine second-stage oxytocin infusion with placebo in 225 nulliparous women who reached full dilatation without oxytocin stimulation. Oxytocin was associated with a significantly shorter second stage (134 versus 151 minutes), a reduction in the incidence of nonrotational forceps deliveries (33 versus 56 percent), and less perineal trauma. Routine oxytocin infusion, however, did not reduce the number of rotational forceps deliveries performed for malposition of the occiput.

FUNCTION OF FORCEPS

Forceps may be used as a tractor, rotator, or both. Its most important function is traction, although particularly in transverse and posterior positions of the occiput, forceps may be invaluable for rotation. In general, Simpson forceps are used to deliver the fetus with a molded head, as is common in nulliparous women. The Tucker-McLane instrument is often used for the fetus with a rounded head, which more characteristically is seen in multiparas. In most situations, however, either instrument is appropriate. In some circumstances, more specialized forceps such as the Kielland instrument may be preferable, as in some cases of deep transverse arrest with the fetal head in the transverse position well down in the pelvis with the occiput below the spines. If there is no apparent cephalopelvic disproportion and uterine contractions are inadequate, transverse arrest may sometimes be overcome with oxytocin stimulation.

FORCES EXERTED BY THE FORCEPS

From experiments conducted on women in labor more than a century ago, [Joulin \(1867\)](#) estimated that a pull in excess of 60 kg might damage the fetal skull. These crude studies and subsequent ones have furnished only a gross approximation, for the force produced by the forceps on the fetal skull is a complex function of pull and compression by the forceps and friction produced by the maternal tissues.

INDICATIONS FOR FORCEPS

The termination of labor by forceps, provided it can be accomplished safely, is indicated in any condition threatening the mother or fetus that is likely to be relieved by delivery. Maternal indications include heart disease, pulmonary injury or compromise, intrapartum infection, certain neurological conditions, exhaustion, or prolonged second-stage labor. The latter is defined by the [American College of Obstetricians and Gynecologists \(2000\)](#) as more than 3 hours with and more than 2 hours without regional analgesia in the nulliparous woman. In the parous woman, it is defined as more than 2 hours with and more than 1 hour without regional analgesia. Midforceps rarely are indicated for labor termination specifically for maternal reasons. Thus, shortening of second-stage labor for maternal reasons should generally be accomplished with either outlet or low forceps.

Fetal indications for operative vaginal delivery with either forceps or vacuum include prolapse of the umbilical cord, premature separation of the placenta, and a nonreassuring fetal heart rate pattern. In the case of a nonreassuring fetal heart rate pattern, it is prudent to describe the fetal heart rate pattern and the station of the planned forceps application in a precisely written note.

ELECTIVE AND OUTLET FORCEPS

The vast majority of forceps operations performed in this country are elective. Some undoubtedly are related to the frequent use of epidural analgesia. Forceps generally should not be used electively until the criteria for outlet forceps have been met. The fetal head must be on the perineal floor with the sagittal suture no more than 45 degrees from the anteroposterior diameter. In these circumstances, forceps delivery is a simple and safe operation ([Carmona and colleagues, 1995](#); [Hagadorn-Freathy and associates, 1991](#)). By allowing the woman in labor ample time, the criteria for outlet forceps can usually be met despite the effects of analgesia.

PROPHYLACTIC OUTLET FORCEPS

[DeLee \(1920\)](#) recommended delivery by prophylactic outlet forceps, because it was held widely at the time that prolonged pressure of the fetal head against a rigid perineum might result in fetal brain damage. There is no evidence that use of prophylactic forceps is beneficial in the otherwise normal term labor and delivery. Likewise, such a practice has no immediate adverse effects on the newborn compared with spontaneous term vaginal delivery ([Yancey and colleagues, 1991](#)). Prophylactic outlet operations may be associated with increased perineal trauma in nulliparous women. [Carmona and associates \(1995\)](#), however, found no differences in maternal or infant outcomes with term pregnancies randomized to spontaneous or elective outlet forceps delivery.

PROPHYLACTIC OUTLET FORCEPS FOR SMALL FETUSES

[Bishop and associates \(1965\)](#), after analyzing data from the Collaborative Perinatal Project, suggested that prophylactic outlet forceps delivery improved neonatal outcome in low-birthweight infants. [Fairweather \(1981\)](#) reported no significant differences in outcomes in neonates who weighed 500 to 1500 g and who were delivered spontaneously or by outlet forceps. [Schwartz and colleagues \(1983\)](#) reported similar findings. [Anderson and associates \(1988\)](#) presented findings consistent with the view that forceps delivery was protective against progression of periventricular hemorrhage in vaginally delivered neonates who weighed less than 1750 g. Currently, it would appear that there is no obvious advantage to routine outlet forceps delivery of a small fetus.

PREREQUISITES FOR FORCEPS APPLICATION

There are at least six prerequisites for successful application of forceps:

1. The head must be engaged. Extensive caput succedaneum formation and molding might make determination of the station of the fetal head difficult at times. When difficulties of station assignment occur, it is important to realize that a "low-forceps" procedure may actually be a more difficult midforceps operation. Forceps should not be used until the station of the head is low enough to ensure a safe operative procedure. The same management principle applies to use of forceps for a nonreassuring fetal heart rate pattern when the head is not close to the pelvic floor.
2. The fetus must present as a vertex or by the face with the chin anterior.
3. The position of the fetal head must be precisely known so that cephalic placement of the forceps can be performed.
4. The cervix must be completely dilated before application of forceps. If prompt delivery becomes imperative before complete dilatation of the cervix, cesarean section is indicated.
5. Before forceps application, the membranes must be ruptured to permit a firm grasp of the fetal head by the forceps blades.
6. There should be no disproportion between the size of the head and that of the pelvic inlet or the midpelvis.

PREPARATION FOR FORCEPS DELIVERY

Although pudendal block may prove adequate for outlet forceps operations, either regional analgesia or general anesthesia is usually preferred for low-forceps or midpelvic procedures. The bladder should be emptied by catheterization if a low- or midforceps delivery is planned. If spinal analgesia is to be used, the anesthetic agent is introduced before placing the woman in the lithotomy position for delivery. If general anesthesia is to be used, the woman is placed in the lithotomy position, the perineum is cleansed and draped, and the physician is ready to perform the delivery before anesthesia is induced.

FORCEPS APPLICATION

Forceps are constructed so that their cephalic curve is closely adapted to the sides of the fetal head ([Fig. 21-6](#)). The biparietal diameter of the fetal head corresponds to the greatest distance between the appropriately applied blades. Consequently, the head of the fetus is perfectly grasped only when the long axis of the blades corresponds to the occipitomeatal diameter, with the major portion of the blade lying over the face, while the concave margins of the blades are directed toward either the sagittal suture (occiput anterior position) or the face (occiput posterior position). Thus applied, the forceps should not slip, and traction may be applied most advantageously as illustrated in [Figure 21-7](#). When forceps are applied obliquely, however ([Fig. 21-8](#)), with one blade over the brow and the other over the opposite mastoid region, the grasp is less secure, and the fetal head is exposed to injurious pressure. With most forceps, if one blade is applied over the brow and the other over the occiput, the instrument cannot be locked, or if locked, the blades slip off when traction is applied ([Fig. 21-9](#)). For these reasons, the forceps must be applied directly to the sides of the fetal head along the occipitomeatal diameter, in what is termed the biparietal or bimalar application.

IDENTIFICATION OF POSITION

Precise knowledge of the exact position of the fetal head is essential to a proper cephalic application. With the head low in the pelvis, determination of position is

made by examination of the sagittal suture and the fontanel. When the head is at a higher station, an absolute determination can be made by locating the posterior ear.

OUTLET FORCEPS DELIVERY

Delivery by outlet forceps is illustrated in [Figure 21-10](#), [Figure 21-11](#), [Figure 21-12](#), [Figure 21-13](#), [Figure 21-14](#), [Figure 21-15](#), and [Figure 21-16](#). The obstacle to delivery is usually insufficient expulsive forces, appreciable resistance of the perineum, or both. In such circumstances, the sagittal suture occupies a principally anteroposterior diameter of the pelvic outlet, with the small (posterior) fontanel directed toward either the symphysis pubis or the concavity of the sacrum. In either event, the forceps, if applied to the sides of the pelvis, grasp the head ideally. The left blade is introduced by the left hand into the left side of the pelvis, and then the right blade is introduced by the right hand into the right side of the pelvis, as follows: Two or more fingers of the right hand are introduced inside the left, posterior portion of the vulva and into the vagina beside the fetal head. The handle of the left branch is then grasped between the thumb and two fingers of the left hand, as in holding a pen, and the tip of the blade is gently passed into the vagina between the fetal head and the palmar surface of the fingers of the right hand, which serve as a guide ([Fig. 21-10](#)). The handle and branch are held at first almost vertically; but as the blade adapts itself to the fetal head, they are depressed, eventually to a horizontal position.

Similarly, two or more fingers of the left hand are then introduced into the right, posterior portion of the vagina to serve as a guide for the right blade, which is held in the right hand and introduced into the vagina ([Fig. 21-11](#)). These guiding fingers are then withdrawn and the horizontally positioned branches are articulated. If necessary, one and then the other blade should be gently maneuvered until the handles are repositioned to effect easy articulation.

APPROPRIATENESS OF APPLICATION

The application now is checked before any traction is applied. For the occiput anterior position, appropriately applied blades are equidistant from the sagittal suture. In the occiput posterior position the blades are equidistant from the midline of the face and brow.

TRACTION

When it is certain that the blades are placed satisfactorily, gentle, intermittent, horizontal traction is exerted until the perineum begins to bulge. In some cases, rotation to occiput anterior (or occiput posterior) is performed before traction is applied ([Fig. 21-12](#)). Traction is always applied gently and never with excessive force. As the vulva is distended by the occiput, episiotomy may be performed if indicated ([Fig. 21-13](#)). More horizontal traction is applied ([Fig. 21-14](#)), and the handles are gradually elevated, eventually pointing almost directly upward as the parietal bones emerge ([Fig. 21-15](#)). With the fetal head in the occiput anterior position, this maneuver takes advantage of the smallest diameters of the fetal head and brings the suboccipital region beneath the symphysis. As the handles are raised, the head is extended. During upward traction, the four fingers should grasp the upper surface of the handles and shanks, while the thumb exerts the necessary force upon their lower surface.

During the birth of the head, spontaneous delivery should be simulated as closely as possible. Traction should therefore be intermittent, and the head should be allowed to recede in intervals, as in spontaneous labor. Except when urgently indicated, as in severe fetal bradycardia, delivery should be sufficiently slow, deliberate, and gentle to prevent undue compression of the fetal head. It is preferable to apply traction with each uterine contraction.

After the vulva has been well distended by the head, and the brow can be felt through the perineum, the delivery may be completed in several ways. Some clinicians keep the forceps in place, in the belief that the greatest control of the advance of the head is thus maintained. The thickness of the blades many times add to the distention of the vulva, however, thus increasing the likelihood of laceration or necessitating a large episiotomy. In such cases, the forceps may be removed and delivery completed by the modified Ritgen maneuver ([Fig. 21-16](#)), slowly extending the head by using upward pressure upon the chin through the posterior portion of the perineum, while covering the anus with a towel to minimize contamination from the bowel. If the forceps are removed prematurely, the modified Ritgen maneuver may prove to be a tedious and inelegant procedure.

LOW- AND MIDFORCEPS OPERATIONS

When the head lies above the perineum, the sagittal suture usually occupies an oblique or transverse diameter of the pelvis. In such cases, the forceps should always be applied to the sides of the head.

LEFT OCCIPUT ANTERIOR POSITION

In the left occiput anterior positions, the right hand, introduced into the left posterior segment of the vagina, should identify the posteriorly located left ear and at the same time serve as a guide for introduction of the left branch of the forceps, which is held in the left hand and applied over the left ear. The handle is held by an assistant or left unsupported, the blade usually retaining its position without difficulty. Two fingers of the left hand are then introduced into the right posterior portion of the pelvis. The right branch of the forceps, held in the right hand, is then introduced along the left hand as a guide. It must then be applied over the anterior ear of the fetus by gently sweeping the blade anteriorly until it lies directly opposite the blade that was introduced first. Of the two branches, when articulated, one occupies the posterior and the other the anterior extremity of the left oblique diameter.

RIGHT OCCIPUT ANTERIOR POSITION

In right positions, the blades are introduced similarly but in opposite directions, for in those cases the right ear of the fetus is the posterior ear, over which the first blade must be placed accordingly. After the blades have been applied to the sides of the head, the left handle and shank lie above the right. Consequently, the forceps do not immediately articulate. Locking of the branches is easily effected, however, by rotating the left around the right to bring the lock into proper position.

OCCIPUT TRANSVERSE POSITIONS

If the occiput is in a transverse position, the forceps are introduced similarly, with the first blade applied over the posterior ear and the second rotated anteriorly to a position opposite the first. In this case, one blade lies in front of the sacrum and the other behind the symphysis. The conventional Simpson or Tucker-McLane forceps ([Figs. 21-1](#) and [21-2](#)), or one of their modifications, or the specialized Kielland forceps ([Fig. 21-3](#)) may be used.

ROTATION FROM ANTERIOR AND TRANSVERSE POSITIONS

When the occiput is obliquely anterior, it gradually rotates spontaneously to the symphysis pubis as traction is exerted. When it is directly transverse, however, in order to bring it anteriorly a rotary motion of the forceps is required. The direction of rotation, of course, varies with the position of the occiput. Rotation counterclockwise from the left side toward the midline is required when the occiput is directed toward the left, and in the reverse direction when it is directed toward the right side of the pelvis.

Infrequently, when forceps are used in transverse positions in anteroposteriorly flattened (platypelloid) pelvises, rotation should not be attempted until the fetal head has reached or approached the pelvic floor. Premature attempts at anterior rotation under such conditions may result in injury to the fetus and the mother. Regardless of the original position of the head, delivery is eventually effected by exerting traction downward until the occiput appears at the vulva; the rest of the operation is completed as previously described.

In exerting traction before the head appears at the vulva, one or both hands may be employed. The operator's body weight must not be used for traction.

OCCIPUT POSTERIOR POSITIONS

Prompt delivery may at times become necessary when the small (occipital) fontanel is directed toward one of the sacroiliac synchondroses, namely, in right occiput posterior and left occiput posterior positions. When delivery is required in either instance, the head is often imperfectly flexed. In some cases, when the hand is introduced into the vagina to locate the posterior ear, the occiput rotates spontaneously toward the anterior, indicating that manual rotation of the fetal head might easily be accomplished.

MANUAL ROTATION

A hand with the palm upward is inserted into the vagina and the fingers are brought in contact with the side of the fetal head that is to be pushed toward the anterior position, while the thumb is placed over the opposite side of the head ([Fig. 21-17](#)). With the occiput in a right posterior position, the left hand is used to rotate the occiput anteriorly in a clockwise direction; the right hand is used for the left occiput posterior position. At the beginning of the rotation, it may be helpful to dislodge the head slightly upward in the birth canal, but the head must not be disengaged. After the occiput has reached the anterior position, labor may be allowed to continue, or more commonly, forceps can be used to effect delivery. First one blade is applied to that side of the head that is held by the fingers to help maintain the occiput in the anterior position. The other blade is immediately applied and delivery accomplished.

FORCEPS DELIVERY

If manual rotation cannot be easily accomplished, application of the blades to the head in the posterior position and delivery from the occiput posterior position may be the safest procedure ([Fig. 21-18](#)). In many cases, the cause of the persistent occiput posterior position and of the difficulty in accomplishing rotation is an anthropoid pelvis, the architecture of which predisposes to posterior delivery and opposes rotation. When the occiput is directly posterior, horizontal traction should be applied until the base of the nose is under the symphysis. The handles should then be slowly elevated until the occiput gradually emerges over the anterior margin of the perineum. Then, by imparting a downward motion to the instrument, the nose, face, and chin successively emerge from the vulva.

Occiput posterior extraction causes greater distention of the vulva, and a large episiotomy may be needed. [Pearl and associates \(1993\)](#) retrospectively reviewed 564 occiput posterior deliveries. These were compared with 1068 controls matched for race, parity, and delivery method. The occiput posterior group had a higher incidence of severe perineal lacerations and extensive episiotomy compared with the occiput anterior group. Within the occiput posterior group, operative delivery was associated with a higher incidence of severe perineal lacerations (35 versus 16 percent), vaginal lacerations (18 versus 7 percent), and episiotomy (95 versus 74 percent) than was spontaneous delivery. The infants delivered from the occiput posterior position had a higher incidence of Erb (1 percent) and facial nerve (2 percent) palsy than did those delivered from the occiput anterior position.

FORCEPS ROTATIONS

Tucker-McLane, Simpson, or Kielland forceps may be used to rotate the fetal head. The oblique occiput may be rotated 45 degrees to the posterior position or 135 degrees to the anterior position ([Fig. 21-19](#)). If rotation is performed with Tucker-McLane or Simpson forceps, the head must be flexed, but this is not necessary with Kielland forceps because they have a more straightened pelvic curve. In rotating the occiput anteriorly with Tucker-McLane or Simpson forceps, the pelvic curvature, originally directed upward, at the completion of rotation is inverted and directed posteriorly. Attempted delivery with the instrument in that position is likely to cause serious maternal injury manifest as vaginal sulcus tears and sidewall lacerations. To avoid such trauma, it is essential to remove and reapply the instrument as described below.

KIELLAND FORCEPS ROTATION OF OCCIPUT TRANSVERSE

[Kielland \(1916\)](#) described forceps with narrow, somewhat bayonet-shaped blades that he claimed could be applied readily to the sides of the head in the occiput transverse position and surpassed all other models as a rotator ([Fig. 21-3](#)). Kielland forceps have a sliding lock and almost no pelvic curve. On each handle is a small knob that indicates the direction of the occiput.

The station of the fetal head must be accurately ascertained to be at, or preferably below, the level of the ischial spines. Often in these cases there has been extreme molding of the fetal head, and the caput succedaneum has descended to below the ischial spines, giving the erroneous impression that the head is engaged when actually the occiput is above the spines ([Knight and colleagues, 1993](#)). Forceps application under these circumstances is classified as high and is not to be attempted.

There are two methods of applying the anterior blade. In one, the anterior blade is introduced first with its cephalic curve directed upward; after it has entered sufficiently far into the uterine cavity, it is turned through 180 degrees to adapt the cephalic curvature to the head. Kielland also described a wandering or gliding method of application for the anterior blade when the uterus is tightly contracted about the head and the lower uterine segment is stretched and thin. In the wandering or gliding method, the anterior blade is introduced at the side of the pelvis over the brow or face to an anterior position, with the handle of the blade held close to the opposite maternal buttock throughout the maneuver. The second blade is introduced posteriorly and the branches are locked.

Because most cases amenable to Kielland forceps rotation are those in which there is deep transverse arrest—the fetal head is deep in the pelvis with the occiput well below the level of the ischial spines—rotation is usually accomplished by unwedging the fetal head from the pelvis by a small amount of upward pressure. From this slightly higher station, the rotation is accomplished. The head should not be pushed high enough to allow disengagement because the cord may prolapse.

In an early study, [Rubin and Coopland \(1970\)](#) summarized their experiences with 1000 consecutive cases of Kielland forceps rotation. Half were occiput posterior and half occiput transverse. Rotation was accomplished successfully in 970. There were eight perinatal deaths, including four with serious anomalies. Injuries to the infant were considered mostly minor for those contemporaneous times; however, there were 27 injuries that would not be considered minor today, including seven infants with a fractured skull!

[Tan and associates \(1992\)](#) reported more contemporaneous results with 137 midpelvic Kielland forceps deliveries. Common indications were prolonged second stage (73 percent), maternal distress (13 percent), or fetal distress (10 percent). Maternal complications included lacerations in 12 percent, and hemorrhage in 12 percent; 3 percent of the 137 women were given blood transfusions. Neonatal complications included cephalohematoma in 9 percent, and one infant each had a facial nerve or C₅ Erb palsy. In a later study by [Krivak and colleagues \(1999\)](#), 55 deliveries using Kielland rotation were compared with 213 nonrotational forceps.

[Jain and colleagues \(1993\)](#) examined trends for delivery of deep transverse arrest from 1970 to 1990. Kielland forceps were used in 44 percent of cases in 1970, but by 1990 they were not used at all. Delivery in 1970 employed either or both manual rotation (63 percent), Kielland rotation (44 percent), or cesarean delivery (11 percent). By 1990, management involved cesarean delivery (42 percent), manual rotation (31 percent), or vacuum extraction (27 percent). Although the total number of women who had a deep transverse arrest is small—only 111—of the 25 infants delivered by Kielland forceps, eight required admission to the newborn intensive care unit. Two had facial nerve palsy and two had fractures of the right parietal bone. Importantly, if first manually rotated and then delivered by forceps, there were no injuries. In comparison, three delivered by cesarean had birth asphyxia.

For all of these reasons, in many centers forceps rotations of persistent occiput transverse positions are usually not done. Exceptions are cases associated with deep transverse arrest due to failure of rotation because of levator sling relaxation from epidural analgesia.

FORCEPS FOR FACE PRESENTATION

In the face presentation, with the chin directed toward the symphysis (mentum anterior), the application of forceps is occasionally used to effect vaginal delivery. The blades are applied to the sides of the head along the occipitofrontal diameter, with the pelvic curve directed toward the neck. Downward traction is exerted until the chin appears under the symphysis. Then, by an upward movement, the face is slowly extracted, with the nose, eyes, brow, and occiput appearing in succession over the anterior margin of the perineum ([Fig. 21-20](#)). Forceps should not be applied to the mentum posterior presentation, because vaginal delivery is impossible as such.

MORBIDITY FROM FORCEPS OPERATIONS

MATERNAL MORBIDITY

A valid and important question concerns the appropriate comparison group as regards forceps-related morbidity. Clearly it is not those women who deliver spontaneously, as forceps are usually not used absent a valid indication. Instead, the appropriate comparison group would be those women whose only options are either cesarean section or operative vaginal delivery by vacuum extractor.

Some generalizations can be made:

1. Elective outlet-forceps with rotations not exceeding 45 degrees may be used to shorten the second stage of labor with little, if any, increase in maternal morbidity ([Carmona and colleagues, 1995](#)).
2. Maternal injury increases significantly with rotations of greater than 45 degrees and at higher stations ([Hagadorn-Freathy and associates, 1991](#); [Hankins and](#)

[Rowe, 1996](#)).

3. Blood transfusions are increased with operative vaginal delivery (vacuum extraction 6.1 percent, forceps 4.2 percent) compared with uncomplicated cesarean (1.4 percent) or spontaneous vaginal delivery (0.4 percent) ([Sherman and co-workers, 1993](#)).

EPISIOTOMY AND LACERATIONS

The very conditions that lead to the requirement for operative vaginal delivery would also be expected to increase the need for episiotomy. This is supported by the observation that women randomized to delivery with low forceps had no increase in perineal lacerations relative to those delivering spontaneously ([Carmona and colleagues, 1995](#)). [Hagadorn-Freathy and co-workers \(1991\)](#) reported rates for third- and fourth-degree episiotomies and vaginal lacerations of 13 percent for outlet, 22 percent for low-forceps with less than 45 degrees rotation, 44 percent for low-forceps with greater than 45 degrees rotation, and 37 percent for midforceps operations. Similarly, [Bofill and colleagues \(1996a, 1996b\)](#) found a significant association of moderate and severe perineal injuries with indicated operative deliveries, use of forceps versus vacuum extractor, need for episiotomy, and delivery other than outlet station.

Although [Williams and associates \(1991\)](#) did not stratify perineal injury by complexity of delivery, they reported an 18 percent vaginal laceration rate, 20 percent third-degree episiotomy rate, and 10 percent fourth-degree rate with forceps compared with 15 percent, 7 percent, and 22 percent respectively with vacuum extraction. [Robinson and colleagues \(1999\)](#) studied perineal trauma in 323 women delivered with forceps or vacuum extraction. Use of episiotomy with forceps delivery did not significantly increase perineal trauma which was already high (55 versus 46 percent, with and without episiotomy, respectively). Vacuum extraction, however, significantly increased such trauma (35 versus 9 percent, with and without episiotomy, respectively).

Others report less trauma with the vacuum extractor. [Low and co-workers \(1993\)](#) reported vaginal lacerations in 4.3 percent of women and fourth-degree episiotomy in 1.6 percent. [Loghis and co-workers \(1992\)](#) reported anal sphincter involvement in 3 percent of vacuum deliveries and vaginal vault extensions in 2.5 percent.

[Ecker and colleagues \(1997\)](#) reported a significant decrease in the rate of episiotomy use over a 10-year period from 1984 to 1994 for both forceps (96 versus 30 percent) and vacuum deliveries (89 versus 39 percent). During the same time period there was a decrease in fourth-degree and no change in third-degree lacerations. [Eason and associates \(2000\)](#) have recently reviewed this subject.

URINARY AND RECTAL INCONTINENCE

It appears that normal, spontaneous delivery may cause urinary and fecal incontinence in some women ([Chap. 13](#), p. 325). For example, [Dimpfl and colleagues \(1992\)](#) suggest that as many as 6 percent of women who were continent before pregnancy develop permanent stress urinary incontinence after vaginal delivery. It is hypothesized that factors that increase trauma to the pelvic floor musculature and its innervation are causative, such as tears, no episiotomy, and forceps and vacuum delivery. This is unproven, however. Short-term effects of midcavity delivery and of rotations of greater than 45 degrees are associated with postpartum urinary retention and bladder dysfunction. Such complications also follow vacuum deliveries. [Low and associates \(1993\)](#) reported that 3 percent of women had voiding difficulties and required an indwelling catheter. Bladder rest by insertion of a Foley catheter, surveillance for urinary tract infection with early diagnosis and treatment, and bladder training usually result in restoration of normal function within a few days.

Anal sphincter trauma and resultant dysfunction may be associated with instrumental vaginal delivery. [Sultan and colleagues \(1993\)](#) described 43 nulliparas who had undergone forceps or vacuum vaginal delivery and compared them with women delivering spontaneously. A mediolateral episiotomy was performed in all 26 women undergoing forceps delivery and 13 of 17 in the vacuum group. In only one case was the rectal sphincter involved. The control group was composed of 47 randomly selected nulliparas delivered spontaneously who sustained a spontaneous second-degree tear or had a mediolateral episiotomy. Defecatory symptoms developed in 38 percent of women following forceps delivery, 12 percent following vacuum delivery, and 4 percent in the control group. Anal sphincter defects, diagnosed by anal endosonography, were present in 80 percent of forceps deliveries, 20 percent of vacuum deliveries, and 35 percent of controls.

In a subsequent study, [Sultan and colleagues \(1994\)](#) evaluated 50 women who had sustained third-degree tears. Anal incontinence or fecal urgency was present in half with tears compared with 13 percent without tears. Sonographic sphincter defects were identified in 85 percent of women who had a third-degree tear compared with 33 percent of controls. Every symptomatic woman had persistent combined internal and external sphincter defects that were associated with significantly lower anal pressures. Pudendal nerve conduction measurements were not different—suggesting that the injury is to the muscle and not the nerve.

In a 5-year follow-up study of women who had initially been randomized to either form of delivery, [Sultan and colleagues \(1998\)](#) reported that 32 percent of women delivered with forceps versus 16 percent of those delivered with vacuum had anal incontinence. Their study was small and the difference between the two groups was not significant. [Tetzschner and colleagues \(1998\)](#) reported that anal and urinary incontinence were associated with degree of sphincter rupture, use of vacuum extraction, and pudendal nerve terminal motor latencies of greater than 2.0 milliseconds.

Although the association of rectal incontinence and operative vaginal delivery, especially with forceps, is certainly disconcerting, the precise etiology of the lesion(s) or condition(s) producing the anal dysfunction is less than clear. Whether anal dysfunction associated with childbirth can even be prevented is also unclear. For example, factors other than operative vaginal delivery that have been associated with fecal incontinence include advanced parity, postmenopausal status, prior hysterectomy, and irritable bowel syndrome ([Donnelly, 1998](#); [Jackson, 1997](#); [Nygaard, 1997](#), and their colleagues).

In a 30-year follow-up study, [Nygaard and colleagues \(1997\)](#) discovered flatus incontinence in 31, 43, and 36 percent of women in the disrupted anal sphincter, episiotomy, and cesarean groups respectively. These authors concluded that "regardless of the type of delivery, anal incontinence occurs in a surprisingly large number of middle-aged women." Moreover, [Rieger and colleagues \(1997\)](#) reported that normal vaginal delivery without evidence of sphincter injury was associated with significant effect on anal sphincter function.

Thus, not only do anal and urinary incontinence follow uncomplicated spontaneous delivery, they also may occur in women following cesarean delivery. [Wilson and colleagues \(1996\)](#) reported urinary incontinence in 5.2 percent of women delivered by cesarean and there was little difference between elective cesarean versus cesarean delivery following labor. [MacArthur and colleagues \(1997\)](#) reported fecal incontinence in six women who underwent emergency cesarean delivery. [Fynes and colleagues \(1998\)](#), in a cohort of 234 women, reported that cesarean delivery performed in late labor does not protect the anal sphincter mechanism.

At this time, the data do not support abandoning operative vaginal delivery techniques in favor of cesarean delivery in all women. Large randomized studies with controls are needed to address the effects of operative vaginal delivery and possible pelvic floor damage and incontinence. Current studies that address this are in progress in several institutions.

FEBRILE MORBIDITY

Postpartum metritis is far more frequent, and often more severe, in women following cesarean compared with operative vaginal delivery. Rates of metritis for vacuum delivery are about 8 percent, for forceps 16 percent, and for combined operations 40 percent ([Williams and associates, 1991](#)). [Robertson and colleagues \(1990\)](#), using the 1988 forceps classification, reported maternal morbidity in 60 to 70 percent of women undergoing cesarean delivery compared with 25 percent for those delivered by midforceps, and 33 percent by low forceps.

PERINATAL MORBIDITY

Operative vaginal delivery, especially if performed from the midpelvic level, may be associated with increased neonatal morbidity. Examples of such morbidity, as well as their frequencies, are shown in [Table 21-4](#). This series consisted of 5 percent midpelvic operations and most low-forceps deliveries were done with less than 45-degree rotation.

[Towner and colleagues \(1999\)](#) studied 583,340 term nulliparous women delivered in California between 1992 and 1994. A third were delivered operatively—by cesarean, forceps, or vacuum. The incidence of intracranial hemorrhage, as shown in [Table 21-5](#), was identified to be greatest in infants delivered by vacuum, forceps, or cesarean after labor. These investigators concluded that abnormal labor was the common risk factor.

[White and associates \(1996\)](#) found a significant association of facial nerve palsy with forceps delivery compared with spontaneous delivery or cesarean section. A seldom-reported complication of delivery is neonatal abducens nerve injury ([Galbraith, 1994](#)). This injury complicates virtually no cesarean deliveries, 0.1 percent of spontaneous vaginal deliveries, 2.4 percent of forceps deliveries (less common with outlet forceps), and 3.2 percent of vacuum extractions. Fortunately, almost all

resolve by 6 weeks. [Gilbert and co-workers \(1999a\)](#), using the California database cited above, found that either forceps (3.4-fold) or vacuum (2.7-fold) significantly increase the risk for brachial plexus injury compared with spontaneous delivery.

MIDFORCEPS DELIVERIES

The immediate consequences of midforceps rotations have been reviewed by several investigators whose reports included controlled series. [Chiswick and James \(1979\)](#) reviewed neonatal morbidity and mortality with Kielland forceps deliveries compared with a matched group of babies born spontaneously. Birth trauma was evident in 15 percent of infants delivered with forceps. Neonatal mortality, most often from tentorial tears, occurred in 3 of 86 babies delivered with forceps, and two of these were in babies delivered by emergency cesarean section after attempts at instrumental delivery. More recent studies with Kielland forceps were discussed earlier ([Jain and colleagues, 1993](#); [Tan and associates, 1992](#)).

[Hughey and colleagues \(1978\)](#) compared 458 midforceps operations with 17 cesarean deliveries. Women delivered by cesarean were selected when the cervix was completely dilated and the occiput failed to rotate to the anterior position from transverse or posterior. Using a perinatal morbidity index, an unfavorable result of 30 percent was reported for fetuses delivered by mid-forceps versus no morbidity with cesarean delivery. [Bowes and Bowes \(1980\)](#) compared fetal outcomes with midforceps deliveries with those delivered by cesarean delivery or vacuum extraction. Morbid events were identified in 14 of 71 midforceps deliveries (20 percent) compared with two morbid events in the 37 cesarean sections (5 percent) and three instances of fetal trauma in 15 vacuum extractions (20 percent).

Several factors must be taken into consideration when attempting to interpret the results of these studies. First and foremost, they were conducted prior to the redefined classification of forceps in 1988; thus, midforceps were not defined as clearly and included deliveries from relatively high stations (0 to +1), as well as difficult rotations. Second, spontaneous vaginal deliveries are not appropriate controls for midforceps as in the study by [Chiswick and James \(1979\)](#). Finally, there is no uniformity in the criteria utilized to define immediate fetal morbidity.

[Gilstrap and colleagues \(1984\)](#) retrospectively compared immediate maternal and neonatal outcomes of 234 women delivered by midforceps with those of women delivered spontaneously, by low forceps, or by cesarean. Importantly, forceps were not applied unless the fetal head was below zero station, or had descended to lower than +1 station (of 3 stations) in the case of transverse arrest. Almost 60 percent of women delivered by midforceps had epidural analgesia. These investigators found no difference in the incidence of neonatal acidosis between the groups when indications for delivery were matched. Likewise, they found no excessive trauma to fetuses delivered by midforceps.

[Dierker and associates \(1985\)](#) provided a retrospective review of 176 midforceps deliveries at Cleveland Metropolitan General Hospital from 1976 through 1982, and compared these with all other deliveries during the study period. Epidural analgesia was associated with slightly more than half of the midforceps deliveries. Although cephalohematomas were identified more commonly in neonates delivered by midforceps (7 percent), they found no increased incidence of low Apgar scores, seizures, shoulder dystocia, and brachial or facial nerve palsy when these infants were compared with the general obstetrical population. Conversely, [Falco and Eriksson \(1990\)](#) described 92 cases of cranial VII nerve palsy in over 44,000 newborns delivered from 1982 to 1987 at Brigham and Women's Hospital. Of these, 74 (91 percent) were associated with forceps delivery.

[Bashore and associates \(1990\)](#) compared neonatal outcome in 358 midforceps deliveries with that of 486 cesarean deliveries. They found no increase in significant neonatal morbidity in the forceps group, although four newborns had transient facial palsy. Conversely, [Robertson and associates \(1990\)](#) used the 1988 classification of forceps and reported significantly higher neonatal morbidity in the midforceps group compared with infants delivered by cesarean.

In a prospective study of 357 forceps deliveries classified by both the old and new systems, [Hagadorn-Freathy and colleagues \(1991\)](#) reported that neonatal morbidity was effectively stratified using the 1988 classification. For example, facial nerve palsy developed in 1.3 percent of infants delivered by outlet forceps and 3.2 percent of those delivered by midforceps using the 1965 classification. This compared with 0.9 percent for outlet forceps, 1.7 percent for low forceps, and 9.2 percent for midforceps using the 1988 classification. Thus, the new classification of midforceps identifies a high-risk group for this complication. In the series of 99 women randomized to either forceps or vacuum by [Williams and associates \(1991\)](#), only five midpelvic deliveries were attempted. Of these, both vacuum deliveries were accomplished, but two of three forceps trials failed due to the inability to satisfactorily place the blades.

Because of the increased maternal and neonatal morbidity associated with midforceps deliveries compared with low forceps operations, they are seldom used contemporaneously. According to the [American College of Obstetricians and Gynecologists \(2000\)](#), midforceps procedures, including rotational delivery, are appropriate to teach and to use under the correct circumstances by an adequately trained individual.

LONG-TERM INFANT MORBIDITY

There has been significant controversy regarding possible associations of forceps delivery with long-term morbidity for the newborn. Although some earlier studies ([Chefet, 1965](#); [Eastman and colleagues, 1962](#)) reported an increased frequency of cerebral palsy with the use of midforceps, others did not find such an association ([Amiel-Tison, 1969](#); [Steer and Boney, 1962](#)).

Of all the aspects of forceps use, none has engendered more controversy than the possible association with decreased intelligence quotient (IQ). This issue is unsettled and is likely to remain so because of the multitude of variables affecting intelligence. [Broman and co-workers \(1975\)](#) used data from the Collaborative Perinatal Project and controlled for socioeconomic status, race, and gender, and reported that infants delivered by midforceps had slightly higher intelligence scores at 4 years of age than children delivered spontaneously. [Friedman and associates \(1977, 1984\)](#), using the same database, described intelligence assessments at least up to 7 years of age, and concluded that those children who had been delivered by midforceps had lower mean IQs¹ compared with children delivered by outlet forceps. [Dierker and colleagues \(1986\)](#) assessed the long-term outcome of children delivered by midforceps, again from the same database, and compared them with children who had been delivered by cesarean section performed for dystocia. Clearly, this is the most appropriate control group. These children were assessed at a minimum of 2 years of age, and the investigators found no increased morbidity associated with delivery by midforceps.

[Nilsen \(1984\)](#) evaluated 18-year-old men drafted into the Norwegian Army and reported that those delivered by Kielland forceps had higher intelligence scores than those delivered spontaneously, by vacuum extraction, or by cesarean.

In a collaborative study of over 3000 school-age children, [Wesley and colleagues \(1992\)](#) found no significant difference in standardized intelligent scores according to the method of delivery. All were evaluated at age 5 for cognitive development. There were 1746 children who were delivered spontaneously compared with 1192 children who had been delivered by either low- or mid-forceps or vacuum operations; 114 were delivered by midforceps or vacuum extraction.

[Seidman and colleagues \(1991\)](#) studied over 52,000 persons who were examined by the Israeli Defense Forces draft board at age 17. They had been born between 1964 and 1972 in four West Jerusalem hospitals. Intelligence test scores were available through 1969, and data from these 32,425 deliveries are shown in [Table 21-6](#). Data were adjusted by multiple regression for confounding effects of gender, birthweight, ethnic origin, birth order, maternal age, paternal and maternal education, and social class. Interestingly, prior to adjustment the mean intelligence scores at 17 years of age were significantly higher in the vacuum and forceps group than in the spontaneous delivery group. After adjustment for confounding factors, the IQ¹ score of the cesarean delivery group was significantly lower than that of the spontaneous delivery group.

CONCLUSIONS REGARDING MORBIDITY FROM FORCEPS

When performed inappropriately, forceps delivery can result in adverse maternal as well as fetal outcomes. It is clear that the greatest risk is incurred with true midforceps operations and when rotations of greater than 45 degrees are required. Most studies in which these morbid events were reported to be increased substantively were done when cesarean rates were still around 5 percent. Moreover, many of these earlier studies undoubtedly included forceps applications that would, in all likelihood, never be attempted today. In contrast, more contemporaneous studies appropriately emphasize that the majority of mid-forceps deliveries are done with the fetal vertex at +1 (of three stations) or lower station ([Dierker and associates, 1986](#); [Gilstrap and colleagues, 1984](#)). It is unlikely that midforceps deliveries included in the Collaborative Perinatal Project during the 1960s were this conservative.

The impact of the popular use of epidural analgesia on the incidence of low- and midforceps deliveries cannot be discounted. The majority of such cases result from inadequate maternal expulsive forces against a relaxed pelvic sling, and thus they are not usually associated with either relative or absolute cephalopelvic disproportion. Although it is prudent in these cases to allow a longer second stage of labor, in some women and under some circumstances, delivery is indicated sooner. Low-forceps rotations for epidural-associated labor abnormalities are likely to be safer than the same operation performed in women with prolonged labors or midpelvic arrest unassociated with conduction analgesia.

It seems reasonable to conclude that outlet and low-forceps operations with rotation of 45 degrees or less, classified by the [American College of Obstetricians and Gynecologists \(2000\)](#) scheme, can be performed with safety for both mother and fetus if the basic guidelines set forth in this chapter are carefully observed.

TRIAL OF FORCEPS AND FAILED FORCEPS

In trial of forceps, the operator attempts delivery with the full knowledge that vaginal delivery may not be successful. With an operating room both equipped and staffed for immediate cesarean delivery, the trial may proceed. If a satisfactory application of the forceps cannot be achieved, then the procedure is abandoned and delivery accomplished by use of either vacuum extraction or cesarean. Once application has been achieved, gentle downward pulls are made on the instrument. If there is no descent, the procedure is abandoned. In some situations, vacuum extraction may be successful ([Ezenagu and colleagues, 1999](#)). If not deemed safe, or if it also fails to effect vaginal delivery, then cesarean delivery is performed.

In a study of 122 women who had a trial of midcavity forceps or vacuum extraction in a setting with full preparations to proceed to cesarean section, [Lowe \(1987\)](#) found no significant difference in immediate neonatal or maternal morbidity compared with 42 women delivered for similar indications by cesarean without such a trial of instrumentation. Conversely, neonatal morbidity was higher in 61 women who had "unexpected" forceps or vacuum failure in which there was no prior preparation for immediate cesarean delivery. [Williams and colleagues \(1991\)](#) reported good outcomes for both mother and infant by use of alternate or sequential forceps/vacuum delivery. They achieved an overall cesarean delivery rate of 3 percent in a group of 99 women, all 35 weeks or greater, and who had indications for assisted vaginal delivery.

Thus, as [Lowe \(1987\)](#) concluded, "a carefully conducted trial of instrumental delivery is an acceptable alternative to cesarean section for delay in the second stage due to a potentially difficult midcavity arrest." We agree with the [American College of Obstetricians and Gynecologists \(2000\)](#), which cautions that these are attempted only if the clinical assessment is highly suggestive of a successful outcome.

VACUUM EXTRACTION

Simpson introduced the idea of vacuum extraction in the 1840s, and there have been numerous attempts since to attach a traction device by suction to the fetal scalp. In the United States, the device is referred to as the vacuum extractor, while commonly in Europe it is referred to as a **ventouse** (from French, literally, *soft cup*). The theoretical advantages of the vacuum extractor over forceps include the avoidance of insertion of space-occupying steel blades within the vagina and their positioning precisely over the fetal head, as is required for forceps delivery; the ability to rotate the fetal head without impinging upon maternal soft tissues; and less intracranial pressure during traction. All previously described instruments were unsuccessful until [Malmstrom \(1954\)](#) applied a new principle, namely, traction on a metal cap so designed that the suction creates an artificial caput, or *chignon*, within the cup that holds firmly and allows adequate traction.

As with forceps choice, the decision to use a metal or a soft cup appears regional. In the United States, the metal cup generally has been replaced by newer soft cup vacuum extractors. As emphasized by [Duchon and associates \(1998\)](#), however, high-pressure vacuum generates large amounts of force regardless of the cup used. The silastic cup vacuum device is a reusable instrument with a soft, 65-mm diameter cup. The Mityvac instrument uses a disposable 60-mm diameter cup ([Fig. 21-21](#)), and the CMI Tender Touch uses a 62-mm cup ([Fig. 21-22](#)). [Bofill and associates \(1996b\)](#) reported good results with the Mityvac M-cup.

[Loghis and colleagues \(1992\)](#) compared results of 200 women delivered using a metal cup with 200 women in whom a pliable cup was used. No differences were found in the rate of birth canal trauma (11 versus 13 percent), major neonatal scalp trauma (6.5 percent versus 5.5 percent), neonatal jaundice (15.5 percent versus 13.5 percent), or Apgar scores. [Kuit and co-workers \(1993\)](#) found the only advantage of the soft cups to be a lower incidence of neonatal scalp injury. In this study, both rigid and pliable cups had an associated episiotomy extension rate of 14 percent. Vaginal lacerations were 16 percent with rigid cups and 10 percent with pliable cups. [Johanson and Menon \(2000a\)](#) searched the Cochrane Pregnancy and Childbirth Group database and found nine randomized trials. They too found that soft cups had a higher failure rate (1.65 ×) but were associated with less scalp injury (0.45 ×) than rigid cups.

INDICATIONS AND PREREQUISITES

Generally, the indications and prerequisites for the use of the vacuum extractor for delivery are the same as for forceps delivery ([American College of Obstetricians and Gynecologists, 2000](#)). The tendency to attempt vacuum deliveries at stations higher than usually attempted with forceps is worrisome. [Broekhuizen and colleagues \(1987\)](#) reported that 3.5 percent of vacuum deliveries were performed with the vertex above zero station, and another 20 percent were at zero station. Relative contraindications for delivery using vacuum extraction include face or other nonvertex presentations, extreme prematurity, fetal coagulopathies, known macrosomia, and following recent scalp blood sampling.

TECHNIQUE

Proper cup placement is the most important determinant of success in vacuum extraction. The center of the cup should be over the sagittal suture and about 3 cm in front of the posterior fontanelle. Anterior placement on the fetal cranium—near the anterior fontanelle rather than over the occiput—will only aggravate the problem of cervical spine extension unless the fetus is small relative to the maternal pelvis. Similarly, asymmetrical placement relative to the sagittal suture may worsen asynclitism. The effects of asymmetrical or anterior misplacement of the cup are shown in [Figure 21-23](#). Cup placement for elective use of the instrument in occiput anterior positions is seldom difficult. In contrast, when the indication for delivery is failure to descend caused by occipital malposition, with or without asynclitism or deflexion, cup placement can be very difficult ([Lucas, 1994](#)).

Entrapment of maternal soft tissue predisposes the mother to lacerations and hemorrhage and virtually assures cup "pop-off." The full circumference of the cup should be palpated both prior to as well as after the vacuum has been created, and prior to traction. When using rigid cups, it is recommended that the vacuum be created gradually by increasing the suction by 0.2 kg/cm² every 2 minutes until a negative pressure of 0.8 kg/cm² is reached. With soft cups, negative pressure can be increased to 0.8 kg/cm² over as little as 1 minute ([Hankins and associates, 1995](#); [Kuit and colleagues, 1993](#)). Some authors suggest that 0.6 kg/cm² is optimal as higher amounts of pressure increase might potentially increase the risk of fetal scalp and/or cerebrocranial trauma without significantly increasing the rate of successful vaginal delivery ([Lucas, 1994](#)). [Table 21-7](#) lists conversions of various units of pressures used by different instruments.

Traction should be intermittent and coordinated with maternal expulsive efforts. Traction may be initiated by using a two-handed technique; fingers of one hand are placed against the suction cup, while the other hand grasps the handle of the instrument. A theoretical advantage of the instrument is that it will usually detach prior to creating tractive forces sufficient to cause fetal injury. Vacuums offer no advantage for avoidance of shoulder dystocia. Manual torque to the cup should be avoided as it may cause cephalohematomas and lacerations—"cookie-cutter" type with metal cups—of the fetal scalp.

Vacuum extraction should be considered a trial, and without early and clear evidence of descent toward delivery, consideration for alternate delivery approach is given. As a general guideline, progress in descent should accompany each traction attempt. Neither data nor consensus are available regarding the number of pulls required to effect delivery, the maximum number of cup detachments that can be tolerated, or total duration of the procedure. A cup pop-off due to technical failure or because placement has been difficult to obtain, and thereby the amount of vacuum that can be developed or maintained is suboptimal, should not be equated with a pop-off under ideal conditions of exact cup placement and optimal vacuum maintenance. The former may merit several additional attempts at placement and delivery, or abandonment and use of forceps ([Ezenagu and colleagues, 1999](#); [Williams and co-workers, 1991](#)). Conversely, the latter is highly suggestive of relative or absolute disproportion or asynclitism that is requiring excessive tractive forces. As with forceps procedures, there should be a willingness to abandon attempts at vacuum extraction if satisfactory progress is not made ([American College of Obstetricians and Gynecologists, 2000](#)).

COMPLICATIONS

Complications include scalp lacerations and bruising, subgaleal hematoma, cephalohematomas, intracranial hemorrhage, neonatal jaundice, subconjunctival hemorrhage, clavicular fracture, shoulder dystocia, injury of sixth and seventh cranial nerves, Erb palsy, retinal hemorrhage, and fetal death ([Broekhuizen, 1987](#); [Dell and associates, 1985](#); [Galbraith, 1994](#); [Govaert and colleagues, 1992](#)). Significant scalp injuries, hematomas, and resulting hyperbilirubinemia are more common with the metal cup instruments compared with the soft cup devices ([American College of Obstetricians and Gynecologists, 2000](#); [Johanson and Menon, 2000a](#)). In a review by [Plauche \(1979\)](#) of the Malmstrom vacuum extractor, scalp injury ranged from 0.8 to 33 percent, cephalohematomas from 1 to 26 percent, and subgaleal hemorrhage from 0 to 10 percent. Similar results have been reported by [Benjamin and Kahn \(1993\)](#) and [Kuit and associates \(1993\)](#). [Berkus and associates \(1985\)](#), on the other hand, found no increase in serious neonatal morbidity, including retinal hemorrhage, for the silastic vacuum extractor compared with spontaneous delivery.

The Food and Drug Administration issued a Public Health Advisory in 1998 regarding the possible association of vacuum-assisted delivery with serious or fetal

complications, including death. During a 4-year period, the FDA received reports of nine serious fetal injuries and 12 newborn deaths, which was a significant increase over the preceding 11 years. In a response to this advisory, the [American College of Obstetricians and Gynecologists \(1998\)](#) issued a Committee Opinion recommending the continued use of vacuum-assisted delivery devices when appropriate. They estimated that there is approximately one adverse event per 45,455 vacuum extractions per year.

RECOMMENDATION REGARDING VACUUM DELIVERY

Considering the [1998 FDA Public Health Advisory](#), the following recommendations seem reasonable:

1. The classification of vacuum deliveries should be the same as that utilized for forceps deliveries (including station).
2. The same indications and contraindications utilized for forceps deliveries should be applied to vacuum-assisted deliveries.
3. The vacuum should not be applied to an unengaged vertex (i.e., above zero station).
4. The individual performing or assisting in the procedure should be an experienced operator.
5. The operator should be willing to abandon the procedure if it does not proceed easily or if the cup pops off more than three times.

COMPARISON OF VACUUM EXTRACTION WITH FORCEPS

There have been numerous studies comparing vacuum extraction with forceps deliveries. [Vacca and associates \(1983\)](#) conducted a randomized, prospective study comparing metal cup vacuum extraction with forceps delivery. They reported a higher frequency of maternal trauma and blood loss in the forceps group, but an increase in the incidence of neonatal jaundice in the vacuum group. [Bofill and colleagues \(1996b\)](#) randomized 637 women to forceps versus vacuum extraction with the Mityvac M-cup. There were significantly more third- and fourth-degree lacerations (29 versus 12 percent) in the forceps-delivered group. Conversely, the incidence of shoulder dystocia and cephalohematoma were doubled in the vacuum group. Others have found decreased maternal trauma and similar neonatal morbidity in babies delivered by vacuum compared with forceps ([Berkus, 1985](#); [Broekhuizen, 1987](#); [Dell, 1985](#); [Williams, 1991](#), and their colleagues). Although retinal hemorrhage is occasionally seen with vacuum usage, it has no apparent long-term effects. [Johanson and Menon \(2000b\)](#) searched the Cochrane Pregnancy and Childbirth Group database and analyzed 10 randomized trials. They confirmed that vacuum extraction was associated with less maternal trauma but increased cephalohematomas and retinal hemorrhages.

There are sparse data regarding long-term neurological outcome in newborns delivered by vacuum extraction. In the report of an 18-year follow-up by [Nilsen \(1984\)](#), the mean intelligence score of 38 male infants delivered by vacuum was not different from the national average. [Seidman and associates \(1991\)](#) reported a higher mean IQ^1 score at age 17 in those delivered by vacuum or forceps compared with spontaneous delivery ([Table 21-6](#)).

[Johanson and colleagues \(1999\)](#) performed a 5-year follow-up of a randomized trial of forceps versus vacuum delivery in over 600 women. Almost half in each group reported urinary incontinence or fecal urgency. There was also no significant differences in child development.

TABLE 21-1. Classification of Forceps Delivery According to Station and Rotation

Procedure	Criteria
Outlet forceps	<ol style="list-style-type: none">1. Scalp is visible at the introitus without separating the labia.2. Fetal skull has reached pelvic floor.3. Sagittal suture is in anteroposterior diameter or right or left occiput anterior or posterior position.4. Fetal head is at or on perineum.5. Rotation does not exceed 45 degrees.
Low forceps	Leading point of fetal skull is at station = +2 cm, and not on the pelvic floor. <ul style="list-style-type: none">• Rotation is 45 degrees or less (left or right occiput anterior to occiput anterior, or left or right occiput posterior to occiput posterior).• Rotation is greater than 45 degrees.
Midforceps	Station above +2 cm but head is engaged.
High	Not included in classification.

22. Breech Presentation and Delivery

Breech presentation is when the buttocks of the fetus enter the pelvis first. The term *breech* probably derives from the same word as *britches*, which described a cloth covering the loins and thighs. For a number of reasons, breech presentation is more common remote from term ([Table 22-1](#)). Most often, however, before the onset of labor the fetus turns spontaneously to a cephalic presentation so that breech presentation persists in only about 3 to 4 percent of singleton deliveries. For example, 3.5 percent of 136,256 singleton infants delivered from 1990 through 1999 at Parkland Hospital presented as breech.

ETIOLOGY

As term approaches, the uterine cavity most often accommodates the fetus in a longitudinal lie with the vertex presenting. Factors other than gestational age that appear to predispose to breech presentation include uterine relaxation associated with great parity, multiple fetuses, hydramnios, oligohydramnios, hydrocephalus, anencephalus, previous breech delivery, uterine anomalies, and pelvic tumors.

[Fianu and Vaclavinkova \(1978\)](#) provided sonographic evidence of a much higher prevalence of placental implantation in the cornual-fundal region for breech presentation (73 percent) than for vertex presentations (5 percent). The frequency of breech presentation is also increased with placenta previa, but only a small minority of breech presentations are associated with a previa. No strong correlation has been shown between breech presentation and a contracted pelvis.

A live fetus is *not* required for a fetus to change presentations spontaneously. One woman admitted to Parkland Hospital at term had a fetus known to be dead, confirmed by real-time sonography. The presentation was cephalic during the first oxytocin induction. Three days later, at the time of the second attempt at labor induction, the fetus was in a breech presentation. Three days later, at the time of a third and successful induction, the fetus was again in a cephalic presentation!

COMPLICATIONS

In the persistent breech presentation, an *increased* frequency of the following complications can be anticipated:

1. Perinatal morbidity and mortality from difficult delivery.
2. Low birthweight from preterm delivery, growth restriction, or both.
3. Prolapsed cord.
4. Placenta previa.
5. Fetal, neonatal, and infant anomalies.
6. Uterine anomalies and tumors.
7. Multiple fetuses.
8. Operative intervention, especially cesarean delivery.

DIAGNOSIS

The varying relations between the lower extremities and buttocks of breech presentations form the categories of frank, complete, and incomplete breech presentations (see [Figs. 12-2, 12-3, and 12-4](#)). [Chasen and D'Angelo \(2000\)](#) reported a positive predictive value of 80 percent and a negative predictive value of 98.5 percent for abdominal and vaginal examination to diagnose breech presentation at 35 to 37 weeks. With a **frank breech** presentation, the lower extremities are flexed at the hips and extended at the knees, and thus the feet lie in close proximity to the head. A **complete breech** presentation differs in that one or both knees are flexed. With **incomplete breech** presentation, one or both hips are not flexed and one or both feet or knees lie below the breech, that is, a foot or knee is lowermost in the birth canal. The frank breech appears most commonly when the diagnosis is established radiologically near term.

ABDOMINAL EXAMINATION. Typically, with the first Leopold maneuver, the hard, round, readily ballotable fetal head is found to occupy the fundus ([Fig. 22-1](#)). The second maneuver indicates the back to be on one side of the abdomen and the small parts on the other. On the third maneuver, if engagement has not occurred—the intertrochanteric diameter of the fetal pelvis has not passed through the pelvic inlet—the breech is movable above the pelvic inlet. After engagement, the fourth maneuver shows the firm breech to be beneath the symphysis. Fetal heart sounds are usually heard loudest slightly above the umbilicus, whereas with engagement of the fetal head the heart sounds are loudest below the umbilicus.

VAGINAL EXAMINATION. With the frank breech presentation, both ischial tuberosities, the sacrum, and the anus are usually palpable, and after further descent, the external genitalia may be distinguished. Especially when labor is prolonged, the buttocks may become markedly swollen, rendering differentiation of face and breech very difficult; the anus may be mistaken for the mouth, and the ischial tuberosities for the malar eminences. Careful examination, however, should prevent this error, because the finger encounters muscular resistance with the anus, whereas the firmer, less yielding jaws are felt through the mouth. Furthermore, the finger, upon removal from the anus, is sometimes stained with meconium. The mouth and malar eminences form a triangular shape, while the ischial tuberosities and anus are in a straight line. The most accurate information, however, is based on the location of the sacrum and its spinous processes, which establishes the diagnosis of position and variety.

In complete breech presentations, the feet may be felt alongside the buttocks, and in footling presentations, one or both feet are inferior to the buttocks ([Fig. 22-2](#)). In footling presentations, the foot can readily be identified as right or left on the basis of the relation to the great toe. When the breech has descended farther into the pelvic cavity, the genitalia may be felt.

IMAGING TECHNIQUES. Ultrasound ideally should be used to confirm a clinically suspected breech presentation and to identify, if possible, any fetal anomalies. [Bruck and Sherer \(1997\)](#) used intrapartum ultrasound to detect large lower uterine segment leiomyomas. If cesarean delivery is planned, x-rays are not indicated. If, however, vaginal delivery is considered, the type of breech presentation is of considerable importance. Radiation exposure may be reduced considerably by using computed tomographic pelvimetry ([Kopelman and associates, 1986](#)). These imaging techniques can be used to provide information regarding the type of breech presentation, presence or absence of a flexed fetal head, and pelvic measurements (see [Chap. 18, p. 438](#)).

The role of x-ray pelvimetry in deciding mode of delivery for breech presentation is controversial ([Morrison and co-authors, 1995](#)). [Cheng and Hannah \(1993\)](#) comprehensively surveyed the literature on breech delivery at term and reviewed 15 studies in which x-ray pelvimetry was used and two studies in which CT pelvimetry was used as one of the criteria for allowing vaginal delivery. They concluded that the role of x-ray pelvimetry was complicated because pelvic dimensions for allowing labor varied among studies. Most authors, however, found no correlation between radiological pelvic measurements and the outcome of labor. Only one study demonstrated that the incidence of complicated labor rose with decreasing pelvic capacity ([Ohlsen, 1975](#)).

Magnetic resonance imaging for pelvimetry is considered more accurate than other methods. As emphasized by [van Loon and colleagues \(1997\)](#), this has no value if the results have no clinical benefits. They performed a randomized controlled trial in 235 women with breech presentation at term. The use of magnetic resonance pelvimetry did not decrease the overall cesarean delivery rate (42 percent) compared with controls not undergoing pelvimetry (50 percent).

PROGNOSIS

Both mother and fetus are at greater risk with breech compared with cephalic presentation, but to nowhere near the same degree. In an analysis of 57,819 pregnancies in the Netherlands, [Schutte and colleagues \(1985\)](#) reported that even after correction for gestational age, congenital defects, and birthweight, perinatal mortality was higher in breech infants. They concluded that it may be possible that breech presentation is not coincidental but is a consequence of poor fetal quality. [Krebs and associates \(1999\)](#) reported that cerebral palsy in breech-presenting fetuses was not related to the mode of delivery. Thus, it may be that medical intervention is unlikely to reduce perinatal mortality associated with breech presentation. This possibility had been suggested earlier by [Hyttén \(1982\)](#) and by [Susuki](#)

and Yamamuro (1985). This concept was strengthened by Nelson and Ellenberg (1986), who observed that a third of children with cerebral palsy who were in a breech presentation at birth had major noncerebral malformations.

MATERNAL MORBIDITY. Because of the greater frequency of operative delivery, including cesarean delivery, there is higher maternal morbidity and slightly higher mortality for pregnancies complicated by persistent breech presentation (Collea and co-authors, 1980). This risk is likely increased even more with emergency operation instead of elective cesarean delivery (Bingham and Lilford, 1987). Labor is usually not prolonged and Hall and Kohl (1956) reported its median duration to be 9.2 hours for nulliparas and 6.1 hours for multiparas.

FETUS-INFANT MORBIDITY AND MORTALITY. The prognosis for the fetus in a breech presentation is considerably worse than when in a vertex presentation. The major contributors to perinatal loss are preterm delivery, congenital anomalies, and birth trauma. Almost 30 years ago, Brenner and associates (1974) reported the overall mortality rate for 1016 breech deliveries to be 25 percent compared with 2.6 percent for nonbreech deliveries. At every stage of gestation, they identified antepartum, intrapartum, and neonatal deaths to be significantly greater among breeches. Congenital abnormalities were identified in 6.3 percent of breech deliveries compared with 2.4 percent of nonbreech deliveries.

In a study of similar vintage, Tank and associates (1971) assessed outcomes of traumatic vaginal delivery. At autopsy, the organs most frequently found to be injured were, in order of frequency, the brain, spinal cord, liver, adrenal glands, and spleen. It is of interest that, in retrospective analysis of cases of "idiopathic" adrenal calcification, breech delivery was very common. Other injuries from vaginal delivery included the brachial plexus; the pharynx, in the form of tears or pseudodiverticula from the finger in the mouth as part of the Mauriceau maneuver (see p. 525); and the bladder, which might rupture if distended. Traction might injure the sternocleidomastoid muscle and, if not appropriately treated, lead to torticollis (Chap. 39, p. 1082).

These older reports are in contrast to more contemporaneous observations in which careful assessment is made before vaginal delivery is attempted, and cesarean delivery rates generally exceed 60 percent. Albrechtsen and colleagues (2000) have reported that perinatal mortality in 45,579 breeches decreased from 9 percent in 1967-1976 to 3 percent in 1987-1994.

COMPLICATIONS WITH VAGINAL DELIVERY

Delivery of the breech draws the umbilicus and attached cord into the pelvis, which compresses the cord. Therefore, once the breech has passed beyond the vaginal introitus, the abdomen, thorax, arms, and head must be delivered promptly. This involves delivery of successively less readily compressible parts. With a term fetus, some degree of head molding may be essential for it to negotiate the birth canal successfully. In this unfortunate circumstance, the alternatives with vaginal delivery are both unsatisfactory:

1. Delivery may be delayed many minutes while the aftercoming head accommodates to the maternal pelvis, but hypoxia and acidemia become severe; or
2. Delivery may be forced, causing trauma from compression, traction, or both.

With a preterm fetus, the disparity between the size of the head and buttocks is even greater than with a larger fetus. At times, the buttocks and lower extremities of the preterm fetus will pass through the cervix and be delivered, and yet the cervix will not be dilated adequately for the head to escape without trauma (Bodmer and associates, 1986). In this circumstance, *Duhrssen incisions* of the cervix may be attempted. Even so, trauma to the fetus and mother may be appreciable, and fetal hypoxia may prove harmful. Robertson and colleagues (1995, 1996) observed no significant difference in the incidence of head entrapment by mode of delivery for breech infants at 28 to 36 weeks or from 24 to 27 weeks. They also found no association of adverse neonatal outcomes after head entrapment. Another mechanical problem with breech delivery is entrapment of the fetal arm behind the neck. A nuchal arm complicates up to 6 percent of vaginal breech deliveries and is associated with increased neonatal mortality (Cheng and Hannah, 1993).

The frequency of cord prolapse is increased when the fetus is small or when the breech is not frank. In the report by Collea and colleagues (1978), the incidence with frank breech presentation was about 0.5 percent, which is similar to 0.4 percent reported for cephalic presentations (Barrett, 1991). In contrast, the incidence of cord prolapse with footling presentation was 15 percent, and it was 5 percent with complete breech presentation.

Soernes and Bakke (1986) confirmed earlier observations that umbilical cord length is significantly shorter in breech compared with cephalic presentations. Moreover, multiple coils of cord entangling the fetus are more common with breech presentations (Spellacy and associates, 1966). These umbilical cord abnormalities likely play a role in the development of breech presentation as well as the relatively high incidence of a nonreassuring fetal heart rate pattern in labor. For example, Flanagan and co-workers (1987) selected 244 women with a variety of breech presentations (72 percent were frank breech) for a trial of labor, and there was a cord prolapse in 4 percent. Fetal distress not due to cord prolapse was diagnosed in another 5 percent of women selected for vaginal delivery. Overall, 10 percent of the women identified for vaginal birth underwent cesarean deliveries for fetal jeopardy in labor.

Apgar scores, especially at 1 minute, of vaginally delivered breech infants are generally lower than when elective cesarean delivery is performed (Flanagan and co-workers, 1987). Similarly, cord blood acid-base values are significantly different for vaginally delivered breech infants. Christian and Brady (1991) reported that umbilical artery blood pH was lower, Pco₂ higher, and HCO₃ lower compared with cephalic deliveries. Socol and colleagues (1988), however, concluded that cesarean delivery improved Apgar scores but not acid-base status. Flanagan and co-workers (1987) emphasized that ultimate infant outcome for breech birth was not worsened by these significant differences in Apgar scores or acid-base status at birth.

Albrechtsen and colleagues (1997) evaluated a protocol to select vaginal or cesarean delivery for breech presentation. In 1212 breech presentations, the vaginal delivery rate increased from 45 to 57 percent and cesarean delivery rate for a failed vaginal delivery declined from 21 to 6 percent. Birth asphyxia was diagnosed clinically among 2.5 percent of those with a vaginal delivery of a breech, but none delivered as vertex ($P = .0001$). Despite this, none of these infants died or had long-term sequelae. Daniel and co-workers (1998) reported similar success with a prospective protocol in 496 women at term with a singleton breech presentation. Conversely, Koo and associates (1998) observed increased perinatal morbidity and mortality in singleton term vaginal breech deliveries despite application of strict selection criteria.

UNFAVORABLE PELVIS. Because there is no time for molding of the aftercoming head, a moderately contracted pelvis that had not previously caused problems in delivery of an average-size cephalic fetus might prove dangerous with a breech. Rovinsky and colleagues (1973) urged not only accurate measurements of the pelvic dimensions but also precise evaluation of the pelvic architecture rather than reliance on pelvic indexes. Gynecoid (round) and anthropoid (elliptical) pelvises are favorable configurations, but platypelloid (anteroposteriorly flat) and android (heart-shaped) pelvises are not (Chap. 3, p. 57).

HYPEREXTENSION OF FETAL HEAD. In perhaps 5 percent of term breech presentations, the fetal head may be in extreme hyperextension (Fig. 22-3). These presentations have been referred to as "the stargazer fetus," and in Britain as "the flying foetus." With such hyperextension, vaginal delivery may result in injury to the cervical spinal cord. In general, marked hyperextension after labor has begun is considered an indication for cesarean delivery (Svenningsen and associates, 1985).

LABOR INDUCTION OR AUGMENTATION

Induction of labor in women with a breech presentation is defended by some and condemned by others. Brenner and associates (1974) found no significant differences in perinatal mortality and Apgar scores between infants with induced versus spontaneous labor. In oxytocin-augmented labor, however, infant mortality rates were higher, and Apgar scores were lower. Fait and colleagues (1998) reported that 12 of 23 women with a breech presentation and an unripe cervix who underwent induction had a successful vaginal delivery with no neonatal complications. At Jackson Memorial Hospital in Miami (Diro and associates, 1999), oxytocin is used in a manner similar to that for vertex presentations. By contrast, at Parkland Hospital, labor induction may be attempted by amniotomy, but cesarean delivery is preferred to oxytocin induction or augmentation of labor with a viable fetus.

FOOTLING BREECH PRESENTATIONS

The possibility of compression of a prolapsed cord or a cord entangled around the extremities as the breech fills the pelvis, if not before, is a threat to the fetus (see Fig. 12-2).

TERM FETUS

Cheng and Hannah (1993) conducted a systematic search of the world literature regarding term breech delivery and found 82 reports published in English between

1966 and 1992. A total of 24 studies were selected for analysis because these compared *planned* vaginal delivery with *planned* cesarean section for the term, singleton breech fetus. The effects of planned vaginal delivery on perinatal mortality, corrected for lethal congenital anomalies and antepartum fetal death, are shown in [Table 22-2](#). The corrected perinatal mortality rate ranged from 0 to 48 per 1000 births and was higher among infants in the planned vaginal delivery groups.

All but two deaths were in the groups of women allowed to labor and deliver vaginally. The main causes of death were head entrapment, cerebral injury and hemorrhage, cord prolapse, and severe asphyxia. [Cheng and Hannah \(1993\)](#) observed that the overall neonatal mortality and morbidity resulting from trauma were increased significantly in the planned vaginal delivery groups, with a typical odds ratio of 3.86. They suggested that until a well-designed randomized trial with sufficient statistical power is performed, planned cesarean delivery should be strongly considered for persistent breech presentation at term. Similarly, [Gifford and co-workers \(1995b\)](#) performed a meta-analysis of outcomes after term breech delivery and observed that, given many methodological limitations of published studies, their analysis suggested an increased risk of injury or death after a trial of labor.

Only two of the 24 reports reviewed by [Cheng and Hannah \(1993\)](#) and [Gifford and co-workers \(1995b\)](#) were randomized trials, and both were from the same institution. [Collea and colleagues \(1980\)](#) reported the results of 208 women with frank breech fetuses at term. Almost half of these women were excluded from further consideration because of possible fetopelvic disproportion based on x-ray pelvimetry. A total of 60 infants were eventually delivered vaginally, and all survived, although two sustained brachial plexus injuries. There were no perinatal deaths, but half of the 148 women who had cesarean deliveries experienced significant morbidity compared with only 7 percent of 60 women who were delivered vaginally. [Gimovsky and colleagues \(1983\)](#) later evaluated 105 nonfrank breech fetuses and reported similar findings. Although these two trials concluded that vaginal breech delivery was relatively safe, only 110 fetuses were actually allowed a trial of labor. As emphasized by [Eller and Van Dorsten \(1995\)](#), this small number would not provide sufficient statistical power to demonstrate differences in uncommon adverse outcomes such as perinatal death and birth injury. [Lindqvist and associates \(1997\)](#), in a register-based nationwide study in Sweden from 1991 and 1992, found similar mortality with vaginal compared with cesarean delivery. The opposite conclusion was reached by [Roman and colleagues \(1998\)](#) in their study of almost 16,000 term breech births in Sweden between 1987 and 1993.

PRETERM FETUS

The aftercoming head of a preterm fetus may be trapped by a cervix that is sufficiently effaced and dilated to allow passage of the thorax but not the less compressible head. The consequences of vaginal delivery in this circumstance all too often have been both hypoxia and physical trauma, both of which are especially deleterious to the preterm infant.

There are no randomized studies regarding delivery of the preterm breech fetus. [Penn and colleagues \(1996\)](#) attempted such a study in 26 hospitals in England and discontinued the trial after 17 months because only 13 women could be recruited. Retrospective studies have yielded conflicting results. [Bowes and colleagues \(1979\)](#) and [Main and co-workers \(1983\)](#) found that infants undergoing cesarean delivery had a better prognosis. Others have concluded that vaginal delivery did not significantly increase perinatal mortality ([Olshan and co-workers, 1984](#); [Rosen and Chik, 1984](#); [Westgren and co-workers, 1985a](#)). More recently, [Wolf and colleagues \(1999\)](#) compared preterm breech fetuses delivered at two tertiary-care facilities in the Netherlands. At one center vaginal delivery was preferred and the cesarean delivery part was only 17 percent. At the other center, the cesarean delivery rate was 85 percent. These investigators found no difference in 2-year survival without disability or handicap.

The National Institute of Child Health and Human Development Neonatal Research Network ([Malloy and co-workers, 1991](#)) analyzed data from 437 very-low-birthweight breech infants admitted to seven neonatal intensive care centers. After adjusting for several variables, the risk of intraventricular hemorrhage and neonatal death was not significantly affected by the mode of delivery for fetuses weighing less than 1500 g. A similar analysis was reported from the Netherlands ([Gravenhorst and co-workers, 1993](#)). Perinatal follow-up data were collected on 899 singleton, nonanomalous infants of less than 32 weeks' gestation, whose birthweight was less than 1500 g. They could not conclusively resolve whether cesarean delivery was advantageous.

CURRENT STATUS OF VAGINAL BREECH DELIVERY

[Eller and Van Dorsten \(1995\)](#) surveyed the centers in the Maternal-Fetal Medicine Units Network to determine the feasibility of resolving the controversy regarding route of delivery by a randomized clinical trial. Virtually all participating obstetricians in the Network agreed that clear scientific evidence was needed to determine if mode of delivery of the breech affects outcome. They concluded, however, that the investigation was not feasible. This was because the number of skilled operators with the ability to safely deliver breech fetuses continues to dwindle and medicolegal concerns make it difficult to train residents to perform such deliveries. Indeed, at least two other groups of investigators who have attempted trials of breech delivery concluded that such studies were likely impossible ([Penn and Steer, 1990](#); Zlatnik, 1993). Despite this, [Hannah and colleagues \(2000\)](#) reported results from a multinational randomized trial of vaginal versus cesarean delivery for term breeches. Almost 57 percent of 1042 women randomized to vaginal delivery were delivered as such. While they observed greater neonatal morbidity in the vaginally delivered group, the heterogeneity of the study populations makes their findings difficult to apply to contemporaneous obstetrical practices in developed countries.

What, then, is "standard of care" for delivery of term and preterm singleton breech fetuses in the United States? Despite the inadequacy of scientific evidence as discussed, most breech presentations are delivered by cesarean section. For example, in 1997, 85 percent of all malpresentations, including breeches, were delivered by cesarean ([Ventura and associates, 1999](#)). Still, as shown in [Table 22-3](#), the number is variable throughout teaching centers. At Parkland Hospital and at the University of Alabama at Birmingham, the route of delivery is individualized depending upon clinical circumstances and with approval of the attending faculty.

Women with selected frank breech presentations estimated to be about 2000 g or more, but less than about 3500 g, are frequently offered planned vaginal delivery. Despite this, more than 80 percent of singleton breeches are delivered by cesarean. Thus, individualized cesarean or vaginal delivery are both reasonable and acceptable in current obstetrical practice.

RECOMMENDATIONS FOR DELIVERY

A diligent search for any other complication, actual or anticipated, that might justify cesarean delivery has become a feature of most philosophies for managing breech delivery. Cesarean delivery is commonly but not exclusively used in the following circumstances:

1. A large fetus.
 2. Any degree of contraction or unfavorable shape of the pelvis.
 3. A hyperextended head.
 4. No labor, with maternal or fetal indications for delivery such as pregnancy-induced hypertension or ruptured membranes for 12 hours or more.
 5. Uterine dysfunction.
 6. Footling presentation.
 7. An apparently healthy but preterm fetus of 25 to 26 weeks or more, with the mother in either active labor or in need of delivery.
 8. Severe fetal growth restriction.
 9. Previous perinatal death or children suffering from birth trauma.
- ∴ A request for sterilization.

TECHNIQUES FOR BREECH DELIVERY

LABOR AND SPONTANEOUS DELIVERY

There are fundamental differences between labor and delivery in cephalic and breech presentations. With a cephalic presentation, once the head is delivered, typically the rest of the body follows without difficulty. With a breech, however, successively larger and very much less compressible parts of the fetus are born.

Spontaneous complete expulsion of the fetus who presents as a breech, as described following, is seldom accomplished successfully. As a rule, either cesarean delivery or vaginal delivery requires skilled participation by the obstetrician for a favorable outcome.

Engagement and descent of the breech in response to labor usually takes place with the bitrochanteric diameter of the breech in one of the oblique diameters of the pelvis. The anterior hip usually descends more rapidly than the posterior hip, and when the resistance of the pelvic floor is met, internal rotation usually follows, bringing the anterior hip toward the pubic arch and allowing the bitrochanteric diameter to occupy the anteroposterior diameter of the pelvic outlet. Rotation usually takes place through an arc of 45 degrees. If the posterior extremity is prolapsed, however, it always rotates to the symphysis pubis, ordinarily through an arc of 135 degrees, but occasionally in the opposite direction past the sacrum and the opposite half of the pelvis through an arc of 225 degrees.

After rotation, descent continues until the perineum is distended by the advancing breech, while the anterior hip appears at the vulva. By lateral flexion of the body, the posterior hip then is forced over the anterior margin of the perineum, which retracts over the buttocks, thus allowing the infant to straighten out when the anterior hip is born. The legs and feet follow the breech and may be born spontaneously or with aid.

After the birth of the breech, there is slight external rotation, with the back turning anteriorly as the shoulders are brought into relation with one of the oblique diameters of the pelvis. The shoulders then descend rapidly and undergo internal rotation, with the bisacromial diameter occupying the anteroposterior diameter of the inferior strait. Immediately following the shoulders, the head, which is normally sharply flexed upon the thorax, enters the pelvis in one of the oblique diameters and then rotates in such a manner as to bring the posterior portion of the neck under the symphysis pubis. The head is then born in flexion.

The breech may engage in the transverse diameter of the pelvis, with the sacrum directed anteriorly or posteriorly. The mechanism of labor in the transverse position differs only in that internal rotation occurs through an arc of 90 degrees.

Infrequently, rotation occurs in such a manner that the back of the infant is directed toward the vertebral column instead of toward the abdomen of the mother. Such rotation should be prevented if possible. Although the head may be delivered by allowing the chin and face to pass beneath the symphysis, the slightest traction on the body may cause extension of the head, which increases the diameter of the head that must pass through the pelvis.

METHODS OF VAGINAL DELIVERY

There are three general methods of breech delivery through the vagina:

- **Spontaneous breech delivery.** The infant is expelled entirely spontaneously without any traction or manipulation other than support of the infant.
- **Partial breech extraction.** The infant is delivered spontaneously as far as the umbilicus, but the remainder of the body is extracted/delivered with operator traction and assisted maneuvers with or without maternal expulsive efforts.
- **Total breech extraction.** The entire body of the infant is extracted by the obstetrician.

Because the technique of breech extraction differs in complete and incomplete breeches and frank breeches, it is necessary to consider these conditions in two separate sections later in the chapter. The varieties of breech presentation are illustrated in [Chapter 12](#) (see [Figs. 12-2](#), [12-3](#), and [12-4](#)).

MANAGEMENT OF LABOR

With a breech presentation, both mother and fetus are at considerably increased risk compared with a woman with a cephalic presentation ([Kunzel, 1994](#)). A rapid assessment should be made to establish the status of the fetal membranes, labor, and condition of the fetus. Close surveillance of fetal heart rate and uterine contractions should begin. An immediate recruitment of the necessary nursing and medical personnel to accomplish a vaginal or abdominal delivery should also be done. Included are nursery and anesthesia personnel.

An intravenous infusion through a venous catheter is begun as soon as the woman arrives in the labor suite. Possible emergency induction of anesthesia, or hemorrhage from lacerations or from uterine atony, are but two of many reasons that may require immediate intravenous access that can be used to administer medications or fluids, including blood.

STAGE OF LABOR. Assessment of cervical dilatation and effacement and the station of the presenting part are essential in planning the route of delivery. If labor is too far advanced, there may not be sufficient time to obtain pelvimetry. This alone should not force the decision for cesarean delivery. [Biswas and Johnstone \(1993\)](#) found that among 267 term breech presentations, fewer cesarean deliveries were done without adversely affecting neonatal outcome when x-ray pelvimetry was not used to select the mode of delivery. Satisfactory progress in labor was the best indicator of pelvic adequacy. [Nwosu and colleagues \(1993\)](#) reported similar findings.

FETAL CONDITION. The presence or absence of gross fetal abnormalities, such as hydrocephaly or anencephaly, can be rapidly ascertained with the use of sonography or x-ray. Such efforts will help to ensure that a cesarean delivery is not done under emergency conditions for an anomalous infant with no chance of survival. If vaginal delivery is planned, the fetal head should not be extended ([Fig. 22-3](#)). It is possible to ascertain head flexion and to exclude extension from sonography ([Rojansky and co-workers, 1994](#)). Most often, digital radiographs using computed tomographic pelvimetry will be adequate to document flexion or absence of extension of the fetal head ([Berger and associates, 1994](#); [Christian and colleagues, 1990](#)). If not, a plain film of the abdomen may be necessary.

FETAL MONITORING. Guidelines for monitoring the high-risk fetus are applied as discussed in [Chapter 13 \(p. 313\)](#). Thus, the fetal heart rate is recorded at least every 15 minutes. Most authorities prefer continuous electronic monitoring of fetal heart rate and uterine contractions. The FIGO Committee on Perinatal Health has endorsed this ([Kunzel, 1994](#)). When membranes are ruptured, the risk of umbilical cord prolapse is appreciably increased. Therefore, a vaginal examination should be done following rupture of the membranes to check for cord prolapse. Special attention should be directed to the fetal heart rate for the first 5 to 10 minutes following membrane rupture, to ensure that there has not been an occult cord prolapse.

RECRUITMENT OF NURSING AND MEDICAL PERSONNEL. Additional help is required for managing labor and delivery of a breech. For labor, one-on-one nursing is ideal because of the risk of cord prolapse or occlusion, and all physicians must be readily available should there be an emergency.

ROUTE OF DELIVERY. Discussions of, and planning for, the route of delivery may have taken place before admission to labor and delivery. If not, they are accomplished as soon as possible after admission. The choice of abdominal or vaginal delivery is based upon the type of breech, flexion of the head, fetal size, quality of uterine contractions, and size of the maternal pelvis. The indications and contraindications for vaginal delivery of a breech have been discussed. The woman should be informed about all relevant facts and uncertainties before the breech delivery. The obstetrician should consider, and usually abide by, the preferences of the informed parents ([Kunzel, 1994](#)).

TIMING OF DELIVERY. In general, the ability to proceed with immediate breech extraction should exist when the buttocks or feet appear at the vulva. This is important because persistent fetal bradycardia is prone to develop from cord compression with further descent through the birth canal. It is essential that the delivery team include:

1. An obstetrician skilled in the art of breech extraction.
2. An associate to assist with the delivery.
3. An anesthesiologist who can assure adequate anesthesia when needed.
4. An individual trained to resuscitate the infant, including tracheal intubation.

Delivery is easier, and in turn, morbidity and mortality are probably lower, when the breech is allowed to deliver spontaneously to the umbilicus. If a nonreassuring fetal heart rate pattern develops before this time, however, a decision must be made whether to perform manual breech extraction or cesarean delivery. For a favorable outcome with any breech delivery, at the very minimum, the birth canal must be sufficiently large to allow passage of the fetus without trauma. The cervix must be fully dilated, and if not, then a cesarean delivery nearly always is the more appropriate method of delivery when suspected fetal compromise develops.

ASSISTED DELIVERY OF FRANK BREECH

The frank breech should ideally be allowed to deliver without assistance to at least the level of the umbilicus. Unless there is considerable relaxation of the perineum, an episiotomy should be made. The episiotomy is an important adjunct to any type of breech delivery. As the breech progressively distends the perineum, the posterior hip will deliver, usually from the 6 o'clock position, and often with sufficient pressure to evoke passage of thick meconium at this point ([Fig. 22-4](#)). The anterior hip then delivers followed by external rotation to the sacrum anterior position ([Fig. 22-5](#)). The mother should be encouraged to continue to push, as the cord is now drawn well down into the birth canal and is being compressed with resultant fetal bradycardia. Continued descent of the fetus will allow easy delivery of the legs by splinting the medial thighs of the fetus with the fingers positioned parallel to the femur and exertion of pressure laterally so as to sweep the legs away from the midline ([Fig. 22-6](#)).

Following delivery of the legs, the fetal bony pelvis is grasped with both hands utilizing a cloth towel moistened with warm water. The fingers should rest on the anterior superior iliac crest and the thumbs on the sacrum, minimizing the chance of fetal abdominal soft tissue injury ([Fig. 22-7](#)). Maternal expulsive efforts are used in conjunction with continued gentle downward operator rotational traction to effect delivery of the fetus. Gentle downward traction is combined with simultaneous 180 degree rotation of the fetal pelvis from either left to right sacrum transverse or from right to left ([Figs. 22-8](#) and [22-9](#)).

The depicted rotational and downward traction maneuver will decrease the occurrence of persistent nuchal arms. The latter may impact at the pelvic inlet and behind the symphysis pubis, thus preventing further descent. Nuchal arms can persist in term, preterm, and second twin vaginal breech deliveries. They are associated with increased fetal-newborn trauma and morbidity, and maneuvers to prevent this complication are warranted. These maneuvers are frequently most easily effected with the operator at the level of the maternal pelvis and with one knee on the floor. When the scapulas are clearly visible, delivery is then completed as subsequently described for the complete or incomplete breech.

FRANK BREECH EXTRACTION

At times, extraction of a frank breech may be required and can be accomplished by moderate traction exerted by a finger in each groin and facilitated by a generous episiotomy ([Fig. 22-10](#)). If moderate traction does not effect delivery of the breech, then vaginal delivery can be accomplished only by breech decomposition. This procedure involves intrauterine manipulation to convert the frank breech into a footling breech. The procedure is accomplished more readily if the membranes have ruptured recently, and it becomes extremely difficult if considerable time has elapsed since escape of amniotic fluid. In such cases, the uterus may have become tightly contracted over the fetus, and pharmacological relaxation by general anesthesia, intravenous magnesium sulfate, or small doses of nitroglycerin, (50 to 100 ug) or a β -mimetic such as terbutaline (250 ug) may be required.

Breech decomposition is accomplished by the maneuver attributed to [Pinard \(1889\)](#). It aids in bringing the fetal feet within reach of the operator. As shown in [Figure 22-11](#), two fingers are carried up along one extremity to the knee to push it away from the midline. Spontaneous flexion usually follows, and the foot of the fetus is felt to impinge upon the back of the hand. The fetal foot then may be grasped and brought down.

COMPLETE OR INCOMPLETE BREECH EXTRACTION

During total extraction of a complete or incomplete breech, the hand is introduced through the vagina and both feet of the fetus are grasped. The ankles are held with the second finger lying between them and, with gentle traction, the feet are brought through the vulva. If difficulty is experienced in grasping both feet, first one foot should be drawn into the vagina but not through the introitus, and then the other foot is advanced in a similar fashion ([Fig. 22-12](#)). Now both feet are grasped and pulled through the vulva simultaneously.

As the legs begin to emerge through the vulva, downward gentle traction is then continued. As the legs emerge, successively higher portions are grasped, first the calves and then the thighs ([Fig. 22-13](#)). When the breech appears at the vulva, gentle traction is applied until the hips are delivered. As the buttocks emerge, the back of the infant usually rotates to the anterior. The thumbs are then placed over the sacrum and the fingers over the hips, and assisted breech delivery is effected as described previously ([Fig. 22-7](#)). As the scapulas become visible, the back of the infant tends to turn spontaneously toward the side of the mother to which it was originally directed ([Fig. 22-13](#)).

A cardinal rule in successful breech extraction is to employ steady, gentle, downward rotational traction until the lower halves of the scapulas are delivered outside the vulva, making no attempt at delivery of the shoulders and arms until one axilla becomes visible. Failure to follow this rule frequently will make an otherwise easy procedure difficult. The appearance of one axilla indicates that the time has arrived for delivery of the shoulders. It makes little difference which shoulder is delivered first, and there are two methods for delivery of the shoulders, as follows.

In the first method, with the scapulas visible, the trunk is rotated in such a way that the anterior shoulder and arm appear at the vulva and can easily be released and delivered first. In [Figure 22-14](#), the operator is shown rotating the trunk of the fetus counterclockwise to deliver the right shoulder and arm. The body of the fetus is then rotated in the reverse direction to deliver the other shoulder and arm.

In the second method, if trunk rotation is unsuccessful, the posterior shoulder must be delivered first. The feet are grasped in one hand and drawn upward over the inner thigh of the mother toward which the ventral surface of the fetus is directed. In this manner, leverage is exerted upon the posterior shoulder, which slides out over the perineal margin, usually followed by the arm and hand ([Fig. 22-15](#)). Then, by depressing the body of the fetus, the anterior shoulder emerges beneath the pubic arch, and the arm and hand usually follow spontaneously ([Fig. 22-16](#)). Thereafter, the back tends to rotate spontaneously in the direction of the symphysis. If upward rotation fails to occur, it is effected by manual rotation of the body. Delivery of the head may then be accomplished.

Unfortunately, the process is not always so simple, and it is sometimes necessary first to free and deliver the arms. These maneuvers are much less frequently required today, presumably because of adherence to the principle of continuing rotational traction to prevent persistent nuchal arms and without attention to the shoulders until an axilla becomes visible. Attempts to free the arms immediately after the costal margins emerge should be avoided.

There is more space available in the posterior and lateral segments of the normal pelvis than elsewhere. Therefore, in difficult cases, the posterior arm should be freed first. Because the corresponding axilla already is visible, upward traction upon the feet is continued, and two fingers of the other hand are passed along the humerus until the elbow is reached ([Fig. 22-15](#), inset). The fingers are placed parallel to the humerus and used to splint the arm, which is swept downward and delivered through the vulva. To deliver the anterior arm, depression of the body of the infant is sometimes all that is required to allow the anterior arm to slip out spontaneously. In other instances, the anterior arm can be swept down over the thorax using two fingers as a splint. Occasionally, however, the body must be held with the thumbs over the scapulas and rotated to bring the undelivered shoulder near the closest sacrosciatic notch. The legs then are carried upward to bring the ventral surface of the infant to the opposite inner thigh of the mother. Subsequently, the arm can be delivered as described previously. If the arms have become extended over the head, their delivery, although more difficult, can usually be accomplished by the maneuvers just described. In so doing, particular care must be taken to carry the fingers up to the elbow and to use the fingers as a splint to prevent fracture of the humerus.

As discussed earlier, one or both fetal arms occasionally is found around the back of the neck (nuchal arm) and impacted at the pelvic inlet. In this situation, delivery is more difficult. If the nuchal arm cannot be freed in the manner described, extraction may be facilitated, especially with a single nuchal arm, by rotating the fetus through half a circle in such a direction that the friction exerted by the birth canal will serve to draw the elbow toward the face. Should rotation of the fetus fail to free the nuchal arm(s), it may be necessary to push the fetus upward in an attempt to release it. If the rotation is still unsuccessful, the nuchal arm is often extracted by hooking a finger(s) over it and forcing the arm over the shoulder, and down the ventral surface for delivery of the arm. In this event, fracture of the humerus or clavicle is very common.

The fetal head may then be extracted with forceps or by one of the following maneuvers.

MAURICEAU MANEUVER. This was first practiced by [Mauriceau in 1721](#), but for some reason fell into disfavor. Much later [Smellie \(1876\)](#) described a similar procedure. [Veit \(1907\)](#) redirected attention to the Mauriceau maneuver, and in Germany the procedure frequently is named after Veit. The most accurate designation, however, is the Mauriceau-Smellie-Veit maneuver.

The index and middle finger of one hand are applied over the maxilla, to flex the head, while the fetal body rests upon the palm of the hand and forearm ([Fig. 22-17](#)). The forearm is straddled by the fetal legs. Two fingers of the other hand then are hooked over the fetal neck, and grasping the shoulders, downward traction is applied until the suboccipital region appears under the symphysis. Gentle suprapubic pressure simultaneously applied by an assistant helps keep the head flexed. The body of the fetus is then elevated toward the maternal abdomen, and the mouth, nose, brow, and eventually the occiput emerge successively over the perineum.

It is emphasized that with this maneuver the operator uses both hands simultaneously and in tandem to exert continuous downward gentle traction bilaterally on the fetal neck and on the maxilla. At the same time, appropriate suprapubic pressure applied by an assistant is helpful in delivery of the head ([Fig. 22-17](#)).

PRAGUE MANEUVER. Rarely, the back of the fetus fails to rotate to the anterior. When this occurs, rotation of the back to the anterior may be achieved by using stronger traction on the fetal legs or bony pelvis. If the back still remains posteriorly, extraction may be accomplished using the Mauriceau maneuver and delivering the fetus back down. If this is impossible, the fetus still may be delivered using the modified Prague maneuver. This maneuver was recommended by [Kiwisch \(1846\)](#), who practiced in Prague. It had been described in London as early as [1754 by Pugh](#). The modified maneuver as practiced today consists of two fingers of one hand grasping the shoulders of the back-down fetus, from below, while the other hand draws the feet up over the maternal abdomen ([Fig. 22-18](#)).

BRACHT MANEUVER. With this maneuver, the breech is allowed to deliver spontaneously to the umbilicus. The fetal body then is held, but not pressed, against the maternal symphysis. This force is meant to be the equivalent of gravity ([Bracht, 1936](#)). The suspension of the fetus in this position, coupled with the effects of uterine contractions and moderate suprapubic pressure by an assistant, often results in a spontaneous delivery. Despite its popularity in Europe, there is no proof that its use is associated with better long-term neurological outcomes ([Krause and associates, 1991](#)).

FORCEPS TO AFTERCOMING HEAD

Specialized forceps can be used to deliver the aftercoming head of the breech-presenting fetus. **Piper forceps**, shown in [Figure 22-19](#), or divergent Laufe forceps may be applied electively or when the Mauriceau maneuver cannot be accomplished easily. The blades of the forceps should not be applied to the aftercoming head until it has been brought into the pelvis by gentle traction, combined with suprapubic pressure, and is engaged. Suspension of the body of the fetus in a towel helps keep the arms out of the way.

ENTRAPMENT OF THE AFTERCOMING HEAD

Occasionally, especially with small preterm fetuses, the incompletely dilated cervix will not allow delivery of the aftercoming head. With gentle traction on the fetal body, the cervix, at times, may be manually slipped over the occiput, or the Bracht maneuver may be tried. If these actions are not rapidly successful, *Duhrssen incisions* can be made in the cervix.

Some advocate the use of intravenous nitroglycerin in doses of 50 to 100 ug to effect rapid uterine relaxation. Its use has been reported to be of benefit for intrapartum external version of a second twin, replacement of uterine inversion, and removal of a retained placenta ([Abouleish and Corn, 1994](#); [Altabef, 1992](#); [DeSimone, 1990](#); [Peng, 1989](#), and their colleagues). Its use for a "trapped" aftercoming fetal head with breech delivery has been suggested by [Mayer and Weeks \(1992\)](#) and [Rolbin and associates \(1991\)](#). Nitroglycerin, however, directly relaxes smooth muscle which constitutes only 15 percent of the cervix ([Mercier and Benhamou, 1995](#)). Its efficacy for fetal head entrapment has not been substantiated.

Replacement of the fetus higher into the vagina and uterus, followed by cesarean delivery, can be used successfully to rescue an entrapped breech that cannot be delivered vaginally. [Iffy and colleagues \(1986\)](#) described **abdominal rescue** by cesarean delivery for a 2050-g first twin whose fully deflexed head was entrapped after the arms had been delivered. The infant, delivered by emergency classical cesarean, had a small subarachnoid hemorrhage but remained neurologically normal. A similar maneuver to perform cesarean delivery for intractable shoulder dystocia is called the Zavanelli maneuver, but [Sandberg \(1999\)](#) found 11 published cases describing its use with a trapped aftercoming head.

ANALGESIA AND ANESTHESIA FOR LABOR AND DELIVERY

Continuous epidural analgesia ([Chap. 15](#)) has been advocated by some as ideal for women in labor with a breech presentation ([Kunzel, 1994](#); [Mokriski, 1994](#)). [Confino and colleagues \(1985\)](#) reviewed the outcomes of 371 nonanomalous singleton breech fetuses delivered vaginally. About 25 percent of these women had been given continuous epidural analgesia, and oxytocin augmentation was necessary to effect delivery in half of them. Although first-stage labor was not longer than in a control group not given epidural analgesia, the second stage was prolonged significantly in women whose fetuses weighed more than 2500 g. It was doubled if the fetus weighed more than 3500 g. [Chadha and associates \(1992\)](#) observed similar outcomes but also reported an increased incidence of cesarean delivery.

These potential disadvantages must be weighed against the advantage of better pelvic relaxation should extensive manipulation be required to effect delivery. Analgesia for episiotomy and intravaginal manipulations that are needed for breech extraction can usually be accomplished with pudendal block and local infiltration of the perineum. Nitrous oxide plus oxygen inhalation provides further relief from pain. If general anesthesia is required, it can be induced quickly with thiopental plus a muscle relaxant and maintained with nitrous oxide. Anesthesia for decomposition and extraction must provide sufficient relaxation to allow intrauterine manipulations. Although successful decomposition has been accomplished using epidural or spinal analgesia, increased uterine tone may render the operation more difficult. Under such conditions, one of the halogenated anesthetic agents may be required to relax the uterus as well as provide analgesia.

MORBIDITY AND MORTALITY

MATERNAL INJURIES. With complicated breech deliveries, there are increased maternal risks. Manual manipulations within the birth canal increase the risk of maternal infection. Intrauterine maneuvers, especially with a thinned-out lower uterine segment, or delivery of the aftercoming head through an incompletely dilated cervix, may cause rupture of the uterus, lacerations of the cervix, or both. Such manipulations also may lead to extensions of the episiotomy and deep perineal tears. Anesthesia sufficient to induce appreciable uterine relaxation may cause uterine atony and, in turn, postpartum hemorrhage. Even so, the prognosis in general for the mother whose fetus is delivered by breech extraction probably is somewhat better than with cesarean delivery.

FETAL INJURIES. For the fetus, the outlook is less favorable, and it is more serious the higher the presenting part is situated at the beginning of the breech extraction. In addition to the possibility of trauma, with incomplete breech presentations, cord prolapse is also much more common than with vertex presentations. Despite this, adverse outcomes for properly selected and managed vaginally delivered breeches are uncommon. [Croughan-Minihane and associates \(1990\)](#) reported that vaginally born infants were not at increased risk for adverse outcomes related to head trauma, neonatal seizures, cerebral palsy, mental retardation, or spasticity. Similarly, [Roumen and Luyben \(1991\)](#) described 247 consecutive women with term singleton breech fetuses, 95 percent of whom were allowed to labor. Excluded were cases of overt disproportion after previous cesarean delivery, abnormal presentation in combination with a congenital uterine anomaly, fetal distress, or a fetal biparietal diameter greater than 100 mm. Normal progression of labor during the first stage without secondary arrest or signs of fetal distress was used as the only factor to determine the feasibility of vaginal delivery. In this study, 196 of 234 (84 percent) delivered vaginally. One fetus died during breech extraction as a result of cephalopelvic disproportion.

[Christian and colleagues \(1990\)](#) reported no differences in Apgar scores, hospital stay, neonatal complications, and cord blood gases between vaginally delivered frank breeches and those delivered by cesarean section. All vaginal deliveries were in women with an adequate pelvis documented by CT pelvimetry, a frank breech presentation, and an estimated weight between 2000 and 4000 g. [Christian and Brady \(1991\)](#), but not [Hommel and associates \(1989\)](#), reported that breeches delivered vaginally had a lower mean cord blood pH and higher mean PCO₂ compared with cephalic-presenting infants delivered vaginally. In a long-term Scottish follow-up study, [Danielian and colleagues \(1996\)](#) found a similar incidence of neurological handicaps in infants born vaginally compared with cesarean delivery.

In a meta-analysis of 24 studies examining mode of planned delivery and perinatal outcome, [Cheng and Hannah \(1993\)](#) found a three- to fourfold significantly higher perinatal mortality rate and neonatal morbidity due to trauma in planned vaginally delivered infants, compared with those undergoing planned cesarean section. [Gifford and associates \(1995b\)](#) performed a similar analysis of nine studies. They concluded that the risk of any fetal injury, or any injury and death was tenfold increased after a trial of labor. [Albrechtsen and colleagues \(1998\)](#) [Bartlett and colleagues \(2000\)](#) studied early motor development of breech and control cephalic presenting infants. They concluded that the mode of delivery did not explain the excess neuromotor impairment detected in breech infants.

Fracture of the humerus and clavicle cannot always be avoided, and fracture of the femur may be sustained during difficult breech extractions ([Fig. 22-20](#)). Such fractures are associated with both vaginal and cesarean deliveries ([Awwad and colleagues, 1993](#); [Vasa and Kim, 1990](#)). Neonatal perineal tears have been reported as a complication of spinal electrode use ([Freud and associates, 1993](#)). Hematomas of the sternocleidomastoid muscles occasionally develop after delivery, though they usually disappear spontaneously. More serious problems, however, may follow separation of the epiphyses of the scapula, humerus, or femur. There is no evidence that the incidence of congenital hip dislocations is increased by vaginal delivery of a breech ([Clausen and Nielsen, 1988](#)). [Bartlett and colleagues \(2000\)](#) studied early motor development of breech and control cephalic presenting infants. They concluded that the mode of delivery did not explain the excess neuromotor impairment detected in breech infants.

Paralysis of the arm may follow pressure upon the brachial plexus by the fingers in exerting traction, but more frequently it is caused by overstretching the neck while

freeing the arms. [Geutjens and colleagues \(1996\)](#) observed a different pattern of brachial plexus injury in 36 newborns following vaginal breech delivery. In 80 percent, there was avulsion of the upper cervical spine roots. This injury cannot be treated by microsurgical nerve grafting and carries a worse prognosis for shoulder function. When the fetus is extracted forcibly through a contracted pelvis, spoon-shaped depressions or actual fractures of the skull may result. Occasionally, even the fetal neck may be broken when great force is employed. Testicular injury, in some cases severe enough to result in anorchia, may occur following vaginal breech delivery ([Tiwary, 1989](#)). Finally, vaginal breech delivery has also been reported to be associated with a sevenfold increased incidence of sudden infant death syndrome ([Buck and co-workers, 1991](#)).

Despite the potential fetal hazards of vaginal breech delivery, maternal morbidity associated with cesarean section must also be considered when planning delivery of the term frank or complete breech fetus ([Gifford and colleagues, 1995a](#)). In appropriately selected and managed cases, and with informed consent, both planned cesarean section and vaginal breech delivery remain appropriate and reasonable management options.

VERSION

Version is a procedure in which the presentation of the fetus is altered artificially, either substituting one pole of a longitudinal presentation for the other, or converting an oblique or transverse lie into a longitudinal presentation. According to whether the head or breech is made the presenting part, the operation is designated cephalic or podalic version, respectively. In *external version*, the manipulations are performed exclusively through the abdominal wall; whereas in *internal version*, the entire hand is introduced into the uterine cavity.

EXTERNAL CEPHALIC VERSION

The problems that have persisted until recently have not been whether external cephalic version could be accomplished and by what technique, but rather, whether the procedure was necessary, safe, and cost effective. With respect to necessity, it appears from the results of five randomized controlled studies totaling only 278 women, that if version is not performed, approximately 80 percent of noncephalic presentations diagnosed in the late third trimester will persist at delivery ([Table 22-4](#)). This is compared with only 30 percent of those who underwent a successful version. In their review, [Laros and colleagues \(1995\)](#) reported that external version was successful in 50 percent, however, even when the successful cesarean delivery rate was 30 percent.

External version was well known to our obstetrical predecessors, and it has received renewed interest in the past two decades coincidental with the availability of ultrasound, electronic fetal monitoring, and effective tocolytic agents. It is likely that these developments have improved the maternal and fetal safety of external version. [Van Dorsten and co-workers \(1981\)](#) rekindled interest in this procedure in the United States. In their first study, almost 70 percent of versions were successful, resulting in a 30 percent cesarean delivery rate compared with 75 percent when version was not attempted. The [American College of Obstetricians and Gynecologists \(2000\)](#) reviewed 20 studies and found a range from 35 to 85 percent success with an average of about 60.

[Zhang and co-authors \(1993\)](#) reviewed 25 selected reports on external cephalic version published between 1980 and 1991. Shown in [Figure 22-21](#), and based on those data, are hypothetical results if all women with otherwise normal singleton breech presentations underwent attempted version at 35 to 37 weeks. Several points are noteworthy:

1. External cephalic version is successful in 65 percent of cases.
2. If version succeeds, almost all fetuses stay cephalic and vice versa.
3. Ultimately, and despite version attempts, 37 percent of women identified to have a late pregnancy breech will require cesarean delivery.

In a prospective study, [Lau and associates \(1997\)](#) observed that women who had a successful external version for breech presentation at term had an increased risk of a cesarean birth based on intrapartum events.

[Zhang and co-workers \(1993\)](#) estimated that universal application of external cephalic version could reduce the overall cesarean rate by no more than 2 percent. [Morrison and co-workers \(1986\)](#) attempted external cephalic version in 2.3 percent of pregnancies cared for at the University of Mississippi Medical Center between 1982 and 1984. Compared with the preceding 3 years at their institution, they decreased breech deliveries from 1.8 to 1.1 percent and cesarean deliveries performed for breeches from 2.8 to 1.6 percent. [Ben-Arie and colleagues \(1995\)](#) reported that introduction of an external version protocol at their institution decreased breech presentation at term from 3.9 to 2.4 percent. This was associated with a decrease of 5.5 percent in the cesarean section rate. Based on a decision analysis, [Gifford and associates \(1995a\)](#) concluded that routine use of external cephalic version would reduce cost and cesarean births. [Adams and associates \(2000\)](#) confirmed the independent cost benefit of attempting external cephalic version based on Medicaid billing. Conversely, [Curet and co-workers \(2000\)](#) reported that routine attempts at cephalic version resulted in *increased* costs per patient.

INDICATIONS. If a breech or shoulder presentation (transverse lie) is diagnosed in the last weeks of pregnancy, its conversion to a vertex may be attempted by external maneuvers, provided there is no marked disproportion between the size of the fetus and the pelvis, and provided there is no placenta previa. [Chmait and colleagues \(2000\)](#) reported good success in women who had undergone prior cesarean delivery.

FACTORS ASSOCIATED WITH SUCCESSFUL VERSION. The most consistent factor associated with the success of external cephalic version is parity ([Zhang and colleagues, 1993](#)). [Hellstrom and co-workers \(1990\)](#) identified only 3 of 16 variables to be associated with successful external version. The most important factor was parity, followed by fetal presentation, and then the amount of amniotic fluid. Version was more successful in a parous woman who has an unengaged fetus surrounded by a normal amount of amniotic fluid. [Lau and associates \(1997\)](#) also identified 3 of 19 studied variables to predict *failed* version. These were engaged presenting part, difficulty in palpating the fetal head, and a uterus tense to palpation. With three of these present, there were no successes. With two, it was less than 20 percent. With none of these, success was 94 percent.

Gestational age is also important; the earlier external version is performed, the more likely it will be successful. Conversely, the more remote from term external version is performed, the higher the rate of spontaneous reversion ([Westgren and colleagues, 1985b](#)). Other reported, albeit controversial, determinants of unsuccessful version include diminished amniotic fluid volume, excessive maternal weight, anterior placental location, cervical dilatation, descent of the breech into the pelvis, and anterior or posterior positioning of the fetal spine ([Newman and colleagues, 1993](#); [Zhang and co-authors, 1993](#)). Remarkably, [Johnson and Elliott \(1995\)](#) used fetal acoustic stimulation to startle breech fetuses to shift their spines laterally for successful [Benifla and associates \(1994\)](#) employed transabdominal amniocentesis to facilitate successful external cephalic version in six women who had had previous unsuccessful version. According to [Fortunato and colleagues \(1988\)](#), external version using tocolysis is more likely to be successful if:

1. The presenting part has not descended into the pelvis.
2. There is a normal amount of amniotic fluid.
3. The fetal back is not positioned posteriorly.
4. The woman is not obese.

TRANSVERSE LIE. Women with a transverse lie are usually excluded from analyses of breech version because the overall success rate approaches 90 percent ([Newman and colleagues, 1993](#)).

TECHNIQUE. External cephalic version should be carried out in an area that has ready access to a facility equipped to perform emergency cesarean deliveries ([American College of Obstetricians and Gynecologists, 2000](#)). The labor and delivery unit is ideal for this, but [Kornman and colleagues \(1995\)](#) have performed selected versions in an office setting. Real-time ultrasonic examination is performed to confirm nonvertex term presentation, adequacy of amniotic fluid volume (vertical pocket of 2 cm or greater), and estimated fetal weight; to rule out obvious fetal anomalies; and to identify placental location. External monitoring is performed to assess fetal heart rate reactivity. A "forward roll" of the fetus is usually attempted first and the "back flip" technique is then tried if unsuccessful. Each hand grasps one of the fetal poles as shown in [Figure 22-22](#). The fetal buttocks are elevated from the maternal pelvis, and displaced laterally. The buttocks are then gently guided toward the fundus, while the head is directed toward the pelvis. Version attempts are discontinued for excessive discomfort, persistently abnormal fetal heart rate, or after multiple failed attempts. D-immune globulin is given to D-negative, unsensitized women. The nonstress test is repeated after version until a normal test result is obtained. This process takes about half a day and may cost as much as \$1700 ([Newman and colleagues, 1993](#)).

Most authorities recommend uterine relaxation with a tocolytic agent, usually terbutaline 0.25 mg given subcutaneously. Some investigators have shown a benefit to tocolysis, while others have not. For example, [Robertson and associates \(1987\)](#) reported that ritodrine tocolysis did not improve their success. Similarly, [Tan and colleagues \(1989\)](#), in a prospective randomized trial, found that salbutamol did not improve their success rate. Conversely, in a randomized clinical trial, [Fernandez and co-workers \(1996\)](#) reported that terbutaline given subcutaneously significantly increased the success rate from 27 to 52 percent. [Marquette and colleagues \(1996\)](#) reported similar results with ritodrine infusion. [Andarsio and Feng \(2000\)](#) reported preliminary data in 35 women randomized to tocolysis with either nitroglycerin or terbutaline. With either agent, the success rate was about 50 percent. [Yanny and associates \(2000\)](#) found no advantages to glyceryl trinitrate over placebo.

Abdominal relaxation may also be helpful. [Schorr and co-workers \(1997\)](#), in a prospective randomized trial, found that epidural analgesia given with terbutaline tocolysis improved success (60 percent) with version, compared with the nonepidural group (30 percent). [Mancuso and collaborators \(2000\)](#) randomized 108 women and reported 59 versus 33 percent with epidural versus control groups. [Neiger and associates \(1998\)](#) used epidural analgesia with 56 percent success for failed versions. Conversely, [Dugoff and colleagues \(1999\)](#) randomized 102 women to terbutaline plus spinal analgesia versus terbutaline alone. The success rates were similar, 44 and 42 percent. According to the [American College of Obstetricians and Gynecologists \(2000\)](#), there is not enough consistent evidence to recommend conduction analgesia.

Lastly, to further emphasize our lack of understanding regarding the persistence of the breech presentation near term, several effective but unconventional interventions have been reported. [Cardini and Weixen \(1998\)](#) performed a randomized clinical trial to evaluate *moxibustion*—burning herbs to simulate acupuncture point BL67—to promote spontaneous breech version, possibly by increasing fetal activity. The intervention group experienced significantly increased fetal movements and cephalic presentations at birth. [Mehl \(1994\)](#) in a prospective matched series of 100 women with a breech presentation at 37 to 40 weeks, evaluated hypnosis with suggestions for relaxation. Significantly more fetuses in the intervention group (81 percent) converted to vertex than in the control group (48 percent).

COMPLICATIONS. Risks of external version include placental abruption, uterine rupture, amniotic fluid embolism, fetomaternal hemorrhage, isoimmunization, preterm labor, fetal distress, and fetal demise. According to [Zhang and colleagues \(1993\)](#), there have been no reported fetal deaths in the United States resulting directly from external version since 1980. Reported nonfatal complications include fetal heart rate decelerations in almost 40 percent of fetuses ([Phelan and co-workers, 1984](#)) and fetomaternal hemorrhage in 4 percent ([Stine and colleagues, 1985](#)). [Petrikovsky and colleagues \(1987\)](#) reported fetal brachial plexus injury after a successful external version. [Stine and co-workers \(1985\)](#) reported a death due to amniotic fluid embolus.

Because of the fear of uterine rupture, women who had undergone prior cesarean delivery were, in the past, excluded from most external cephalic version protocols. [Flamm and co-workers \(1991\)](#), however, reported no serious maternal or fetal complications associated with such attempts in 56 women with previous low transverse uterine incisions. They were successful in 82 percent. [De Meeus and colleagues \(1998\)](#) reported similar experiences in 38 women.

INTERNAL PODALIC VERSION

This maneuver consists of turning the fetus by inserting a hand into the uterine cavity, seizing one or both feet, and drawing them through the cervix while pushing transabdominally the upper portion of the fetal body in the opposite direction. The operation is followed by breech extraction. There are very few, if any, indications for internal podalic version other than for delivery of a second twin, which is discussed in detail in [Chapter 30 \(p. 800\)](#).

23. Cesarean Delivery and Postpartum Hysterectomy

Cesarean delivery is defined as the birth of a fetus through incisions in the abdominal wall (laparotomy) and the uterine wall (hysterotomy). This definition does not include removal of the fetus from the abdominal cavity in the case of rupture of the uterus or in the case of an abdominal pregnancy.

CESAREAN DELIVERY

FREQUENCY

Currently, 1 out of every 10 American women delivered each year in the United States has had a previous cesarean delivery ([Ventura and associates, 2000](#)). This high prevalence represents the culmination of many years of escalating cesarean deliveries in the United States. Indeed, more than 825,000 women were delivered by cesarean in 1998, and 37 percent of these women had repeat procedures.

The overall cesarean delivery rate increased progressively in the United States each year between 1965 and 1988, rising from 4.5 percent of all deliveries to almost 25 percent ([United States Public Health Service, 1991](#)). Most of this increase took place in the 1970s and early 1980s and occurred throughout the western world ([Fig. 23-1](#)). According to [Belizan and colleagues \(1999\)](#), this also occurred in Latin America. In one response to this increase, the [United States Public Health Service \(1991\)](#) set a goal of an overall 15 percent cesarean rate for the year 2000 ([Fig. 23-2](#)). An example of a unique response was the 1992 legislative mandate in Florida that stipulated dissemination of practice guidelines for obstetrical physicians ([Studnicki and colleagues, 1997](#)).

Between 1989 and 1996, and shown in [FIGURE 23-3](#), the rate of cesarean delivery decreased in the United States. This was in large part due to increased vaginal birth after prior cesarean (VBAC) and to a lesser extent a small decrease in the primary cesarean rate ([Table 23-1](#)). As also shown in [FIGURE 23-2](#) and [Table 23-1](#), however, the rate of cesarean delivery has increased in the most recent years for which national data are available. Undoubtedly, one explanation for this change in direction of the national cesarean rate is increased concern about the fetal safety of labor in women with prior cesarean births ([Sachs and colleagues, 1999](#)).

It is now evident that the United States Public Health Service cesarean rate goal for the year 2000 was not achieved. The [American College of Obstetricians and Gynecologists Task Force on Cesarean Delivery Rates \(2000\)](#) has recommended two benchmarks for the United States for the year 2010:

1. A 15.5 percent cesarean rate in nulliparous women at 37 weeks or greater with singleton, cephalic presentations.
2. A 37 percent VBAC rate in women at 37 weeks or more with singleton cephalic presentations and one prior low-transverse cesarean delivery.

Reasons for quadrupling of the cesarean rate between 1965 and 1988 are not completely understood, but some explanations include the following.

1. There is **reduced parity**, and almost half of pregnant women are nulliparas. Therefore an increased number of cesarean births might be expected for conditions that are more common in nulliparous women.
2. Older women are having children. As shown in [FIGURE 23-4](#) the frequency of cesarean deliveries increases with advancing age (see also [Chap. 9, p. 208](#)). In the past two decades, the rate of nulliparous births more than doubled for women aged 30 to 39 and increased by 50 percent in women 40 to 44 years old ([Adashek and associates, 1993](#); [Peipert and Bracken, 1993](#)).
3. Since the early 1970s, **electronic fetal monitoring** has been used extensively. There is little question that this technique is associated with an increased cesarean rate compared with intermittent fetal heart rate auscultation. Although cesarean delivery performed primarily for "fetal distress" comprises only a minority of all such procedures, in many more cases concern for an abnormal fetal heart rate tracing prompts operative delivery with the listed indication being some form of labor arrest.
4. By 1990, 83 percent of all **breech presentations** were delivered abdominally ([Notzon and associates, 1994](#)).
5. The incidence of **midpelvic vaginal deliveries** has decreased. Indeed, according to the [American College of Obstetricians and Gynecologists \(1994\)](#), operative vaginal deliveries performed at stations higher than +2 should be performed only in rare emergencies and with simultaneous preparation for cesarean delivery.
6. Concern for **malpractice litigation** has contributed significantly to the present cesarean delivery rate. Failure to perform a cesarean and thus avoid adverse neonatal neurological outcome or cerebral palsy is the dominant claim in obstetrical malpractice litigation in the United States ([Physicians Insurance Association of America, 1992](#)). This trend is especially troubling in view of the well-documented lack of association between cesarean delivery and any reduction in childhood neurological problems, including both cerebral palsy and seizures ([Lien and co-workers 1995](#); [Scheller and Nelson, 1994](#)).
7. Socioeconomic and demographic factors may play a role in cesarean birth rates. [Gould and associates \(1989\)](#) reported that the primary cesarean delivery rate in Los Angeles County was 23 percent for women from areas with a median family income of more than \$30,000 compared with 13 percent for women with a median income less than \$11,000. Similarly, [Stafford \(1990\)](#) reported significantly fewer vaginal births after a prior cesarean when comparing for-profit hospitals with university hospitals, those with private insurance with indigent patients, and low-volume to high-volume hospitals. Other factors implicated include unexplained variations in cesarean rates after risk adjustment, as shown in [FIGURE 23-5](#).

According to the [American College of Obstetricians and Gynecologists \(2000\)](#), the highest variation occurs among nulliparous women with term singleton fetuses with cephalic presentation and without other complications. High-risk patients have much lower variations in cesarean delivery rates between practitioners and hospitals.

INDICATIONS

As shown in [Table 23-2](#), repeat cesarean deliveries and those performed for labor dystocia have been the leading indications both in the United States and other western industrialized countries. Although it is not possible to catalog comprehensively all appropriate indications for cesarean delivery, over 85 percent are performed because of:

1. Prior cesareans.
2. Labor dystocia.
3. Fetal distress.
4. Breech presentation.

PRIOR CESAREAN DELIVERY. For many years, the scarred uterus was believed to contraindicate labor out of fear of uterine rupture. In 1916, [Cragin](#) made his famous and now seemingly excessive pronouncement, "Once a cesarean, always a cesarean." It must be remembered, however, that when [Cragin](#) made this statement, obstetricians routinely used a "classical" vertical incision in the uterus. Indeed, the Kerr transverse incision was not recommended until 1921. It should also be pointed out that some of [Cragin's](#) contemporaries did not agree with his statement. Writing in the fourth edition of *Williams Obstetrics*, [J. Whitridge Williams \(1917\)](#) termed the statement "an exaggeration."

The year 1978 was an important year in the history of prior cesarean delivery. [Merrill and Gibbs \(1978\)](#) reported from the University of Texas at San Antonio that subsequent vaginal delivery was safely attempted in 83 percent of their patients with prior cesarean deliveries. This report served to rekindle interest in vaginal birth after prior cesarean (VBAC) at a time when only 2 percent of American women who had previously undergone cesarean birth were attempting vaginal delivery. Use of VBAC increased very significantly in the United States such that there was a 14-fold increase to 28 percent of women with prior cesareans delivering vaginally by 1996 ([Table 23-1](#)). Dr. Roy Pitkin, editor of *Obstetrics and Gynecology*, wrote in 1991 that ". . . without question, the most remarkable change in obstetric practice over the last decade was management of the woman with prior cesarean delivery."

Beginning in 1989, there have been several reports published from around the United States and Canada that suggest that VBAC may be riskier than anticipated

([Leveno, 1999](#)). For example, [Scott \(1991\)](#) suggested an "alternative viewpoint on mandatory trial of labor" based upon experiences with uterine rupture in Utah. He described 12 women who experienced uterine rupture during a trial of labor. Two women required hysterectomy, there were three perinatal deaths, and two infants suffered significant long-term neurological impairment. [Porter and colleagues \(1998\)](#) subsequently reported that there were 26 uterine ruptures in Salt Lake City between 1990 and 1996 and that 23 percent of the infants were dead or damaged as a result of intrapartum asphyxia.

Reports such as these raised serious concern about the safety of VBAC and have contributed to heightened controversy ([Flamm, 1997](#)). Indeed, the American College of Obstetricians and Gynecologists issued an updated Practice Bulletin in 1998 and 1999 urging a more cautious approach to attempting a trial of labor. In part, it reads: "Because uterine rupture may be catastrophic, VBAC should be attempted in institutions equipped to respond to emergencies with physicians immediately available to provide emergency care."

The [American College of Obstetricians and Gynecologists \(1999\)](#) observed that "It has become apparent that VBAC is associated with a small but significant risk of uterine rupture with poor outcomes for both mother and infant. . . . These developments, which have led to a more circumspect approach to trial of labor by even the most ardent supporters of VBAC, illustrate the need to reevaluate VBAC recommendations." In this section we will emphasize current VBAC recommendations ([Table 23-3](#)) by the [American College of Obstetricians and Gynecologists \(1998, 1999\)](#), which although urging caution, also strongly supports VBAC.

Recent reports from Northwestern Hospital in Chicago support the safety of VBAC as well as its cost-effectiveness in women with one or two prior low-transverse uterine incisions (Grobman and associates, 2000; [Socol and Peaceman, 1999](#)). [Clark and colleagues \(2000\)](#) concluded differently after comparing total medical costs of a trial of labor with those of elective repeat cesarean delivery. They found that "when costs as opposed to charges are considered and the cost of long-term care for neurologically injured infants is taken into account, trial of labor after previous cesarean is unlikely to be associated with a significant cost saving for the health care system."

TYPE OF PRIOR UTERINE INCISION. Patients with transverse scars confined to the lower uterine segment have a small risk of symptomatic scar separation during a subsequent pregnancy. Shown in [Table 23-4](#) are the rates of uterine rupture reported for various types of uterine incision at cesarean delivery. Generally, the lowest rates of rupture have been reported for low-transverse incisions and the highest for incisions extending into the fundus—the classical incision. [Greene and colleagues \(1997\)](#) reported a 7 percent uterine rupture rate before labor in 62 women with classical uterine incisions. The rates of uterine rupture have been reported to be similarly high (8 percent) in women with prior cesarean deliveries and unicornuate, bicornuate, didelphic, and septate uterine malformations ([Ravasia and associates, 1999](#)).

The rate of uterine rupture in women with prior vertical incisions not extending into the fundus is controversial. Given the indications today for vertical incisions, however, few do not extend into the active segment. [Martin and co-authors \(1997\)](#) and [Shipp and colleagues \(1999\)](#) reported that women with prior low-vertical uterine incisions were not at increased risk for uterine rupture compared with women with transverse incisions. The [American College of Obstetricians and Gynecologists \(1999\)](#) concluded that although there is limited or inconsistent scientific evidence, women with a vertical incision within the lower uterine segment that does not extend into the fundus may be candidates for VBAC. In contrast, prior classical or T-shaped uterine incisions were considered contraindications to VBAC.

Women who have previously sustained a uterine rupture are at increased risk for recurrence. Those with a rupture confined to the lower segment were reported to have a 6 percent recurrence risk in subsequent labor, whereas those whose prior rupture included the upper uterus had a 32 percent recurrence risk ([Reyes-Ceja and associates, 1969](#); [Ritchie, 1971](#)).

We are of the view that ideally women with prior uterine ruptures or classical or T-shaped incisions are delivered by cesarean upon achievement of fetal pulmonary maturity prior to the onset of labor, and that such women should be warned of the hazards of unattended labor and signs of possible uterine rupture. In preparing an operative report following any vertical uterine incision, it is essential to document the exact extent of the scar in a manner that cannot be misunderstood by subsequent surgeons.

NUMBER OF PRIOR CESAREANS. The risk of uterine rupture increases with the number of previous incisions. [Miller and colleagues \(1994\)](#) in a study of 12,707 women undergoing a trial of labor after cesarean delivery, reported rates of 0.6 percent and 1.8 percent for those with one and two prior cesarean deliveries, respectively. [Caughey and colleagues \(1999\)](#) compared uterine rupture rates in 3757 women with one prior uterine scar with 134 women with two prior incisions. The type of prior uterine incision was not specified other than to mention that classical incisions were usually delivered by elective repeat cesarean. The rate of uterine rupture was significantly increased fivefold in women with two previous uterine scars compared with those with one scar (3.7 percent versus 0.8 percent). The [American College of Obstetricians and Gynecologists \(1999\)](#) has taken the position that women with two prior low-transverse cesarean deliveries may be considered for VBAC ([Table 23-3](#)).

INDICATION FOR PRIOR CESAREAN. The success rate for trial of labor depends to a small extent upon the indication for the previous cesarean. Generally, about 60 to 80 percent of trials of labor after prior cesarean birth result in vaginal delivery ([American College of Obstetricians and Gynecologists, 1999](#)). The success rates are somewhat improved when the original cesarean was performed for breech presentation or fetal distress compared with dystocia. For example, in one large series, the VBAC success rate for women whose first cesarean was for breech presentation was 91 percent and the success rate was 84 percent when fetal distress was the original indication (Wing and Paul, 1998). In contrast, the success rate dropped to 77 percent in those with dystocia as the indication for cesarean delivery.

[Impey and O'Herlihy \(1998\)](#) reported that even when the strictest criteria are used to diagnose dystocia, a VBAC rate of 68 percent can be achieved. [Hoskins and Gomez \(1997\)](#) analyzed VBAC success rates in 1917 women in relation to the cervical dilation they achieved before the original cesarean delivery was performed for dystocia. The VBAC success rate was 67 percent for those whose cesarean was done at cervical dilatation of 5 cm or less, and it was 73 percent when the cervix was 6 to 9 cm dilated. The VBAC success rate fell to 13 percent when dystocia had been diagnosed in the second stage of labor. In contrast, [Jongen and colleagues \(1998\)](#) reported an 80 percent VBAC success rate in women delivered after prior cesarean performed during the second stage.

Previous vaginal delivery, either before or after a cesarean birth, significantly improves the prognosis for successful VBAC ([Caughey and colleagues, 1998](#); [Flamm and Geiger, 1997](#)). Indeed, the most favorable prognostic factor is prior vaginal delivery.

According to the [American College of Obstetricians and Gynecologists \(1999\)](#), there has been a tendency to expand the indications for which VBAC may be appropriate. These include multiple previous cesarean deliveries, unknown uterine scar, breech presentation, twin gestation, postterm pregnancy, and suspected macrosomia. It has recommended, and we agree, that continuing study be done of the risk of adverse outcome before VBAC is routinely accepted in these circumstances.

ELECTIVE STERILIZATION. Desire for permanent sterilization in a woman with prior cesarean is not an indication for a repeat operation because the morbidity of vaginal birth and postpartum tubal ligation is considerably less than that of a repeat cesarean.

OXYTOCIN AND EPIDURAL ANALGESIA. Use of oxytocin to induce or augment labor has been implicated in uterine ruptures in women with prior cesarean deliveries. [Turner \(1997\)](#) observed that 13 of the 15 women with uterine ruptures encountered at the Coombe Hospital in Dublin between 1982 and 1991 occurred in women with prior cesareans and who had received an oxytocic agent, usually for induction of labor.

In contrast, cautious use of intravenous oxytocin to *augment* labor in women with prior cesarean at this hospital was rarely associated with uterine rupture. [Zelop and associates \(1999\)](#) analyzed uterine ruptures at Brigham and Women's Hospital after induced or augmented labor in women with one prior cesarean delivery. Uterine rupture occurred in 2.3 percent of those induced compared with 1 and 0.4 percent of those whose labor was augmented or spontaneous, respectively. They urged caution when using oxytocin for labor stimulation in women with prior cesarean delivery. The [American College of Obstetricians and Gynecologists \(1999\)](#) has recommended close patient monitoring when oxytocin or prostaglandin gel are used in women with prior cesareans and undergoing a trial of labor.

The use of epidural analgesia has been debated in the past out of fear that such a technique might mask the pain of uterine rupture. In actuality, however, less than 10 percent of women with scar separation experience pain and bleeding, and fetal heart rate decelerations are the most likely sign of such an event ([Flamm and associates, 1990](#)). Several studies attest to the safety of properly conducted epidural analgesia ([Farmer and colleagues, 1991](#); [Flamm and associates, 1994](#)).

EXAMINING THE SCAR. Although some obstetricians routinely document the integrity of the old scar by palpation following successful vaginal delivery, such uterine exploration is felt to be unnecessary by others. Currently it is not known what effect documentation of an asymptomatic scar has on subsequent reproduction or route of delivery. There is general agreement, however, that surgical correction of a scar dehiscence is necessary only if significant bleeding is encountered. Asymptomatic separations do not generally require exploratory laparotomy and repair.

ELECTIVE REPEAT CESAREAN DELIVERY. If repeat cesarean is elected, it is essential that fetal maturity be achieved prior to elective delivery. The American College of Obstetricians and Gynecologists (1991/1995) has established guidelines for timing an elective operation. According to these criteria, elective delivery may be considered at or beyond 39 weeks if at least one of the criteria outlined in [Table 23-5](#) are met. In all other instances, fetal pulmonary maturity must be documented by amniotic fluid analysis before elective repeat cesarean is undertaken ([Chap. 39, p. 1042](#)). Alternately, the onset of spontaneous labor is awaited.

LABOR DYSTOCIA. This is the most frequent indication for primary cesarean delivery in the United States. An analysis of labor dystocia as a contributing factor to the cesarean rate is difficult, however, because of the heterogeneity inherent in the condition ([Chap. 18](#)). According to [Notzon and associates \(1994\)](#), there are 15 different ICD-9 codes describing cesarean delivery for labor dystocia! Descriptive terms vary from more precise definitions promulgated by [Friedman \(1978\)](#)—secondary arrest of dilatation, arrest of descent—to more ambiguous and commonly used terms such as *cephalopelvic disproportion* and *failure to progress*. It is meaningless to classify cesarean delivery performed after 8 hours of contractions at 3 cm dilatation for "failure to progress" in the same category as a woman undergoing cesarean delivery for arrest of descent after 3 hours of second-stage pushing with uterine contractions demonstrating 300 Montevideo units.

FETAL DISTRESS. The 1970s witnessed the development of electronic fetal heart rate monitoring as well as elegant descriptions of various fetal heart rate patterns and their association with fetal oxygenation and acid-base status. Such observations raised hopes that widespread recognition of various subtle parameters of "uteroplacental insufficiency" and timely cesarean delivery would allow the obstetrician to avoid childhood neurological abnormalities including cerebral palsy. Despite relatively poor specificity in the prediction of an abnormal newborn, a lack of scientific foundation for defining "normal" and "abnormal" newborn acid-base status, and widespread disagreement among experts regarding fetal heart rate interpretation, prompt recognition of various subtle patterns was often seen as the key to diagnosing "fetal distress" and preventing neurological damage ([Chap. 14, p. 349](#)).

Subsequently, it has become well established that management based upon electronic monitoring neither reduces the risk of cerebral palsy, nor improves any measurable indices of newborn outcome compared with intermittent heart rate auscultation ([American College of Obstetricians and Gynecologists, 1992, 1995b](#); [Freeman, 1992](#); [Nelson and co-workers, 1996](#)). [Scheller and Nelson \(1994\)](#), in a report from the National Institutes of Health, and [Lien and associates \(1995\)](#) presented data specifically refuting any association between cesarean delivery and either cerebral palsy or seizures.

The [American College of Obstetricians and Gynecologists \(1992\)](#) recommends that facilities giving obstetrical care have the capability of initiating a cesarean delivery within 30 minutes of the decision for operation. This recommendation addresses facilities and does not govern clinical decision making. Misinterpretations of this guideline are common. There is no nationally recognized standard of care that codifies an acceptable time interval for performance of cesarean delivery. In most instances, operative delivery is **not** necessary within this 30-minute time frame. Indeed, [Chauhan and co-workers \(1997\)](#) reported that failure to achieve a cesarean decision-to-incision time of less than 30 minutes was not associated with a negative impact on neonatal outcome. In many cases of cesarean for indications such as labor arrest, a timely cesarean often will involve an interval considerably in excess of 30 minutes. On the other hand, when faced with an acute, catastrophic deterioration in fetal condition, cesarean may be indicated as rapidly as possible, and purposeful delays of any time period would be inappropriate.

BREECH PRESENTATION. Fetuses presenting as a breech are at increased risk of cord prolapse and head entrapment if delivered vaginally compared with those presenting cephalic. Nevertheless, prospective controlled trials are suggestive that with proper selection, certain fetuses may be delivered vaginally in breech presentations with minimal risk. The indications for cesarean versus vaginal delivery are discussed in [Chapter 22](#). Suffice it to say, concern for fetal injury, as well as the infrequency with which a breech fetus meets criteria for a trial of labor, make it unlikely that significant reduction in the cesarean birth rate will come from a more liberal approach to vaginal breech delivery.

METHODS TO DECREASE CESAREAN DELIVERY RATES

Several investigators have documented the feasibility of achieving significant reductions in institutional cesarean rates without increased perinatal morbidity or mortality ([DeMott, 1990](#); [DeMuylder, 1990](#); [Porreco, 1990](#); [Pridjian, 1991](#); [Sanchez-Ramos, 1990](#), and their co-workers). Programs aimed at reducing unnecessary cesarean deliveries are generally focused upon educational efforts and peer review, encouraging a trial of labor after prior transverse cesareans, and restricting cesareans for labor dystocia to women who meet strictly defined criteria.

MATERNAL MORTALITY AND MORBIDITY

In the United States, maternal death associated with cesarean delivery is rare. In 1980, Frigoletto and colleagues reported a series of 10,000 consecutive cesareans with no maternal deaths. In 1988, Sachs and associates observed only seven deaths as a direct result of cesarean births in over 121,000 cesareans performed between 1976 and 1984. In [1990](#), [Lilford and co-workers](#), while documenting a sevenfold relative risk for maternal mortality associated with cesarean delivery, observed that most deaths were associated with complicated nonelective procedures. Indeed, the relative risk of death for elective cesareans under epidural analgesia was actually *lower* than that associated with all vaginal births. [Yoles and Maschiach \(1998\)](#) reviewed all deliveries in Israel between 1984 and 1992, and as shown in [Table 23-6](#), the excess maternal mortality associated with cesarean delivery was attributable to emergency procedures rather than elective operations.

There is no doubt that maternal morbidity is increased dramatically in cesarean compared with vaginal delivery. Principle sources are endomyometritis, hemorrhage, urinary tract infection, and thromboembolism. As discussed in [Chapter 48 \(p. 1298\)](#), morbidity associated with cesarean delivery is increased dramatically in obese women ([Isaacs and associates, 1994](#); [Perlow and Morgan, 1994](#)). These factors, as well as the increased recovery time associated with cesareans, result in a twofold increase in costs for cesarean compared with vaginal delivery (Book of Health Insurance Data, 1993).

BIRTH TRAUMA

Although cesarean delivery is sometimes performed in cases of malpresentation or with known excessive fetal size in an effort to avoid birth trauma, it is incorrect to assume that a cesarean delivery provides a guarantee against such injury. Numerous reports attest to the occurrence of Erb palsy, skull fractures, and fractures of other long bones in infants delivered by cesarean ([Kaplan and colleagues, 1987](#); [Skajaa and associates, 1987](#); [Vasa and Kim, 1990](#)).

TECHNIQUE FOR CESAREAN DELIVERY

ABDOMINAL INCISIONS

VERTICAL INCISION. An infraumbilical midline vertical incision is quickest to make. The incision should be of sufficient length to allow delivery of the infant without difficulty. Therefore, its length should correspond with the estimated fetal size. Sharp dissection is performed to the level of the anterior rectus sheath, which is freed of subcutaneous fat to expose a strip of fascia in the midline about 2 cm wide. Some surgeons prefer to incise the rectus sheath with the scalpel throughout the length of the fascial incision. Others prefer to make a small opening and then incise the fascial layer with scissors. The rectus and the pyramidalis muscles are separated in the midline by sharp and blunt dissection to expose transversalis fascia and peritoneum.

The transversalis fascia and preperitoneal fat are dissected carefully to reach the underlying peritoneum. The peritoneum near the upper end of the incision is opened carefully. Some surgeons elevate the peritoneum with two hemostats placed about 2 cm apart. The tented fold of peritoneum between the clamps is then visualized and palpated to be sure that omentum, bowel, or bladder are not adjacent. In women who have had previous intra-abdominal surgery, including cesareans, omentum or bowel may be adherent to the undersurface of the peritoneum. The peritoneum is incised superiorly to the upper pole of the incision and downward to just above the peritoneal reflection over the bladder.

TRANSVERSE INCISIONS. With the modified **Pfannenstiel incision**, the skin and subcutaneous tissue are incised using a lower transverse, slightly curvilinear incision. The incision is made at the level of the pubic hairline and is extended somewhat beyond the lateral borders of the rectus muscles. After the subcutaneous tissue has been separated from the underlying fascia for 1 cm or so on each side, the fascia is incised transversely the full length of the incision. The superior and inferior edges of the fascia are grasped with suitable clamps and then elevated by the assistant as the operator separates the fascial sheath from the underlying rectus muscles by blunt dissection with the scalpel handle. Blood vessels coursing between the muscles and fascia are clamped, cut, and ligated. Meticulous hemostasis is imperative. The fascial separation is carried near enough to the umbilicus to permit an adequate midline longitudinal incision of the peritoneum. The rectus muscles are then separated in the midline to expose the underlying peritoneum. The peritoneum is opened as discussed earlier. Closure in layers is carried out the same as with a vertical skin incision.

The cosmetic advantage of the transverse skin incision is apparent. While most believe the incision is stronger and less likely to undergo dehiscence, [Hendrix and co-workers \(2000\)](#) provided evidence that this is not the case. There are some disadvantages in its use. Exposure of the pregnant uterus and appendages in some women is not as good as with a vertical incision. Whenever more room is needed, the vertical incision can be rapidly extended around and above the umbilicus,

whereas the Pfannenstiel incision cannot. If the woman is obese, the operative field may be even more restricted. In terms of morbidity it is not appropriate to compare the vertical incision, often performed under adverse conditions, with the transverse incision carried out under much more favorable circumstances. Importantly, at the time of repeat cesarean, reentry through a Pfannenstiel incision is likely to be more time consuming because of scarring.

When a transverse incision is desired and more room is needed, the **Maylard incision** provides a safe option. In this incision, the rectus muscles are divided with scissors or a scalpel. The incision may also be especially useful in women with significant scarring resulting from previous Pfannenstiel incisions. In the study by [Ayers and Morley \(1987\)](#), the mean incision length was 18.3 cm with the Maylard incision compared with 14.0 cm for the Pfannenstiel incision.

UTERINE INCISIONS

The so-called **classical cesarean incision**, a vertical incision into the body of the uterus above the lower uterine segment and reaching the uterine fundus, is seldom used today. Most always the incision is made in the lower uterine segment transversely ([Kerr, 1926](#)) or, less often, vertically ([Kronig, 1912](#)). The lower-segment transverse incision has the advantage of requiring only modest dissection of the bladder from the underlying myometrium. If the incision extends laterally, a laceration may involve one or both of the uterine vessels. The low-vertical incision may be extended upward so that in those circumstances where more room is needed, the incision can be carried into the body of the uterus. More extensive dissection of the bladder is necessary to keep the vertical incision within the lower uterine segment. Moreover, if the vertical incision extends downward, it may tear through the cervix into the vagina and possibly involve the bladder. Importantly, during the next pregnancy a vertical incision that extends into the upper myometrium is more likely to rupture than a transverse incision, especially during labor.

For a cephalic presentation, a transverse incision through the lower uterine segment is most often the operation of choice. Generally, the transverse incision:

1. Is easier to repair.
2. Is located at a site least likely to rupture with extrusion of the fetus into the abdominal cavity during a subsequent pregnancy.
3. Does not promote adherence of bowel or omentum to the incisional line.

TECHNIQUE FOR TRANSVERSE CESAREAN INCISION

Commonly, the uterus is found to be dextrorotated so that the left round ligament is more anterior and closer to the midline than the right. With thick meconium or infected amniotic fluid, some operators prefer to lay a moistened laparotomy pack in each lateral peritoneal gutter to absorb fluid and blood that escape from the opened uterus.

Typically the rather loose reflection of peritoneum above the upper margin of the bladder and overlying the anterior lower uterine segment is grasped in the midline with forceps and incised with a scalpel or scissors ([Fig. 23-6](#)). Scissors are inserted between the serosa and myometrium of the lower uterine segment and are pushed laterally from the midline, while partially opening the blades intermittently, to separate a 2-cm-wide strip of serosa, which is then incised. As the lateral margin on each side is approached, the scissors are aimed somewhat more cephalad ([Fig. 23-7](#)). The lower flap of peritoneum is elevated and the bladder is gently separated by blunt or sharp dissection from the underlying myometrium ([Fig. 23-8](#)). In general, the separation of bladder should not exceed 5 cm in depth and usually less. It is possible, especially with an effaced, dilated cervix, to dissect downward so deeply as inadvertently to expose and then enter the underlying vagina rather than the lower uterine segment.

The uterus is opened through the lower uterine segment about 1 cm below the upper margin of the peritoneal reflection. It is important to place the uterine incision relatively higher in women with advanced or complete cervical dilatation in order to minimize lateral extension of the incision into the uterine arteries. The uterine incision can be made by a variety of techniques. Each is initiated by incising with a scalpel the exposed lower uterine segment transversely for 1 to 2 cm or so halfway between the lateral margins. This must be done carefully so as to cut completely through the uterine wall but not deeply enough to wound the underlying fetus ([Fig. 23-9](#)). Careful blunt entry using hemostats to split the muscle may be helpful. Once the uterus is opened, the incision can be extended by cutting laterally and then slightly upward with bandage scissors. Alternatively, when the lower uterine segment is thin, the entry incision can be extended by simply spreading the incision, using lateral and upward pressure applied with each index finger ([Fig. 23-10](#)). [Rodriguez and associates \(1994\)](#) demonstrated that blunt and sharp extensions of the initial uterine incision are equivalent in terms of safety and postoperative complications. **It is very important to make the uterine incision large enough to allow delivery of the head and trunk of the fetus without either tearing into or having to cut into the uterine arteries and veins that course through the lateral margins of the uterus.** If the placenta is encountered in the line of incision, it must either be detached or incised. When the placenta is incised, fetal hemorrhage may be severe, and thus, the cord should be clamped as soon as possible in such cases.

DELIVERY OF THE INFANT. In cephalic presentation, a hand is slipped into the uterine cavity between the symphysis and fetal head, and the head is elevated gently with the fingers and palm through the incision aided by modest transabdominal fundal pressure ([Fig. 23-11](#)). After a long labor with cephalopelvic disproportion, the fetal head may be rather tightly wedged in the birth canal. Upward pressure exerted through the vagina by an assistant will help to dislodge the head and allow its delivery above the symphysis. To minimize aspiration by the fetus of amniotic fluid and its contents, the exposed nares and mouth are aspirated with a bulb syringe before the thorax is delivered. The shoulders then are delivered using gentle traction plus fundal pressure. The rest of the body readily follows.

As soon as the shoulders are delivered ([Fig. 23-12](#)), an intravenous infusion containing about 20 units of oxytocin per liter is allowed to flow at a brisk rate of 10 mL/min until the uterus contracts satisfactorily, after which the rate can be reduced. Bolus doses of 5 to 10 units are avoided due to associated hypotension. The cord is clamped with the infant held at the level of the abdominal wall, and the infant is given to the member of the team who will conduct resuscitative efforts as they are needed.

If the fetus is not presenting cephalic, or if there are multiple fetuses or a very immature fetus in a woman who has had no labor, a vertical incision through the lower segment may, at times, prove to be advantageous. The fetal legs must be carefully distinguished from the arms to avoid premature extraction of an arm and a difficult delivery of the rest of the fetus.

The uterine incision is observed for any vigorously bleeding sites. These should be promptly clamped with Pennington or ring forceps, or similar instruments. Most surgeons recommend that the placenta be removed promptly manually, unless it is separating spontaneously ([Fig. 23-13](#)). Fundal massage, begun as soon as the fetus is delivered, reduces bleeding and hastens delivery of the placenta. In a randomized trial, [Lasley and colleagues \(1997\)](#) found a significant twofold postoperative infection rate with manual removal compared with spontaneous delivery. Some obstetricians prefer manual expression of the placenta using external uterine manipulation, but this has not been shown to be superior to manual removal ([Cernadas and co-workers, 1998](#)).

Recommendations from the *Guidelines for Perinatal Care* ([American College of Obstetricians and Gynecologist, 1992](#)) suggest that all births require the attendance of personnel capable of resuscitating the newborn. There are no specific recommendations for cesarean deliveries ([Jacob and Pfenniger, 1997](#)). In many institutions the standard of care mandates that pediatricians attend all cesarean deliveries regardless of fetal risk, whereas nurses attend to the newborn infant in low-risk vaginal deliveries. [Jacob and Pfenniger \(1997\)](#) compared 834 cesarean deliveries with 834 low-risk vaginal deliveries. They concluded that repeat cesarean deliveries, and cesareans for dystocia without fetal heart rate abnormalities and performed under regional anesthesia, do not need a pediatrician in attendance because of rare need for infant resuscitation. At Parkland Hospital, pediatric nurse practitioners attend uncomplicated, scheduled cesarean deliveries.

REPAIR OF THE UTERUS. After delivery of the placenta, the uterus may be lifted through the incision onto the draped abdominal wall and the fundus covered with a moistened laparotomy pack. Although some clinicians prefer to avoid this latter step, uterine exteriorization often has advantages that outweigh any disadvantages. The relaxed, atonic uterus can be recognized quickly and massage applied. The incision and bleeding points are visualized more easily and repaired, especially if there have been extensions laterally. Adnexal exposure is superior and thus tubal sterilization is easier. The principal disadvantage is from discomfort and vomiting caused by traction in the woman given spinal or epidural analgesia. Neither febrile morbidity nor blood loss appears to be increased in women undergoing uterine exteriorization prior to repair ([Magann and associates, 1993a](#); [Wahab and co-workers, 1999](#)).

Immediately after delivery and inspection of the placenta, the uterine cavity is inspected and wiped out with a gauze pack to remove avulsed membranes, vernix, clots, or other debris. The upper and lower cut edges and each angle of the uterine incision are examined carefully for bleeding vessels. The lower margin of an incision made through a thinned-out lower uterine segment may be so thin as to be inadvertently ignored. At the same time, the posterior wall of the lower uterine segment may occasionally buckle anteriorly in such a way as to suggest that it is the lower margin of the incision.

The uterine incision is closed with one or two layers of continuous 0 or #1 absorbable suture. Traditionally, chromic suture is used, but some prefer synthetic

nonabsorbable sutures. [Zuidema and colleagues \(1996\)](#) reviewed subsequent outcomes in 537 women in whom 237 had uterine chromic closure and 302 had closure with Vicryl. Subsequent scar separation was increased almost fourfold in the Vicryl group (4.6 versus 1.2 percent). From their review, [Bivins and Gallup \(2000\)](#) recommend one-layer uterine closure. [Hauth and colleagues \(1992\)](#) randomized 906 women to either one- or two-layer closure using 1-0 chromic gut. A continuous locking one-layer closure required less operative time and fewer uterine hemostatic sutures. In a follow-up report of 164 women delivered subsequently, the type of uterine closure did not significantly affect the next pregnancy ([Chapman and associates, 1997](#)).

Individually clamped large vessels are best ligated with a suture ligature. Concern has been expressed by some clinicians that sutures through the decidua may lead to endometriosis in the scar, but this is a rare complication. The initial suture is placed just beyond one angle of the incision. A running-lock suture is then carried out, with each suture penetrating the full thickness of the myometrium ([Fig. 23-14](#)). It is important to select carefully the site of each stitch and to avoid withdrawing the needle once it penetrates the myometrium. This minimizes the perforation of unligated vessels and subsequent bleeding. The running-lock suture is continued just beyond the opposite incision angle. Especially when the lower segment is thin, satisfactory approximation of the cut edges usually can be obtained with one layer of suture. If approximation is not satisfactory after a single-layer continuous closure, or if bleeding sites persist, either another layer of sutures may be placed so as to achieve approximation and hemostasis, or individual bleeding sites can be secured with figure-of-eight or mattress sutures.

After hemostasis is obtained from uterine closure, serosal edges overlying the uterus and bladder in the past have been approximated with a continuous 2-0 chromic catgut suture ([Fig. 23-15](#)). After their review, [Bivins and Gallup \(2000\)](#) favor nonclosure of the peritoneum. Studies have demonstrated reduced need for postoperative analgesia and a quicker return of bowel function when both visceral and parietal peritoneum were left open ([Hull and Varner, 1991](#); [Pietrantonio and associates, 1991](#)). It does not increase adhesion formation ([Tulandi and co-workers, 1988](#)).

If tubal sterilization is to be performed, it is now done. A partial midsegment salpingectomy, described in [Chapter 59 \(p. 1557\)](#), has a low failure rate.

ABDOMINAL CLOSURE. All packs are removed, and the gutters and cul-de-sac are emptied of blood and amniotic fluid by gentle suction. If general anesthesia is used, the upper abdominal organs may be palpated systematically. With conduction analgesia, however, this may produce considerable discomfort. After the sponge and instrument counts are found to be correct, the abdominal incision is closed ([Fig. 23-16](#)). Many omit peritoneal edge approximation. As each layer is closed, bleeding sites are located, clamped, and ligated. The rectus muscles are allowed to fall into place, and the subfascial space is meticulously checked for hemostasis. The overlying rectus fascia is closed either with interrupted 0 nonabsorbable sutures that are placed lateral to the fascial edges and no more than 1 cm apart, or by continuous, nonlocking suture of a long-lasting absorbable or permanent type.

The subcutaneous tissue usually need not be closed separately if it is 2 cm or less in thickness, and the skin is closed with vertical mattress sutures of 3-0 or 4-0 silk or equivalent suture or skin clips. If there is more adipose tissue than this, or if clips or subcuticular closure are to be used, a few interrupted 3-0 plain catgut sutures will obliterate dead space and reduce tension on the skin edges. In a randomized prospective study of more than 1400 women undergoing cesarean delivery, [Bohman and colleagues \(1992\)](#) reported a significantly decreased frequency of superficial wound disruption when the subcutaneous layer was approximated. This was confirmed in a similar study by [Naumann and co-workers \(1995\)](#).

TECHNIQUE FOR CLASSICAL CESAREAN INCISION

Occasionally it is necessary to use a classical incision for delivery. Some indications are:

1. If the lower uterine segment cannot be exposed or entered safely because the bladder is adherent densely from previous surgery, or if a myoma occupies the lower uterine segment, or if there is invasive carcinoma of the cervix.
2. When there is a transverse lie of a large fetus, especially if the membranes are ruptured and the shoulder is impacted in the birth canal.
3. In some cases of placenta previa with anterior implantation.
4. In some cases of very small fetuses, especially presenting as breech, in which the lower uterine segment is not thinned out.
5. In some cases of massive maternal obesity where only the upper uterus is easily accessible.

UTERINE INCISION. Vertical uterine incision is initiated with a scalpel beginning as low as possible, but above the level of the attached bladder. Once sufficient room is made with the scalpel, the incision is extended cephalad with bandage scissors until it is sufficiently long to permit delivery of the fetus. Numerous large vessels that bleed profusely are commonly encountered within the myometrium. As soon as the fetus has been removed, these vessels may best be clamped and eventually ligated with chromic catgut sutures. Following birth of the infant, care is as described earlier.

UTERINE REPAIR. One method employs a layer of continuous 0- or 1-chromic catgut to approximate the inner halves of the incision. The outer half of the uterine incision is then closed with similar suture, using either a continuous stitch or figure-of-eight sutures. No unnecessary needle tracts should be made lest myometrial vessels be perforated with subsequent hemorrhage or hematomas. To achieve good approximation and to prevent the suture from tearing through the myometrium, it is helpful to have an assistant compress the myometrium on each side of the wound medially as each suture is placed and tied. The edges of the uterine serosa, if not already so, are approximated with continuous 2-0 chromic catgut. The operation is completed as described earlier.

EXTRAPERITONEAL CESAREAN DELIVERY

Early in the 20th century, [Frank \(1907\)](#) and [Latzko \(1909\)](#) recommended extraperitoneal cesarean rather than cesarean hysterectomy as a method of managing pregnancies with infected uterine contents. The goal of the operation was to open the uterus extraperitoneally by dissecting through the space of Retzius and then along one side and beneath the bladder to reach the lower uterine segment. Enthusiasm for the procedure has been transient, probably in large part because of the availability of a variety of effective antimicrobial agents ([Wallace and associates, 1984](#)).

POSTMORTEM CESAREAN DELIVERY

At times, cesarean delivery is performed on a woman who has just died, or who is expected to do so momentarily. A satisfactory infant outcome in such a situation is dependent upon:

1. Anticipation, if possible, of the death of the mother.
2. Gestational age of fetus.
3. Availability of personnel and appropriate equipment.
4. Availability of perimortem ventilation and cardiac massage for the mother.
5. Prompt delivery and effective neonatal resuscitation.

Although a few infants have survived with no apparent physical or intellectual compromise, most are not so fortunate. Both [Katz and associates \(1986\)](#) and [Clark and colleagues \(1995\)](#) stress the need for immediate cesarean delivery upon diagnosis of maternal cardiac arrest if neonatal outcome is to be optimized. In such cases, cesarean delivery is unlikely to adversely affect maternal outcome; indeed, only about 10 percent of patients suffering in-hospital cardiac arrest will survive to hospital discharge ([Blackhall and associates, 1992](#); [Niemann, 1992](#)). Unfortunately, even with ideal management, maternal cardiac arrest often leads to survival of a neurologically impaired infant. [Field and co-workers \(1988\)](#) reported the successful delivery by cesarean of an infant whose mother, although brain dead, was maintained for 10 weeks on life-support systems in order for fetal maturation to occur. The issue of cesarean delivery to aid in cardiopulmonary resuscitation of the mother is further discussed in [Chapter 43 \(p. 1176\)](#).

POSTOPERATIVE COMPLICATIONS

Morbidity following cesarean delivery is influenced by the circumstances in which the procedure is performed. [McMahon and colleagues \(1996\)](#), in their analysis of

women with prior cesarean delivery, reported the incidence of complications in women delivered by this method electively compared with after labor had failed in effecting vaginal delivery ([Table 23-7](#)). Potential complications included hysterectomy, operative injury to pelvic structures, as well as infection and need for transfusion. The incidence of some of these morbidities may be magnified by uterine rupture because the study included only those women with prior cesarean deliveries. [Rajasekar and Hall \(1997\)](#) specifically studied bladder and ureteral injuries. The incidence of bladder laceration at the time of cesarean operation was 1.4 per 1000 procedures, and that for ureteral injury was 0.3 per 1000. While bladder injury was immediate, diagnosis of ureteric injury was often delayed.

[Lyndon-Rochelle and colleagues \(2000\)](#) studied rehospitalizations within 60 days following cesarean deliveries in 54,074 women in Washington State. They compared these with 142,768 women delivered vaginally, and as shown in [Table 23-8](#), rehospitalization was significantly increased in women with cesarean births. They calculated the risk of rehospitalization for women with cesarean births and discharged before 3 days, 3 to 5 days, and 6 days or longer after the operation. The risk of rehospitalization was significantly decreased for women discharged between 3 and 5 days following cesarean delivery compared with earlier discharge, suggesting that this interval may be optimal.

The diagnosis and treatment of pelvic and wound infections following cesarean delivery is discussed in [Chapter 26](#). A rare but serious complication of cesarean delivery is necrotizing fasciitis. [Goepfert and co-workers \(1997\)](#) identified nine such women based on identification of necrotic fascia in febrile women undergoing postcesarean wound debridement. The incidence was approximately 2 per 1000 cesarean deliveries. Fasciitis was diagnosed an average of 10 days following cesarean delivery and these infections were polymicrobial. One woman died from sepsis.

POSTPARTUM HYSTERECTOMY

In some cases, and usually in those complicated by severe obstetrical hemorrhage, postpartum hysterectomy may be lifesaving. It is done primarily at laparotomy following vaginal delivery, or it may be done after cesarean delivery.

INDICATIONS

The majority of procedures are done to arrest hemorrhage either from intractable uterine atony, lower-segment bleeding associated with the uterine incision or placental implantation, a laceration of major uterine vessels, large myomas, severe cervical dysplasia, and carcinoma in situ. Placental implantation disorders, to include placenta previa and variations of placenta accreta, often in association with repeat cesarean delivery, are now the most common indications for cesarean hysterectomy ([Miller and colleagues, 1997](#)). These are discussed in [Chapter 25 \(p. 632\)](#).

Major deterrents to cesarean hysterectomy are concern for increased blood loss and the possibility of urinary tract damage. A major factor in the complication rate appears to be whether the operation is performed as an elective procedure or as an emergency. As shown in [Table 23-9](#), morbidity associated with emergency hysterectomy is substantively increased. Recently, [Seago and associates \(1999\)](#) also reported increased blood loss, operative time, infection morbidity, and transfusion rates in women undergoing emergency compared with elective postpartum hysterectomy.

OPERATIVE TECHNIQUE. If done following vaginal delivery, the transverse bladder flap is deflected downward as for a cesarean incision, but extended farther down to the level of the cervix is possible. If done after delivery of the infant by cesarean, the bladder flap is also deflected farther down. Supracervical or preferably total hysterectomy can be accomplished by standard operative techniques. Although all vessels are appreciably larger than those of the nonpregnant uterus, hysterectomy is usually facilitated by the ease of development of tissue planes in pregnant women. Blood loss is commonly appreciable because of the indications for the operation. When performed for hemorrhage, blood loss almost always is torrential. Indeed, as shown in [Table 23-9](#), over 90 percent of women undergoing emergency postpartum hysterectomy required transfusions.

Following delivery, the major bleeding vessels are clamped and ligated quickly. The placenta is removed, and the uterine incision can be approximated with either a continuous suture or a few interrupted sutures. Alternatively, Pennington or sponge forceps can be applied, and if the incision is not bleeding appreciably, neither is necessary.

Next the round ligaments close to the uterus are divided between Heaney or Kocher clamps and doubly ligated. Either 0 or #1 sutures can be used. The incision in the vesicouterine serosa, made to mobilize the bladder for cesarean delivery, is extended laterally and upward through the anterior leaf of the broad ligament to reach the incised round ligaments ([Fig. 23-17](#)). The posterior leaf of the broad ligament adjacent to the uterus is perforated just beneath the fallopian tubes, utero-ovarian ligaments, and ovarian vessels ([Fig. 23-18A](#)). These then are doubly clamped close to the uterus ([Fig. 23-18B](#)), divided, and the lateral pedicle doubly suture ligated. The posterior leaf of the broad ligament is divided inferiorly toward the uterosacral ligaments ([Fig. 23-19](#)). Next, the bladder and attached peritoneal flap are again deflected and dissected from the lower uterine segment and retracted out of the operative field ([Fig. 23-20](#)). If the bladder flap is unusually adherent, as it may be after previous cesarean incisions, careful sharp dissection may be necessary.

Special care is necessary from this point on to avoid injury to the ureters, which pass beneath the uterine arteries. The ascending uterine artery and veins on either side are identified and near their origin are doubly clamped immediately adjacent to the uterus, divided, and doubly suture ligated ([Fig. 23-21](#)).

In cases of profuse hemorrhage, it may be more advantageous to rapidly clamp all of the vascular pedicles and remove the uterus before suture ligating the pedicles.

SUPRACERVICAL HYSTERECTOMY. To perform a subtotal hysterectomy, it is necessary only to amputate the body of the uterus at this level. The cervical stump may be closed with continuous or interrupted chromic sutures.

TOTAL HYSTERECTOMY. To perform a total hysterectomy, it is necessary to mobilize the bladder much more extensively in the midline and laterally. This will help carry the ureters caudad as the bladder is retracted beneath the symphysis and will also prevent laceration or suturing of the bladder during cervical excision and vaginal cuff closure. The bladder is dissected free for about 2 cm below the lowest margin of the cervix to expose the uppermost part of the vagina. If the cervix is effaced and dilated appreciably, the uterine cavity may be entered anteriorly in the midline either through the lower hysterotomy incision or through a stab wound made at the level of the ligated uterine vessels. A finger is directed inferiorly through the incision to identify the free margin of the dilated, effaced cervix and the anterior vaginal fornix. The contaminated glove is removed and the hand regloved. Another useful method to identify the cervical margins is to place transvaginally four metal skin clips or brightly colored sutures at 12, 3, 6, and 9 o'clock positions on the cervical edges prior to planned hysterectomy.

The cardinal ligaments, uterosacral ligaments, and the many large vessels these ligaments contain are doubly clamped systematically with Heaney-type curved clamps, Ochsner-type straight clamps, or similar instruments ([Fig. 23-22](#)). The clamps are placed as close to the cervix as possible, and it is imperative not to include excessive tissue in each clamp. The tissue between the pair of clamps is incised, and suture ligated appropriately. These steps are repeated until the level of the lateral vaginal fornix is reached. In this way, the descending branches of the uterine vessels are clamped, cut, and ligated as the cervix is dissected from the cardinal ligaments posteriorly.

Immediately below the level of the cervix, a curved clamp is swung in across the lateral vaginal fornix, and the tissue is incised medially to the clamp ([Fig. 23-23](#)). The excised lateral vaginal fornix can be simultaneously doubly ligated and sutured to the stump of the cardinal ligament. The entire cervix is then excised from the vagina.

The cervix is inspected to insure that it has been completely excised, and the vagina is repaired. Each of the angles of the lateral vaginal fornix are secured to the cardinal and uterosacral ligaments ([Fig. 23-24](#)). Following this, some surgeons prefer to close the vagina using figure-of-eight chromic catgut sutures. Others achieve hemostasis by using a running-lock stitch of chromic catgut suture placed through the mucosa and adjacent endopelvic fascia around the circumference of the vagina ([Fig. 23-25](#)). The open vagina may promote drainage of fluids that would otherwise accumulate and contribute to hematoma formation and infection.

All sites of incision from the upper fallopian tube and ovarian ligament pedicles to the vaginal vault and bladder flap are examined carefully for bleeding. Bleeding sites are ligated with care to avoid the ureters.

Some clinicians choose to reperitonealize the pelvis ([Fig. 23-26](#)). One method employs a continuous chromic suture starting with the tip of the ligated pedicle of fallopian tube and ovarian ligament, which is inverted retroperitoneally. Sutures are then placed continuously so as to:

1. Approximate the leaves of the broad ligament.
2. Bury the stump of the round ligament.

3. Approximate the cut edge of the vesicouterine peritoneum over the vaginal vault posteriorly to the cut edge of peritoneum above the cul-de-sac.
4. Approximate the leaves of the broad ligament on the opposite side.
5. Bury the stump of the round ligament and pedicle of fallopian tube on the opposite side.

The abdominal wall normally is closed in layers, as previously described.

APPENDECTOMY AND OOPHORECTOMY

The benefits compared with the risks from incidental appendectomy at the time of cesarean or hysterectomy continue to be argued ([Gilstrap, 1991](#)). In one prospective study of 40 women undergoing elective appendectomy, [Parsons and associates \(1986\)](#) reported no significant morbidity and found that 20 percent of the removed appendices were abnormal. However, the procedure added 15 minutes to the operative time and a half-day to the hospital stay. [Lydon-Rochelle and colleagues \(2000\)](#) found an 80 percent increased risk of rehospitalization for appendicitis among women with cesarean delivery, an association not previously observed ([Table 23-8](#)). A plausible explanation is that the manipulation of abdominal contents during cesarean delivery may exacerbate or stimulate subclinical infection ([Andersson and associates, 1995](#)). Lacking, however, are results that demonstrate clearly that puerperal morbidity and mortality are not increased by appendectomy, especially with emergency cesarean delivery.

Most studies indicate that in 5 percent of postpartum hysterectomies, one adnexa will have to be removed to stop bleeding ([Plauche, 1995](#)). That said, during any hysterectomy, a decision as to the fate of the ovaries must be made. For women who are approaching menopause, the decision is not difficult, but few women who undergo cesarean hysterectomy are of this age. Thus, ovarian preservation is favored unless the ovaries are diseased. Even if oophorectomy is required, it rarely is necessary or desirable to remove both ovaries.

PERIPARTUM MANAGEMENT

PREOPERATIVE CARE

The woman scheduled for repeat cesarean delivery is typically admitted the day of surgery and evaluated by the obstetrician who will perform surgery and the anesthesiologist who will provide anesthesia. The hematocrit is rechecked, and if the indirect Coombs test is positive, then availability of compatible blood must be assured. A sedative, such as secobarbital 100 mg, may be given at bedtime the night before the operation. In general, no other sedatives, narcotics, or tranquilizers are administered until after the infant is born. Oral intake is stopped at least 8 hours before surgery. An antacid, such as Bicitra 30 mL, given shortly before the induction of a general anesthesia, minimizes the risk of lung injury from gastric acid should aspiration occur ([Chap. 15, p. 366](#)). This should be done routinely, even when conduction analgesia will be used, because at times it is necessary to switch to, or at least supplement, the regional analgesia with inhalation anesthesia.

INTRAVENOUS FLUIDS

Requirements for intravenous fluids, including blood during and after cesarean delivery, can vary considerably. The woman of average size with a hematocrit of 30 or more and a normally expanded blood volume and extracellular fluid volume most often will tolerate blood loss up to 2000 mL without difficulty. Unappreciated bleeding through the vagina during the procedure, bleeding concealed in the uterus after its closure, or both, commonly lead to underestimation. While blood loss averages about 1500 mL with elective cesarean hysterectomy, it is quite variable ([Pritchard, 1965](#)).

Intravenously administered fluids consist of either lactated Ringer solution or a similar crystalloid solution with 5 percent dextrose. Typically, 1 to 2 liters that contain electrolytes are infused during and immediately after the operation. Throughout the procedure, and subsequently while in the recovery area, the blood pressure and urine flow are monitored closely to ensure that perfusion of vital organs is satisfactory.

RECOVERY SUITE

In the recovery suite, the amount of bleeding from the vagina must be monitored closely, and the uterine fundus must be identified frequently by palpation to assure that the uterus is remaining firmly contracted. Unfortunately, as the woman awakens from general anesthesia or the conduction analgesia fades, palpation of the abdomen is likely to produce considerable discomfort. This can be made much more tolerable by giving an effective analgesic intravenously, such as meperidine, 75 to 100 mg, or morphine, 10 to 15 mg. A thick dressing with an abundance of adhesive tape over the abdomen interferes with fundal palpation and massage and later causes discomfort as the tape and perhaps skin are removed. Deep breathing and coughing are encouraged.

Once the mother is fully awake, bleeding is minimal, the blood pressure is satisfactory, and urine flow is at least 30 mL/hr, she may be returned to her room.

SUBSEQUENT CARE

ANALGESIA. For the woman of average size, meperidine, 75 to 100 mg, is given intramuscularly as often as every 3 hours as needed for discomfort, or morphine sulfate, 10 to 15 mg, is similarly administered. An antiemetic, such as promethazine, 25 mg, is usually given along with the narcotic. Intravenous meperidine or morphine via a patient-controlled pump is an even more effective alternative to bolus therapy in the immediate postoperative period.

VITAL SIGNS. After transfer, the woman is now evaluated at least hourly for 4 hours at the minimum, and blood pressure, pulse, urine flow, amount of bleeding, and status of the uterine fundus are checked at intervals of 4 hours, along with the temperature.

FLUID THERAPY AND DIET. Unless there has been pathological constriction of the extracellular fluid compartment from diuretics, sodium restriction, vomiting, fever, or prolonged labor without adequate fluid intake, the puerperium is characterized by excretion of fluid that was retained during pregnancy. Moreover, with the typical cesarean delivery, significant extracellular fluid sequestration in bowel wall and lumen does not occur, unless it was necessary to pack the bowel away from the operative field or peritonitis develops. Thus, the woman who undergoes cesarean delivery rarely develops fluid sequestration in the so-called third space. Quite the contrary, she normally begins surgery with a physiologically enlarged third space that she acquired during pregnancy and that she now mobilizes and excretes after delivery. Therefore, large volumes of intravenous fluids during and subsequent to surgery are not needed to replace sequestered extracellular fluid. As a generalization, 3 L of fluid should prove adequate during the first 24 hours after surgery. If urine output falls below 30 mL/hr, however, then the woman should be reevaluated promptly. The cause of the oliguria may range from unrecognized blood loss to an antidiuretic effect from infused oxytocin.

BLADDER AND BOWEL FUNCTION. The bladder catheter most often can be removed by 12 hours after operation or, more conveniently, the morning after surgery. Subsequent ability to empty the bladder before overdistention develops must be monitored as with vaginal delivery. In uncomplicated cases, solid food may be offered within 8 hours of surgery ([Burrows and associates, 1995](#); [Kramer and colleagues, 1996](#)). Although some degree of adynamic ileus follows virtually every abdominal operation, in most cases of cesarean delivery, it is negligible. Symptoms include abdominal distention and gas pains, and an inability to pass flatus or stool. The pathophysiology of postoperative ileus is complex, and involves hormonal, neural, and local factors that are incompletely understood ([Livingston and Passaro, 1990](#)). Treatment has changed little over the past several decades, and involves nasogastric decompression and intravenous fluid and electrolyte supplementation. Frequently, a 10-mg bisacodyl rectal suppository provides appreciable relief.

AMBULATION. In most instances, by at least the day after surgery the woman should get out of bed briefly at least twice with assistance. Ambulation can be timed so that a recently administered analgesic will minimize the discomfort. By the second day she may walk with assistance. With early ambulation, venous thrombosis and pulmonary embolism are uncommon.

WOUND CARE. The incision is inspected each day, and the skin sutures (or clips) are removed on the fourth day after surgery. By the third postpartum day, bathing by shower is not harmful to the incision. Thick subcutaneous tissue (greater than 3 cm) is a risk factor for wound infection ([Vermillion and associates, 2000](#)).

LABORATORY. The hematocrit is routinely measured the morning after surgery. It is checked sooner when there was unusual blood loss or when there is oliguria or other evidence to suggest hypovolemia. If the hematocrit is decreased significantly from the preoperative level, it is repeated, and a search is instituted to identify the cause of the decrease. If the lower hematocrit is stable, the mother can ambulate without any difficulty, and if there is little likelihood of further blood loss, hematological repair in response to iron therapy is preferred to transfusion.

BREAST CARE. Breast feeding can be initiated the day of surgery. If the mother elects not to breast feed, a binder that supports the breasts without marked compression will usually minimize discomfort ([Chap. 17, p. 411](#)).

HOSPITAL DISCHARGE. Unless there are complications during the puerperium, the mother is generally discharged on the third postpartum day ([Chap. 17, p. 417](#)). [Strong and associates \(1993\)](#) have presented data suggesting that discharge on day 2 may be appropriate for properly selected women. The woman's activities during the following week should be restricted to self-care and care of her baby with assistance. [Brooten and colleagues \(1994\)](#) successfully combined early discharge with nurse specialist transitional home care. In many cases, it may be advantageous to perform an initial postpartum evaluation during the first to third week after delivery for the reasons presented in [Chapters 17 and 58](#).

PREVENTION OF POSTOPERATIVE INFECTION. Febrile morbidity is rather frequent after cesarean deliveries and appears to be more common among indigent than affluent women. A number of randomized clinical trials have demonstrated that a single-dose of an antimicrobial agent given at the time of cesarean delivery will serve to decrease infection morbidity appreciably. For women in labor or with ruptured membranes, most clinicians recommend a single 2-g dose of ampicillin, a cephalosporin, or an extended-spectrum penicillin after delivery of the infant. Postoperative pelvic infection is the most frequent cause of febrile morbidity and occurs despite peripartum prophylactic antimicrobials in approximately 20 percent of women ([Brumfield and colleagues, 2000](#)). Treatment of uterine infection and its complications are discussed in [Chapter 26](#).

HISTORICAL BACKGROUND

The origin of the term cesarean is obscure. Three principal explanations have been suggested:

1. According to legend, Julius Caesar was born in this manner, with the result that the procedure became known as the Caesarean operation. Several circumstances weaken this explanation. First, the mother of Julius Caesar lived for many years after his birth in 100 BC, and as late as the 17th century, the operation was almost invariably fatal. Second, the operation, whether performed on the living or dead, is not mentioned by any medical writer before the Middle Ages. Historical details of the origin of the family name Caesar are found in [Pickrell's monograph \(1935\)](#).
2. It has been widely believed that the name of the operation is derived from a Roman law, supposedly created by Numa Pompilius (8th century BC), ordering that the procedure be performed upon women dying in the last few weeks of pregnancy in the hope of saving the child. This explanation then holds that this *lex regia*, as it was called at first, became the *lex caesarea* under the emperors, and the operation itself became known as the caesarean operation. The German term *Kaiserschnitt* ("Kaiser cut") reflects this derivation.
3. The word *caesarean* was derived sometime in the Middle Age from the Latin verb *caedere*, "to cut." An obvious cognate is the word *caesura*, a cutting, or pause, in a line of verse. This explanation of the term *caesarean* seems most logical, but exactly when it was first applied to the operation is uncertain. Because "section" is derived from the Latin verb *seco*, which also means "cut," the term *caesarean section* seems tautological.

It is customary in the United States to replace the "ae" in the first syllable of *caesarean* with the letter "e"; in Great Britain and Australia, however, the "ae" is still retained.

From the time of Virgil's Aeneas to Shakespeare's Macduff, poets repeatedly have referred to persons "untimely ripped" from their mother's womb. Ancient historians, such as Pliny, moreover, say that Scipio Africanus (the conqueror of Hannibal), Martius, and Julius Caesar were all born by cesarean. In regard to Julius Caesar, Pliny adds that it was from this circumstance that the surname arose by which the Roman emperors were known. Birth in this extraordinary manner, as described in ancient mythology and legend, was believed to confer supernatural powers and elevated the heroes so born above ordinary mortals.

In evaluating these references to abdominal delivery in antiquity, it is pertinent that no such operation is even mentioned by Hippocrates, Galen, Celsus, Paulus, Soranus, or any other medical writer of those periods. If a cesarean was actually employed, it is particularly surprising that Soranus, whose extensive work written in the second century AD covers all aspects of obstetrics, does not refer to cesarean delivery.

Several references to abdominal delivery appear in the Talmud, compiled between the second and sixth centuries AD, but whether they had any background in terms of clinical usage is conjectural. There can be no doubt, however, that cesareans in the dead were first practiced soon after the Christian Church gained dominance, as a measure directed at baptism of the child. Faith in the validity of some of these early reports is rudely shaken, however, when they glibly state that a living, robust child was obtained 8 to 24 *hours* after the death of the mother.

Cesarean deliveries in the living were first recommended, and the current name of the operation used, in the celebrated work of Francois [Rousset \(1581\)](#) entitled *Traite Nouveau de l'Hysterotomotokie ou l'Enfantement Cesaerien*. Rousset had never performed or witnessed the operation; his information was based chiefly on letters from friends. He reported 14 successful cesarean deliveries, a fact in itself difficult to accept. When it is further stated that 6 of the 14 operations were performed on the same woman, the credulity of the most gullible is exhausted!

The apocryphal nature of most early reports on cesareans has been stressed because many of them have been accepted without question. Authoritative statements by dependable obstetricians about early use of the operation, however, did not appear in the literature until the mid-17th century, as for instance in the classical work of the French obstetrician, Francois Mauriceau, first published in 1668. These statements show without doubt that the operation was employed on the living in rare and desperate cases, and it was usually fatal. Details of the history of cesarean deliveries are to be found in [Fasbender's classical text \(1906\)](#).

The appalling maternal mortality rate of cesareans continued until the beginning of the 20th century. In Great Britain and Ireland, the maternal death rate from the operation in 1865 was 85 percent. In Paris, during the 90 years ending in 1876, not a single successful cesarean had been performed. [Harris \(1879\)](#) noted that as late as 1879, cesareans actually were more successful when performed by the patient herself or when the abdomen was ripped open by the horns of a bull! He collected from the literature nine such cases with five recoveries, and contrasted them with 12 cesareans performed in New York City during the same period, with only one recovery.

The turning point in the evolution of cesareans came in 1882, when Max Sanger, then a 28-year-old assistant of Crede in the University Clinic at Leipzig, introduced suturing of the uterine wall. The long neglect of so simple an expedient as uterine suture was not the result of oversight but stemmed from a deeply rooted belief that sutures in the uterus were superfluous as well as harmful by virtue of serving as the site for severe infection. In meeting these objections, Sanger, who had himself used sutures in only one case, documented their value not from the sophisticated medical centers of Europe but from frontier America. There, in outposts from Ohio to Louisiana, 17 cesarean deliveries had been reported in which silver wire sutures had been used, with the survival of eight mothers—an extraordinary record in those days. In a table included in his monograph, Sanger gives full credit to these frontier surgeons for providing the supporting data for his hypothesis. The problem of hemorrhage was the first and most serious problem to be solved. Details are found in [Eastman's review \(1932\)](#).

Although the introduction of uterine sutures reduced the mortality rate of the operation from hemorrhage, generalized peritonitis remained the dominant cause of death. Hence, various types of operations were devised to combat this scourge. The earliest was the [Porro procedure \(1876\)](#), which combined subtotal cesarean hysterectomy with marsupialization of the cervical stump. The first extraperitoneal operation was described by [Frank in 1907](#) and, with various modifications, as introduced by [Latzko \(1909\)](#) and [Waters \(1940\)](#), was employed until recent years.

In 1912, [Kronig](#) contended that the main advantage of the extraperitoneal technique consisted not so much in avoiding the peritoneal cavity as in opening the uterus through its thin lower segment and then covering the incision with peritoneum. To accomplish this end, he cut through the vesical reflection of the peritoneum from one round ligament to the other and separated it and the bladder from the lower uterine segment and cervix. The lower portion of the uterus was then opened through a vertical median incision, and the child was extracted by forceps. The uterine incision was then closed and buried under the vesical peritoneum. With minor modifications, this low-segment technique was introduced into the United States by [Beck \(1919\)](#) and popularized by [DeLee \(1922\)](#) and others. A particularly important modification was recommended by [Kerr in 1926](#), who preferred a transverse rather than a longitudinal uterine incision. The Kerr technique is the most commonly employed type of cesarean used today.

Two reviews of the history of cesarean delivery are recommended ([Boley, 1991](#); [Sewell, 1993](#)).

TABLE 23-3. Recommendations of the American College of Obstetricians and Gynecologists (1999) for Selection of Candidates for Vaginal Birth after Cesarean Delivery (VBAC)

Selection Criteria

One or two prior low-transverse cesarean deliveries
Clinically adequate pelvis
No other uterine scars or previous rupture
Physician immediately available throughout active labor capable of monitoring labor and performing an emergency cesarean delivery
Availability of anesthesia and personnel for emergency cesarean delivery
From the American College of Obstetricians and Gynecologists (1999), with permission.

TABLE 23-5. Criteria for Timing of Elective Repeat Cesarean Delivery

At least one of these criteria must be met in a woman with normal menstrual cycles and no immediate antecedent use of oral contraceptives:

1. Fetal heart sounds have been documented for 20 weeks by nonelectronic fetoscope or for 30 weeks by Doppler.
2. It has been 36 weeks since a positive serum or urine chorionic gonadotropin pregnancy test was performed by a reliable laboratory.
3. An ultrasound measurement of the crown-rump length, obtained at 6-11 weeks, supports a gestational age of at least 39 weeks.
4. An ultrasound obtained at 12-20 weeks confirms the gestational age of at least 39 weeks determined by clinical history and physical examination.

SECTION VII - COMMON COMPLICATIONS OF PREGNANCY

24. Hypertensive Disorders in Pregnancy

Hypertensive disorders complicating pregnancy are common and form one of the deadly triad, along with hemorrhage and infection, that results in much of the maternal morbidity and mortality related to pregnancy. According to the National Center for Health Statistics in 1998, hypertension associated with pregnancy was the most common medical risk factor ([Ventura and colleagues, 2000](#)). It was identified in 146,320 women, or 3.7 percent of all pregnancies that ended in live births. In 12,345 of these women eclampsia was diagnosed, and maternal deaths from this complication still remain a threat. [Berg and colleagues \(1996\)](#) reported that almost 18 percent of 1450 maternal deaths in the United States from 1987 to 1990 were from complications of pregnancy-related hypertension.

How pregnancy incites or aggravates hypertension remains unsolved despite decades of intensive research, and hypertensive disorders remain among the most significant unsolved problems in obstetrics. Important ongoing research currently is sponsored by the National Institutes of Child Health and Human Development (NICHD) and its Maternal-Fetal Medicine Units Network. Another important stimulus for research is the International Society for the Study of Hypertension in Pregnancy (ISSHP). Also, the National Heart, Lung, and Breast Institute (NHLBI) encourages ongoing research and coordination through the National High Blood Pressure Education Program (NHBPEP) and its Working Group Report on High Blood Pressure in Pregnancy.

TERMINOLOGY

In former editions of this textbook, the authors preferred to use the term *pregnancy-induced hypertension* to describe any new-onset pregnancy-related hypertension. This designation was chosen because it served to emphasize the cause-and-effect connection between pregnancy and a unique form of hypertension manifest in women only during reproduction. It was also intended that *pregnancy-induced hypertension* would include the development of hypertension without proteinuria, including in nulliparous women. In this latter circumstance, *pregnancy-induced hypertension* was also a potential precursor to preeclampsia or eclampsia, which require proteinuria for diagnosis. Our purpose was to communicate that the development of hypertension in a previously normotensive pregnant woman should and must be considered potentially dangerous to both her and her fetus. The designation *pregnancy-induced hypertension* also had the advantage of signifying that most hypertensive nulliparous women had only *transient* uncomplicated hypertension that subsided promptly after delivery. Recently, the working group of the [National High Blood Pressure Education Program \(2000\)](#) has proposed a classification system that accomplishes all the foregoing goals of the authors and thus will be adopted in this edition of *Williams Obstetrics*. The authors have taken this approach in an effort to deal with the nonuniform and confusing terminology that has long plagued the diagnosis of hypertension in pregnancy ([American College of Obstetricians and Gynecologists, 1996](#)).

DIAGNOSIS

The diagnosis of hypertensive disorders complicating pregnancy, as outlined by the Working Group (2000), is shown in [Table 24-1](#). There are five types of hypertensive disease that include:

1. Gestational hypertension (formerly pregnancy-induced hypertension or transient hypertension).
2. Preeclampsia.
3. Eclampsia.
4. Preeclampsia superimposed on chronic hypertension.
5. Chronic hypertension.

An important consideration in this classification is differentiating hypertensive disorders that precede pregnancy from preeclampsia, which is a potentially more ominous disease.

Hypertension is diagnosed when *blood pressure* is 140/90 mm Hg or greater, using Korotkoff phase V to define diastolic pressure. Edema has been abandoned as a diagnostic criteria because it occurs in too many normal pregnant women to be discriminant. In the past, it had been recommended that an increment of 30 mm Hg systolic or 15 mm Hg diastolic blood pressure be used as a diagnostic criterion, even when absolute values were below 140/90 mm Hg. This criterion is no longer recommended because evidence shows that women in this group are not likely to suffer increased adverse pregnancy outcomes ([Levine, 2000](#); [North and colleagues, 1999](#)). That said, women who have a rise of 30 mm Hg systolic or 15 mm Hg diastolic warrant close observation.

GESTATIONAL HYPERTENSION

As shown in [Table 24-1](#), the diagnosis of gestational hypertension is made in women whose blood pressure reaches 140/90 mm Hg or greater for the first time during pregnancy, but in whom *proteinuria has not developed*. Gestational hypertension is termed *transient hypertension* if preeclampsia does not develop and the blood pressure has returned to normal by 12 weeks' postpartum. In this classification the final diagnosis that the woman does not have preeclampsia is made only postpartum. Thus, gestational hypertension is a diagnosis of exclusion. Importantly, however, women with gestational hypertension may develop other signs associated with preeclampsia, for example, headaches, epigastric pain, or thrombocytopenia, which influence management.

When blood pressure rises appreciably during the latter half of pregnancy, it is dangerous—especially to the fetus—not to take action simply because proteinuria has not yet developed. As [Chesley \(1985\)](#) emphasized, 10 percent of eclamptic seizures develop before overt proteinuria. Thus, it is clear that when blood pressure begins to rise, both mother and fetus are at increased risk. Proteinuria is a sign of worsening hypertensive disease, specifically preeclampsia; and when it is overt and persistent, maternal and fetal risks are increased even more.

PREECLAMPSIA

Preeclampsia is a pregnancy-specific syndrome of reduced organ perfusion secondary to vasospasm and endothelial activation. *Proteinuria* is an important sign of preeclampsia, and [Chesley \(1985\)](#) rightfully concluded that the diagnosis is questionable in its absence. Proteinuria is described as 300 mg or more of urinary protein per 24 hours or persistent 30 mg/dL (1+ dipstick) in random urine samples. The degree of proteinuria may fluctuate widely over any 24-hour period, even in severe cases. Therefore, a single random sample may fail to demonstrate significant proteinuria.

[McCartney and co-workers \(1971\)](#), in their extensive study of renal biopsy specimens obtained from hypertensive pregnant women, invariably found that proteinuria was present when the glomerular lesion considered to be characteristic of preeclampsia was evident. Importantly, both proteinuria and alterations of glomerular histology develop late in the course of hypertensive disorders due to pregnancy. In fact, preeclampsia becomes evident clinically only near the end of a covert pathophysiological process that may begin 3 to 4 months before hypertension develops ([Gant and associates, 1973](#)). As shown in [Table 24-1](#), the minimum criteria for the diagnosis of preeclampsia are hypertension plus minimal proteinuria. The more severe the hypertension or proteinuria, the more certain is the diagnosis of preeclampsia ([Table 24-2](#)). Similarly, abnormal laboratory findings in tests of renal, hepatic, and hematological function increase the certainty of preeclampsia. Persistent premonitory symptoms of eclampsia such as headache and epigastric pain also increase the certainty of preeclampsia.

The combination of proteinuria and hypertension during pregnancy markedly increases the risk of perinatal mortality and morbidity ([Ferrazzani and associates, 1990](#)). Results from a 13-year prospective study reported by [Friedman and Neff \(1976\)](#) in over 38,000 pregnancies are shown in [Table 24-3](#). Hypertension alone, defined by a diastolic blood pressure of 95 mm Hg or greater, was associated with a threefold increase in the fetal death rate. Worsening hypertension, especially if accompanied by proteinuria, was more ominous. Conversely, proteinuria without hypertension had little overall effect on the fetal death rate. [Naeye and Friedman \(1979\)](#) concluded that 70 percent of the excess fetal deaths in these same women were due to large placental infarcts, markedly small placental size, and abruptio placentae. They concluded that these causes usually develop late in the course of the disease. Certainly, persistent proteinuria of 2+ or more, or 24-hour urinary excretion of 2 g or more, is severe preeclampsia. With severe renal involvement, glomerular filtration may be impaired, and plasma creatinine may rise.

Epigastric or right upper quadrant pain likely results from hepatocellular necrosis, ischemia, and edema that stretches Glisson's capsule. This characteristic pain is frequently accompanied by elevated serum liver enzymes, and usually is a sign to terminate the pregnancy. The pain presages hepatic infarction and hemorrhage as

well as catastrophic rupture of a subcapsular hematoma. Fortunately, hepatic rupture is rare and most often associated with hypertension in older and multiparous women.

Thrombocytopenia is characteristic of worsening preeclampsia, and probably is caused by platelet activation and aggregation and microangiopathic hemolysis induced by severe vasospasm. Evidence for gross hemolysis such as hemoglobinemia, hemoglobinuria, or hyperbilirubinemia is indicative of severe disease.

Other factors indicative of severe hypertension include cardiac dysfunction with pulmonary edema as well as obvious fetal growth restriction.

SEVERITY OF PREECLAMPSIA. The severity of preeclampsia is assessed by the frequency and intensity of the abnormalities listed in [Table 24-2](#). The more profound these aberrations, the more likely is the need for pregnancy termination. **Importantly, the differentiation between mild and severe preeclampsia can be misleading because apparently mild disease may progress rapidly to severe disease.**

Although hypertension is a requisite to diagnosing preeclampsia, blood pressure alone is not always a dependable indicator of its severity. For example, a thin adolescent woman may have 3+ proteinuria and convulsions while her blood pressure is 140/85 mm Hg, whereas most women with blood pressures as high as 180/120 mm Hg do not have seizures. Convulsions are usually preceded by an unrelenting severe headache or visual disturbances; thus, these symptoms are considered ominous.

ECLAMPSIA

Eclampsia is the occurrence of seizures in a woman with preeclampsia that cannot be attributed to other causes. The seizures are grand mal and may appear before, during, or after labor. Seizures that develop more than 48 hours postpartum, however, especially in nulliparas, may be encountered up to 10 days postpartum ([Brown and colleagues, 1987](#); [Lubarsky and associates, 1994](#)).

PREECLAMPSIA SUPERIMPOSED UPON CHRONIC HYPERTENSION

All *chronic hypertensive disorders*, regardless of their cause, predispose to development of superimposed preeclampsia or eclampsia. These disorders can create difficult problems with diagnosis and management in women who are not seen until after midpregnancy. The diagnosis of chronic underlying hypertension is suggested by:

1. Hypertension (140/90 mm Hg or greater) antecedent to pregnancy.
2. Hypertension (140/90 mm Hg or greater) detected before 20 weeks (unless there is gestational trophoblastic disease).
3. Persistent hypertension long after delivery ([Table 24-1](#)).

Additional historical factors that help support the diagnosis are multiparity and hypertension complicating a previous pregnancy other than the first. There is also usually a strong family history of essential hypertension.

The diagnosis of chronic hypertension may be difficult to make if the woman is not seen until the latter half of pregnancy. This is because blood pressure decreases during the second and early third trimesters in both normotensive and chronically hypertensive women ([Chap. 45, p. 1211](#)). Thus, a woman with chronic vascular disease, who is seen for the first time at 20 weeks, will frequently have a normal blood pressure. During the third trimester, however, blood pressure may return to its former hypertensive level, thus presenting a diagnostic problem as to whether the hypertension is chronic or induced by pregnancy.

Some of the many causes of underlying hypertension that are encountered during pregnancy are listed in [Table 24-4](#). Essential hypertension is the cause of underlying vascular disease in more than 90 percent of pregnant women. [McCartney \(1964\)](#) studied renal biopsies from women with "clinical preeclampsia," and found chronic glomerulonephritis in 20 percent of nulliparas and in nearly 70 percent of multiparas. [Fisher and co-workers \(1969\)](#), however, did not confirm this high prevalence of chronic glomerulonephritis.

Chronic hypertension causes morbidity whether or not a woman is pregnant. Specifically, as discussed in [Chapter 45](#), it may lead to ventricular hypertrophy and cardiac decompensation, cerebrovascular accidents, or intrinsic renal damage. In some young women, hypertension develops as a consequence of underlying renal parenchymal disease. Dangers specific to pregnancy complicated by chronic hypertension include the risk of superimposed preeclampsia, which may develop in up to 25 percent of these women ([Sibai and colleagues, 1998](#)). Additionally, the risk of abruptio placentae is increased substantively especially in those women who develop superimposed preeclampsia ([Chap. 25, p. 623](#)). Moreover, the fetus of the woman with chronic hypertension is at increased risk for growth restriction and death.

Preexisting chronic hypertension worsens in some women, typically after 24 weeks. If accompanied by proteinuria, superimposed preeclampsia is diagnosed. Often, superimposed preeclampsia develops earlier in pregnancy than "pure" preeclampsia, and it tends to be quite severe and accompanied in many cases by fetal growth restriction.

The diagnosis requires documentation of chronic underlying hypertension. Superimposed gestational hypertension is characterized by worsening hypertension, keeping in mind that both systolic and diastolic pressures normally rise after 26 to 28 weeks. Preeclampsia is accompanied by proteinuria. Indicators of severity shown in [Table 24-2](#) are also used to further characterize these disorders.

INCIDENCE AND RISK FACTORS

Gestational hypertension more often affects nulliparous women. Older women, who accrue an increasing incidence of chronic hypertension with advancing age, are at greater risk for superimposed preeclampsia. Thus, women at either end of reproductive age are considered to be more susceptible ([Chap. 9, p. 207](#)).

The incidence of preeclampsia is commonly cited to be about 5 percent, although remarkable variations are reported. The incidence is markedly influenced by parity; it is related to race and ethnicity—and thus to genetic predisposition; and environmental factors may also have a role. For example, [Palmer and colleagues \(1999\)](#) reported that high altitude in Colorado increased the incidence of preeclampsia. Some investigators have concluded that socioeconomically advantaged women have a lesser incidence of preeclampsia, even after racial factors are controlled. Conversely, in carefully controlled epidemiological studies in Scottish women, [Baird and colleagues \(1969\)](#) found that the incidence of preeclampsia was not different among five social classes.

The incidence of hypertensive disorders due to pregnancy in healthy nulliparous women has been carefully studied in a recent randomized trial of daily maternal dietary calcium supplementation ([Hauth and colleagues, 2000](#)). Of 4302 nulliparous women delivered at or beyond 20 weeks' gestation, a fourth developed a pregnancy-related hypertensive disorder. Of all nulliparas, preeclampsia was diagnosed in 7.6 percent and severe disease as defined in [Table 24-2](#) developed in 3.3 percent.

Other risk factors associated with preeclampsia include multiple pregnancy, history of chronic hypertension, maternal age over 35 years, obesity, and African-American ethnicity (Conde-Agudelo and Belizan, 2000; [Sibai and colleagues, 1997](#); [Walker, 2000](#)). The relationship between maternal weight and risk of preeclampsia is progressive, increasing from 4.3 percent for women with a body mass index less than 19.8 kg/m² to 13.3 percent for those greater than or equal to 35 kg/m². In women with twin gestations compared with those with singletons, the incidence of gestational hypertension (13 versus 6 percent) and preeclampsia (13 versus 5 percent) are both significantly increased ([Sibai and co-authors, 2000](#)). Moreover, women with twins and hypertensive disorders due to pregnancy experience higher rates of adverse neonatal outcomes than do those with singletons. Although maternal smoking causes a variety of adverse pregnancy outcomes, ironically, smoking during pregnancy has consistently been associated with a reduced risk of hypertension during pregnancy ([Zhang and colleagues, 1999](#)). Placenta previa has also been claimed to reduce the risk of hypertensive disorders due to pregnancy ([Ananth and colleagues, 1997](#)).

ECLAMPSIA. In general, eclampsia is preventable, and it has become less common in the United States because most women now receive adequate prenatal care. For example, in the 15th edition of [Williams Obstetrics \(1976\)](#), the incidence of eclampsia at Parkland Hospital was cited to be 1 in 700 deliveries for the prior 25-year period. For the 4-year period 1983 to 1986, the incidence was 1 in 1150 deliveries, and for 1990 to 2000 the incidence was approximately 1 in 2300 deliveries. Using figures from the National Vital Statistics Report, [Ventura and colleagues \(2000\)](#) estimated an incidence of about 1 in 3250 for the United States in 1998. [Douglas and Redman \(1994\)](#) cite an incidence of 1 in 2000 for the United Kingdom in 1992.

[Mattar and Sibai \(2000\)](#) have chronicled the hazards in 399 consecutive eclamptic women delivered between 1977 and 1998 at their center in Memphis. Major complications included abruptio placentae (10 percent), neurological deficits (7 percent), aspiration pneumonia (7 percent), pulmonary edema (5 percent), cardiopulmonary arrest (4 percent), acute renal failure (4 percent), and maternal death (1 percent).

PATHOLOGY

Pathological deterioration of function in a number of organs and systems, presumably as a consequence of vasospasm and ischemia, has been identified in severe preeclampsia and eclampsia. For descriptive purposes, these effects are separated into maternal and fetal consequences; however, these aberrations often occur simultaneously. Although there are many possible maternal consequences of hypertensive disorders due to pregnancy, for simplicity these effects are considered by analysis of cardiovascular, hematological, endocrine and metabolic, and regional blood flow changes with subsequent end-organ derangements. The major cause of fetal compromise occurs as a consequence of reduced uteroplacental perfusion.

CARDIOVASCULAR CHANGES

Severe disturbance(s) of normal cardiovascular function is common with preeclampsia or eclampsia. These basically are related to increased cardiac afterload caused by hypertension, cardiac preload which is substantively affected by pathologically diminished hypervolemia of pregnancy or iatrogenically increased by intravenous crystalloid or oncotic solutions, and endothelial activation with extravasation into the extracellular space, especially the lung. These interactions are discussed further in [Chapter 43 \(p. 1164\)](#).

HEMODYNAMIC CHANGES. The cardiovascular changes due to preeclampsia have been studied using invasive hemodynamic monitoring. Once preeclampsia has become clinically evident, however, such invasive hemodynamic studies are unlikely to provide meaningful information about the nature of the disease in earlier pregnancy. [Bosio and colleagues \(1999\)](#) used noninvasive Doppler hemodynamic monitoring in a longitudinal study commencing early in pregnancy in 400 nulliparous women. Gestational hypertension developed in 24 women, and 20 developed preeclampsia. Compared with normotensive women, those who developed preeclampsia had significantly elevated cardiac outputs before clinical diagnosis, but total peripheral resistance was not significantly different during this preclinical phase. With clinical preeclampsia, there was a marked reduction in cardiac output and increased peripheral resistance. By contrast, women with gestational hypertension had significantly elevated cardiac outputs before and during the development of clinical hypertension.

Much of the data based upon invasive hemodynamic studies ([Table 24-5](#)) are confounded because (1) women with preeclampsia often have different severity and duration of disease, (2) underlying disease may modify the clinical presentation, or (3) therapeutic interventions may significantly alter these findings. Variables that define cardiovascular status range from high cardiac output with low vascular resistance to low cardiac output with high vascular resistance. Similarly, left ventricular filling pressures, estimated by pulmonary capillary wedge pressure determination, range from low to pathologically high. At least three factors may explain these differences:

1. Women with preeclampsia might present with a spectrum of cardiovascular findings dependent upon both severity and duration.
2. Chronic underlying disease may modify the clinical presentation.
3. Therapeutic interventions may significantly alter these findings.

It is likely that more than one of these is operative.

The studies listed in [Table 24-5](#) are separated into three groups based on clinical management prior to initial hemodynamic observations:

1. No therapy for preeclampsia.
2. Magnesium sulfate and hydralazine without large volumes of intravenous fluid.
3. Magnesium sulfate and hydralazine plus intravenous volume loading.

Ventricular function from the studies listed in [Table 24-5](#) is plotted in [Figure 24-1](#). Cardiac function was hyperdynamic in all women, but filling pressures varied markedly.

Hemodynamic data obtained prior to active treatment of preeclampsia ([Table 24-5](#)) identified normal left ventricular filling pressures, high systemic vascular resistances, and hyperdynamic ventricular function. [Benedetti \(1980a\)](#), [Hankins \(1984\)](#), and their associates reported similar findings in women with severe preeclampsia or eclampsia who were being treated with magnesium sulfate, hydralazine, and intravenous crystalloid given at 75 to 100 mL/hour. Cardiac function in these women was appropriate, and the lower systemic vascular resistance was most likely due to hydralazine treatment.

Women similarly treated with magnesium sulfate and hydralazine plus aggressive intravenous therapy or volume expansion had the lowest systemic vascular resistances and highest cardiac outputs. A comparison of volume restriction with aggressive hydration shows hyperdynamic ventricular function in most women in both groups, and two responses with respect to left ventricular stroke work index and pulmonary capillary wedge pressure ([Fig. 24-2](#)). Fluid restriction resulted in wedge pressures of less than 10 mm Hg, and most were less than 5 mm Hg. Thus, hyperdynamic ventricular function was largely a result of low wedge pressures and not a result of augmented left ventricular stroke work index, which more directly measures myocardial contractility. By comparison, women given appreciably larger volumes of fluid commonly had pulmonary capillary wedge pressures that exceeded normal; however, ventricular function remained hyperdynamic because of increased cardiac output. Subsequently, [Visser and Wallenburg \(1995\)](#) reported findings from 87 women with severe preeclampsia or eclampsia and described high systemic vascular resistance and hyperdynamic ventricular function in most.

From these studies, it is reasonable to conclude that aggressive fluid administration given to women with severe preeclampsia causes normal left-sided filling pressures to become substantively elevated, while increasing an already normal cardiac output to supranormal levels.

BLOOD VOLUME. It has been known for over 75 years that *hemoconcentration* is a hallmark of eclampsia. [Pritchard and co-workers \(1984\)](#) reported that in eclamptic women the normally expected hypervolemia is usually absent ([Table 24-6](#)). Women of average size should have a blood volume of nearly 5000 mL during the last several weeks of a normal pregnancy, compared with about 3500 mL when nonpregnant. With eclampsia, however, much or all of the anticipated 1500 mL of blood normally present late in pregnancy is absent. The virtual absence of an expanded blood volume is likely the consequence of generalized vasoconstriction made worse by increased vascular permeability. In women with preeclampsia, these differences are not as marked, and women with gestational hypertension usually have a normal blood volume ([Silver and Seebeck, 1996](#); [Silver and colleagues, 1998](#)). [Silver and associates \(2001\)](#) presented preliminary data that blood volume is decreased in women homozygous for the T235 angiotensinogen genotype associated with preeclampsia. An acute fall in hematocrit is more likely the consequence of blood loss at delivery in the absence of normal pregnancy hypervolemia; or occasionally it is the result of intense erythrocyte destruction, as described next.

In the absence of hemorrhage, the intravascular compartment in eclamptic women is usually not underfilled. Vasospasm has contracted the space to be filled and the reduction persists until after delivery when the vascular system typically dilates, blood volume increases, and hematocrit falls. **The woman with eclampsia, therefore, is unduly sensitive to vigorous fluid therapy administered in an attempt to expand the contracted blood volume to normal pregnancy levels. She is sensitive as well to even normal blood loss at delivery.** Management of blood loss in these circumstances is considered in [Chapter 25](#).

HEMATOLOGICAL CHANGES

Hematological abnormalities develop in some, but certainly not all, women who develop hypertensive disorders due to pregnancy. Among these are thrombocytopenia, which at times may become so severe as to be life threatening; the level of some plasma clotting factors may be decreased; and erythrocytes may be so traumatized that they display bizarre shapes and undergo rapid hemolysis.

COAGULATION. Subtle changes consistent with intravascular coagulation, and less often erythrocyte destruction, commonly are found with preeclampsia and especially eclampsia ([Baker and Cunningham, 1999](#)). Since the early description by [Pritchard and co-workers \(1954\)](#) of an eclamptic coagulopathy, we have found little evidence that it is clinically significant. As presented in [Table 24-7](#), thrombocytopenia, infrequently severe, was the most common finding. Unless some degree of

placental abruption develops, plasma fibrinogen does not differ remarkably from levels found late in normal pregnancy and fibrin degradation products were elevated only occasionally. [Barron and colleagues \(1999\)](#) found routine laboratory evaluation of coagulation, including prothrombin time, activated partial thromboplastin time, and plasma fibrinogen level, to be unnecessary in the management of pregnancy-associated hypertensive disorders.

The *thrombin time* is somewhat prolonged in a third of the cases of eclampsia even when elevated levels of fibrin degradation products are not identified. The reason for this elevation is not known, but it has been attributed to hepatic derangements discussed subsequently ([Leduc and associates, 1992](#)). The coagulation changes just described are also identified in women with severe preeclampsia, but are certainly no more common. These observations in eclampsia are most consistent with the concept that coagulation changes are the consequence of preeclampsia-eclampsia, rather than the cause.

THROMBOCYTOPENIA. Maternal thrombocytopenia can be induced acutely by preeclampsia-eclampsia. After delivery, the platelet count begins to increase progressively to reach a normal level within 3 to 5 days. The frequency and intensity of maternal thrombocytopenia vary in different studies, apparently dependent upon the intensity of the disease process, the length of delay between the onset of preeclampsia and delivery, and the frequency with which platelet counts are performed. Overt thrombocytopenia, defined by a platelet count less than 100,000/uL, indicates severe disease. In most cases, delivery is indicated because the platelet count continues to decrease.

The cause of thrombocytopenia likely results from platelet activation and consumption at the same time that platelet production is increased. Thrombopoietin, a cytokine that promotes proliferation of platelets from existing megakaryocytes, is increased in preeclamptic women with thrombocytopenia ([Frolich and associates, 1998](#)). In most studies, platelet aggregation is decreased compared with the normal increase seen in pregnancy ([Baker and Cunningham, 1999](#)). This likely is due to platelet "exhaustion" following in vivo activation. While the cause(s) is unknown, immunological processes or simply platelet deposition at sites of endothelial damage may be implicated ([Pritchard and colleagues, 1976](#)). [Samuels and colleagues \(1987\)](#) performed direct and indirect antiglobulin tests and found that platelet-bound and circulating platelet-bindable immunoglobulin were increased in preeclamptic women and their neonates. They interpreted these findings to suggest platelet surface alterations.

The clinical significance of thrombocytopenia, in addition to the obvious impairment in coagulation, is that it reflects the severity of the pathological process. In general, the lower the platelet count, the greater are maternal and fetal morbidity and mortality ([Leduc and co-workers, 1992](#)). The addition of elevated liver enzymes to this clinical picture is even more ominous. [Weinstein \(1982\)](#) referred to this combination of events as the *HELLP¹ syndrome*—that is, hemolysis (H), elevated liver enzymes (EL), and low platelets (LP) (see "Fragmentation Hemolysis" below and "HELLP Syndrome" on p. 579).

NEONATAL THROMBOCYTOPENIA. [Thiagarajah and co-workers \(1984\)](#) and [Weinstein \(1985\)](#) reported thrombocytopenia in neonates whose mothers had preeclampsia. Conversely, [Pritchard and colleagues \(1987\)](#), in a large clinical study, did *not* observe severe thrombocytopenia in the fetus or infant at or very soon after delivery. In fact, no cases of fetal or neonatal thrombocytopenia were identified, despite severe maternal thrombocytopenia. Thrombocytopenia did develop later in some of these infants after hypoxia, acidosis, and sepsis developed. **Hence, maternal thrombocytopenia in hypertensive women is not a fetal indication for cesarean delivery.**

FRAGMENTATION HEMOLYSIS. Thrombocytopenia that accompanies severe preeclampsia and eclampsia may be accompanied by evidence of erythrocyte destruction characterized by hemolysis, schizocytosis, spherocytosis, reticulocytosis, hemoglobinuria, and occasionally hemoglobinemia ([Pritchard and colleagues, 1954, 1976](#)). These derangements result in part from microangiopathic hemolysis, and human and animal studies are suggestive that intense vasospasm causes endothelial disruption, with platelet adherence and fibrin deposition. [Cunningham and associates \(1985\)](#) described erythrocyte morphological characteristics using scanning electron microscopy. Women with eclampsia, and to a lesser degree those with severe preeclampsia, demonstrated schizocytosis and echinocytosis but not spherocytosis when compared with normally pregnant women. [Sanchez-Ramos and colleagues \(1994a\)](#) described increased erythrocyte membrane fluidity in women with *HELLP¹* syndrome and postulated that these changes predispose to hemolysis. [Grisaru and associates \(1997\)](#) have shown that erythrocytic membrane changes may facilitate the hypercoagulable state.

OTHER CLOTTING FACTORS. A severe deficiency of any of the soluble coagulation factors is very uncommon in severe preeclampsia-eclampsia unless another event coexists that predisposes to consumptive coagulopathy, such as placental abruption or profound hemorrhage due to hepatic infarction.

Antithrombin III has been reported to be lower in women with preeclampsia compared with normally pregnant women and those with chronic hypertension ([Chang and co-workers, 1992](#)). Unfortunately, early hope that antithrombin III levels could be used to predict the future development of preeclampsia and separate chronic hypertensive women from those with preeclampsia has not proven to be true ([Sen and colleagues, 1994](#)). *Fibronectin*, a glycoprotein associated with vascular endothelial cell basement membrane, is elevated in women with preeclampsia ([Brubaker and colleagues, 1992](#)). This observation is consistent with the view that preeclampsia causes vascular endothelial injury with subsequent hematological aberrations.

A number of clotting factor deficiencies or mutations lead to hypercoagulability that may be associated with early-onset preeclampsia. These are termed *thrombophilias* and are discussed in [Chapter 49 \(p. 1330\)](#).

ENDOCRINE AND METABOLIC CHANGES

ENDOCRINE CHANGES. Plasma levels of *renin*, *angiotensin II*, and *aldosterone* are increased during normal pregnancy. Hypertensive disorders due to pregnancy result in a decrease of these values toward the normal nonpregnant range ([Weir and colleagues, 1973](#)). With sodium retention, hypertension, or both, renin secretion by the juxtaglomerular apparatus decreases. Because renin catalyzes the conversion of angiotensinogen to angiotensin I (which is then transformed into angiotensin II by converting enzyme), angiotensin II levels decline, resulting in a decrease in aldosterone secretion. Despite this, women with preeclampsia avidly retain infused sodium ([Brown and colleagues, 1988b](#)).

Another potent mineralocorticoid, deoxycorticosterone (DOC), is increased strikingly in third-trimester plasma ([Chap. 8, p. 194](#)). This does not result from increased maternal adrenal secretion, but from conversion from plasma progesterone. Thus, it is not reduced by sodium retention or hypertension, and it may serve to explain why women with preeclampsia retain sodium.

Vasopressin levels are normal despite decreased plasma osmolality ([Durr and Lindheimer, 1999](#)). As discussed in [Chapter 8 \(p. 177\)](#), *atrial natriuretic peptide* increases slightly during normal pregnancy. This peptide is released upon atrial wall stretching that results from blood volume expansion. It is vasoactive and promotes sodium and water excretion likely by inhibiting aldosterone, renin activity, angiotensin II, and vasopressin. Atrial natriuretic peptide is further increased in women with preeclampsia ([Gallery and Lindheimer, 1999](#)). Increases in atrial natriuretic peptide following volume expansion result in comparable increases in cardiac output and decreases in peripheral vascular resistance in both normotensive and preeclamptic women ([Nisell and associates, 1992](#)). This observation may in part explain observations of a fall in peripheral vascular resistance following volume expansion in preeclamptic women.

FLUID AND ELECTROLYTE CHANGES. Commonly, the volume of *extracellular fluid*, manifest as edema, in women with severe preeclampsia-eclampsia has expanded beyond the normally increased volume that characterizes pregnancy. The mechanism responsible for the pathological expansion is not clear. Women with endothelial injury—manifest by significant proteinuria—have reduced plasma oncotic pressure which creates a filtration imbalance, displacing intravascular fluid into the surrounding interstitium.

Electrolyte concentrations do not differ appreciably in women with preeclampsia compared with those of normal pregnancy unless there has been vigorous diuretic therapy, sodium restriction, or administration of water with sufficient oxytocin to produce antidiuresis. Edema does not ensure a poor prognosis, and absence of edema does not ensure a favorable outcome.

Following an eclamptic convulsion, the *bicarbonate* concentration is lowered due to lactic acid acidosis and compensatory respiratory loss of carbon dioxide. The intensity of acidosis relates to the amount of lactic acid produced and its metabolic rate, as well as the rate at which carbon dioxide is exhaled.

KIDNEY

During normal pregnancy, renal blood flow and glomerular filtration rate are increased appreciably ([Chap. 8, p. 186](#)). With development of preeclampsia, renal perfusion and glomerular filtration are reduced. Levels that are much below normal nonpregnant values are the consequence of severe disease. Plasma uric acid concentration is typically elevated, especially in women with more severe disease. The elevation exceeds the reduction in glomerular filtration rate and creatinine clearance that accompanies preeclampsia ([Chesley and Williams, 1945](#)).

In the majority of preeclamptic women, mild to moderately diminished glomerular filtration appears to result from a reduced plasma volume resulting in plasma creatinine values approximately twice those expected for normal pregnancy of about 0.5 mg/dL. In some cases of severe preeclampsia, however, renal involvement is profound, and plasma creatinine may be elevated several times over nonpregnant normal values or up to 2 to 3 mg/dL. This is likely due to intrinsic renal changes caused by severe vasospasm ([Pritchard and colleagues, 1984](#)). [Lee and associates \(1987\)](#) reported normal ventricular filling pressures in seven severely preeclamptic women with oliguria, and concluded that this was consistent with intrarenal vasospasm. In most, urine sodium concentration was elevated abnormally, also suggesting an intrinsic renal etiology. Urine osmolality, urine:plasma creatinine ratio, and fractional excretion of sodium were also indicative that a prerenal mechanism was involved. *Importantly, intensive intravenous fluid therapy was not indicated for these women with oliguria.* When dopamine was infused into oliguric preeclamptic women, this renal vasodilator caused increased urine output, fractional sodium excretion, and free water clearance ([Kirshon and co-workers, 1988](#)).

[Taufield and associates \(1987\)](#) reported that preeclampsia is associated with diminished urinary excretion of calcium because of increased tubular reabsorption. This mechanism would explain the decreased calcium excretion in hypertensive pregnant women.

After delivery, in the absence of underlying chronic renovascular disease, complete recovery of renal function usually can be anticipated. This would not be the case, of course, if *renal cortical necrosis*, an irreversible but rare lesion, develops ([Sibai and associates, 1990](#); also see [Chap. 47, p. 1266](#)).

PROTEINURIA. There should be some degree of proteinuria to establish the diagnosis of preeclampsia-eclampsia. Because proteinuria develops late, however, some women may be delivered before it appears. [Meyer and colleagues \(1994\)](#) emphasized that 24-hour urine excretion should be measured. They found that a urinary dipstick of 1+ proteinuria or greater was predictive of at least 300 mg per 24 hours in 92 percent of cases. Conversely, trace or negative proteinuria had a negative predictive value of only 34 percent in hypertensive women. Urine dipstick values of 3+ to 4+ were positively predictive of severe preeclampsia in only 36 percent of cases.

Albuminuria is an incorrect term to describe proteinuria of preeclampsia. As with any other glomerulopathy, there is increased permeability to most large-molecular-weight proteins; thus, abnormal albumin excretion is accompanied by other proteins, such as hemoglobin, globulins, and transferrin. Normally, these large protein molecules are not filtered by the glomerulus, and their appearance in urine signifies a glomerulopathic process. Some of the smaller proteins that usually are filtered but reabsorbed are also detected in urine.

ANATOMICAL CHANGES. Changes identifiable by light and electron microscopy are commonly found in the kidney. [Sheehan \(1950\)](#) observed that the glomeruli were enlarged by about 20 percent. The capillary loops variably are dilated and contracted. The endothelial cells are swollen, and deposited within and beneath them are fibrils that have been mistaken for thickening of the basement membrane.

Most electron microscopy studies of renal biopsies are consistent with glomerular capillary endothelial swelling. These changes, accompanied by subendothelial deposits of protein material, were called *glomerular capillary endotheliosis* by [Spargo and associates \(1959\)](#). The endothelial cells are often so swollen that they block or partially block the capillary lumens. Homogeneous deposits of an electron-dense substance are found between basal lamina and endothelial cells and within the cells themselves. On the basis of immunofluorescent staining, [Lichtig and co-workers \(1975\)](#) identified deposited fibrinogen or its derivatives in 13 of 30 renal biopsy specimens from women with preeclampsia. [Kincaid-Smith \(1991\)](#) found that these deposits disappear progressively in the first week postpartum.

Renal tubular lesions are common in women with eclampsia, but what has been interpreted as degenerative changes may represent only an accumulation within cells of protein reabsorbed from the glomerular filtrate. The collecting tubules may appear obstructed by casts from derivatives of protein, including, at times, hemoglobin.

Acute renal failure from *tubular* necrosis may develop. Such kidney failure is characterized by oliguria or anuria and rapidly developing azotemia (approximately 1 mg/dL increase in serum creatinine per day). Although this is more common in neglected cases, it is invariably induced by hypovolemic shock, usually associated with hemorrhage at delivery, for which adequate blood replacement is not given ([Chap. 47, p. 1266](#)). [Haddad and colleagues \(2000\)](#) reported that 5 percent of 183 women with hemolysis, elevated liver enzymes, and thrombocytopenia—**HELLP¹ syndrome**—developed acute renal failure. Moreover, half of these also had a placental abruption, and most had postpartum hemorrhage. Rarely, *renal cortical necrosis* develops when the major portion of the cortex of both kidneys undergoes necrosis. Renal cortical necrosis is irreversible, and although it develops in nonpregnant women and in men, the lesion has most often been associated with pregnancy.

LIVER

With severe preeclampsia, at times there are alterations in tests of hepatic function and integrity, including delayed excretion of bromosulfophthalein and elevation of serum aspartate aminotransferase levels ([Combes and Adams, 1972](#)). Severe hyperbilirubinemia is uncommon even with severe preeclampsia ([Pritchard and colleagues, 1976](#)). Much of the increase in serum alkaline phosphatase is due to heat-stable alkaline phosphatase of placental origin. [Oosterhof and co-workers \(1994\)](#) described increased hepatic artery resistance using Doppler sonography in 37 women with preeclampsia.

Periportal hemorrhagic necrosis in the periphery of the liver lobule is the most likely reason for increased serum liver enzymes ([Fig. 24-3](#)). Such extensive lesions are seldom identified in nonfatal cases with liver biopsy ([Barton and colleagues, 1992](#)). Bleeding from these lesions may cause *hepatic rupture*, or they may extend beneath the hepatic capsule and form a *subcapsular hematoma*. Such hemorrhages without rupture may be more common than previously suspected. Using computed tomography, [Manas and colleagues \(1985\)](#) showed that five of seven women with preeclampsia and upper abdominal pain had hepatic hemorrhage ([Fig. 24-4](#)). Prompt surgical intervention may be life saving. [Rinehart and co-workers \(1999\)](#) reviewed 121 cases of spontaneous hepatic rupture associated with preeclampsia, and the mortality rate was 30 percent. One woman at Parkland Hospital survived hepatic rupture after receiving blood and blood products from more than 200 donors. [Hunter and co-workers \(1995\)](#) described a similar woman in whom liver transplant was considered life saving.

HELLP¹ SYNDROME. Liver involvement in preeclampsia-eclampsia is serious and is frequently accompanied by evidence of other organ involvement, especially the kidney and brain, along with hemolysis and thrombocytopenia ([De Boer and co-workers, 1991](#); [Pritchard and associates, 1954](#); [Weinstein, 1985](#)). This is commonly referred to as **HELLP¹ syndrome**—*H*emolysis, *E*levated liver enzymes, and *L*ow Platelets. The Memphis group identified this constellation in almost 20 percent of women with severe preeclampsia or eclampsia ([Sibai and co-workers, 1993b](#)). Five of the 437 women died. In 13 of 33 women (40 percent) with laboratory evidence of HELLP syndrome and severe right upper quadrant pain, they found evidence of a subcapsular hematoma using imaging studies ([Barton and Sibai, 1996](#)). From the same group, [Audibert and associates \(1996\)](#) cited other complications, including placental abruption (7 percent), acute renal failure (2 percent), pulmonary edema (6 percent), and subcapsular liver hematoma (1 percent). [Isler and co-authors \(1999\)](#) have identified factors contributing to the death of 54 women with the HELLP syndrome, and these are shown in [Figure 24-5](#).

Adverse outcomes in subsequent pregnancies are increased in women with **HELLP¹ syndrome**. [Sibai and colleagues \(1995\)](#) observed a 3 percent incidence of recurrence of HELLP syndrome in 192 subsequent pregnancies, and [Sullivan and associates \(1994\)](#) found this to be 27 percent. Both groups confirmed a high incidence of recurrent preeclampsia, preterm delivery, fetal growth restriction, placental abruption, and cesarean delivery.

BRAIN

Central nervous system manifestations of preeclampsia, and especially the convulsions of eclampsia, have been long known. In particular, visual symptoms have received much attention. The earliest description of brain involvement came from gross and histological examination, but with modern noninvasive techniques, imaging and Doppler studies have added new insight into cerebrovascular involvement.

ANATOMICAL PATHOLOGY. Two distinct but related types of cerebral pathology include gross hemorrhages due to ruptured arteries caused by severe hypertension. These can be seen in any woman with gestational hypertension, and preeclampsia is not necessary for their development. These complications are more common with underlying chronic hypertension ([Chap. 45](#)).

The other lesions, variably demonstrated with preeclampsia, but likely universal with eclampsia, are more widespread and seldom fatal. The principal postmortem cerebral lesions are edema, hyperemia, focal anemia, thrombosis, and hemorrhage. [Sheehan \(1950\)](#) examined the brains of 48 eclamptic women very soon after death, and hemorrhages, ranging from petechiae to gross bleeding, were found in 56 percent. According to Sheehan, if the brain is examined within an hour after death, most often it is as firm as normal, and there is no obvious edema. This correlates with our findings that only 10 of 175 eclamptic women had evidence for cerebral edema ([Cunningham and Twickler, 2000](#)).

In another anatomical study, [Govan \(1961\)](#) concluded that cerebral hemorrhage was the cause of death in 39 of 110 fatal cases of eclampsia. In 40 of 47 women who died of cardiorespiratory failure, small cerebral hemorrhagic lesions were also found. A regular finding was fibrinoid changes in the walls of cerebral vessels. The lesions sometimes appeared to have been present for some time, as judged from the surrounding leukocytic response and hemosiderin-pigmented macrophages.

These findings are consistent with the view that prodromal neurological symptoms and convulsions may be related to these lesions.

NEUROIMAGING STUDIES. The earliest abnormal imaging studies emerged with the use of computed tomographic scanning. In the earliest report from Parkland Hospital, [Brown and colleagues \(1988a\)](#) found that nearly half of eclamptic women studied had abnormal radiological findings. The most common were hypodense areas in the cerebral cortex, which corresponded to the petechial hemorrhages and infarction sites described at autopsy by [Sheehan and Lynch \(1973\)](#). While providing valuable insight to their number and locations, these studies did not answer the question concerning the cause of these localized areas of edema. It was still unknown if they were due to ischemic necrosis or hyperperfusion. The advent of magnetic resonance imaging allowed better resolution, but again the basic cause was not elucidated. For example, in another study from Parkland Hospital, [Morris and colleagues \(1997\)](#) confirmed remarkable changes, especially in the area of the posterior cerebral artery.

These findings help to provide an explanation of why some women with preeclampsia convulse but others do not. The brain, like the liver and kidney, appears to be more involved in some women than in others. The extent and location of ischemic and petechial subcortical lesions likely influences the incidence of eclampsia. Their extent also explains more worrisome neurological complications such as blindness or coma. Recent findings indicate that these symptoms represent a continuum of involvement.

BLINDNESS. Although visual disturbances are common with severe preeclampsia, blindness, either alone or accompanying convulsions, is not. Most women with varying degrees of *amaurosis* are found to have radiographic evidence of extensive occipital lobe hypodensities. An example is shown in [Figure 24-6](#) and is likely an exaggeration of the lesions described earlier. Over a 14-year period, we described 15 women with severe preeclampsia or eclampsia who also had blindness ([Cunningham and associates, 1995](#)). This persisted for 4 hours to 8 days, but in all it resolved completely.

Retinal artery vasospasm may also be associated with visual disturbances ([Ohno and colleagues, 1999](#)). Fortuitously, [Belfort and associates \(1992\)](#) showed that a 6-g bolus of magnesium sulfate caused retinal artery vasodilation. *Retinal detachment* may also cause altered vision, although it is usually one sided and seldom causes total visual loss as in some women with cortical blindness. Surgical treatment is seldom indicated; prognosis is good, and vision usually returns to normal within a week.

CEREBRAL EDEMA. Central nervous system manifestations from more widespread cerebral edema are worrisome. In some cases, obtundation and confusion are major features, and symptoms wax and wane. In a few cases, overt coma develops. Prognosis for these latter women is guarded and brainstem herniation is a serious complication.

During a 13-year period, we identified 10 of 175 eclamptic women at Parkland Hospital who had symptomatic cerebral edema ([Cunningham and Twickler, 2000](#)). Their symptoms ranged from lethargy, confusion, and blurred vision to obtundation and coma. Mental status changes correlated with the degree of involvement seen with computed tomographic and magnetic resonance imaging studies ([Fig. 24-7](#)). Three women with generalized cerebral edema were comatose and had impending transtentorial herniation on imaging studies and one of these died from herniation. It seems reasonable that this degree of involvement is related to both ischemic (cytotoxic) as well as hyperperfusion (vasogenic) edema. Conversely, [Apollon and co-workers \(2000\)](#) used single-photon-emission computed tomography and provided evidence for hyperperfusion and vasogenic (hydrostatic) edema.

CEREBRAL BLOOD FLOW. As discussed, it is not known precisely what effects preeclampsia or eclampsia have on cerebral blood flow. [Williams and Wilson \(1999\)](#) used transcranial Doppler ultrasonography to study cerebral blood flow in six women with severe preeclampsia and in three women with eclampsia. Preeclampsia was associated with increased cerebral perfusion pressure counterbalanced by increased cerebrovascular resistance with no net change in cerebral blood flow. In eclampsia, and presumably due to loss of autoregulation of cerebral blood flow manifest as decreased vascular resistance, there was cerebral hyperperfusion similar to that seen in hypertensive encephalopathy unrelated to pregnancy. [Belfort and colleagues \(1999\)](#) also used transcranial Doppler ultrasound to estimate cerebral perfusion pressure in the middle cerebral artery in 79 preeclamptic women with and without headache. Women with headaches were more likely to have abnormal cerebral perfusion (either increased or decreased) than those without headaches. Those women with severe headaches tended to have high cerebral perfusion. Another important finding was that cerebral perfusion pressure may be normal in one hemisphere and very disordered in the other.

This evidence suggests that women with preeclampsia have cerebral vasospasm characterized by high or low cerebral perfusion pressure which varies from one hemisphere to the other. Women who develop eclampsia, however, ostensibly have suffered a transient loss of cerebral vascular autoregulation. This conclusion is also supported by evidence of widespread low-density areas confirmed by computed tomographic and magnetic resonance imaging ([Cunningham and Twickler, 2000](#)). According to [Apollon and co-workers \(2000\)](#), hyperperfusion likely causes vasogenic edema. [Brackley and colleagues \(2000\)](#) attributed cerebral vasospasm in preeclamptic women to increased cerebral arterial wall stiffness and vasoconstriction.

ELECTROENCEPHALOGRAPHY. Nonspecific *electroencephalographic abnormalities* can usually be demonstrated for some time after eclamptic convulsions. [Sibai and colleagues \(1985a\)](#) observed that 75 percent of 65 eclamptic women had abnormal electroencephalograms within 48 hours of seizures. Half of these abnormalities persisted past 1 week, but most were normal by 3 months. An increased incidence of electroencephalographic abnormalities has been described in family members of eclamptic women, a finding suggestive that some eclamptic women have an inherited predisposition to convulse ([Rosenbaum and Maltby, 1943](#)).

UTEROPLACENTAL PERFUSION

Compromised placental perfusion from vasospasm is almost certainly a major culprit in the genesis of increased perinatal morbidity and mortality associated with preeclampsia. For example, [Brosens and associates \(1972\)](#) reported that the mean diameter of myometrial spiral arterioles of 50 normal pregnant women was 500 μ m. The same measurement in 36 women with preeclampsia was 200 μ m. Attempts to measure human maternal and placental blood flow have been hampered by several obstacles, including inaccessibility of the placenta, the complexity of its venous effluent, and the unsuitability of certain investigative techniques for humans.

INDIRECT METHODS. [Everett and colleagues \(1980\)](#) presented evidence that the clearance rate of dehydroisoandrosterone sulfate through placental conversion to estradiol-17 β was an accurate reflection of maternal placental perfusion. [Fritz and colleagues \(1985\)](#) reported that the technique paralleled uteroplacental perfusion in primates. Normally, as pregnancy advances, this measurement increases greatly. The placental clearance rate decreases before the onset of overt hypertension ([Worley and associates, 1975](#)). Finally, placental clearance is decreased in women given diuretics or hydralazine ([Gant and co-workers, 1976](#)).

DOPPLER VELOCIMETRY. Doppler measurement of blood velocity through uterine arteries has been used to estimate uteroplacental blood flow ([Chap. 41, p. 1133](#)). Vascular resistance is estimated by comparing arterial systolic and diastolic velocity waveforms. [Ducey and associates \(1987\)](#) described systolic-diastolic velocity ratios from both uterine and umbilical arteries in 136 pregnancies complicated by hypertension. Among 51 women considered to have preeclampsia, 20 percent had normal umbilical artery velocity ratios; 15 percent had normal umbilical but abnormal uterine artery ratios; and in 40 percent both ratios were abnormal. [Fleischer and colleagues \(1986\)](#) and [Trudinger and associates \(1990\)](#) have also reported increased systolic-diastolic ratios in uterine arteries of women with preeclampsia. Others have not confirmed this ([Hanretty and colleagues, 1988](#)). These studies, in the aggregate, can be interpreted to imply that only a few women with preeclampsia have compromised uteroplacental circulations.

HISTOLOGICAL CHANGES IN THE PLACENTAL BED. [Hertig \(1945\)](#) identified in preeclamptic pregnancies a lesion of uteroplacental arteries characterized by prominent lipid-rich foam cells. [Zeek and Assali \(1950\)](#) termed this *acute atherosclerosis* ([Fig. 24-8](#)). Most investigators are now in accord that there is a lesion, but they do not agree on its precise nature. Classically, in normal pregnancy, spiral arteries are invaded by endovascular trophoblast ([Fig. 24-9](#)). It seems that, in preeclampsia, decidual vessels, but not myometrial vessels, are invaded by endovascular trophoblasts. Using electron microscopy studies of arteries taken from the uteroplacental implantation site, [De Wolf and co-workers \(1980\)](#) reported that early preeclamptic changes included endothelial damage, insudation of plasma constituents into vessel walls, proliferation of myointimal cells, and medial necrosis. They also found that lipid accumulates first in myointimal cells and then in macrophages. [Madazli and colleagues \(2000\)](#) showed that the magnitude of defective trophoblastic invasion of the spiral arteries correlated with the severity of the hypertensive disorder.

PATHOPHYSIOLOGY

In 1903, and in some ways remarkably prescient as will be surmised in reading this section, J. Whitridge Williams reported on the pathophysiology of preeclampsia as follows:

The present status of the question may therefore be summarized as follows: The clinical history and anatomical findings afford presumptive evidence that the disease is due to the circulation of some poisonous substance in the blood which gives rise to thrombosis in many of the smaller vessels, with consequent degenerative necrosis in the various organs.

Any satisfactory theory on the pathophysiology of preeclampsia must account for the observation that hypertensive disorders due to pregnancy are very much more likely to develop in the woman who:

1. Is exposed to chorionic villi for the first time.
2. Is exposed to a superabundance of chorionic villi, as with twins or hydatidiform mole.
3. Has preexisting vascular disease.
4. Is genetically predisposed to hypertension developing during pregnancy.

Although chorionic villi are essential, they need not support a fetus or be located within the uterus. An overview of the pathophysiology to be considered in this section is shown in [Figure 24-10](#).

Vasospasm is basic to the pathophysiology of preeclampsia-eclampsia. This concept, first advanced by [Volhard \(1918\)](#), is based upon direct observations of small blood vessels in the nail beds, ocular fundi, and bulbar conjunctivae, and it has been surmised from histological changes seen in various affected organs ([Hinselmann, 1924](#); [Landesman and co-workers, 1954](#)). Vascular constriction causes resistance to blood flow and accounts for the development of arterial hypertension. It is likely that vasospasm itself also exerts a damaging effect on vessels. Moreover, angiotensin II causes endothelial cells to contract. These changes likely lead to endothelial cell damage and interendothelial cell leaks through which blood constituents, including platelets and fibrinogen, are deposited subendothelially ([Brunner and Gavras, 1975](#)). These vascular changes, together with local hypoxia of the surrounding tissues, presumably lead to hemorrhage, necrosis, and other end-organ disturbances that have been observed at times with severe preeclampsia. With this scheme, fibrin deposition is then likely to be prominent, as seen in fatal cases ([McKay, 1965](#)).

INCREASED PRESSOR RESPONSES. Normally pregnant women develop refractoriness to infused vasopressors ([Abdul-Karim and Assali, 1961](#)). Increased vascular reactivity to pressors in women with early preeclampsia has been identified by [Raab and co-workers \(1956\)](#) and [Talledo and associates \(1968\)](#) using either norepinephrine or angiotensin II, and by [Dieckmann and Michel \(1937\)](#) and [Browne \(1946\)](#) using vasopressin.

[Gant and co-workers \(1973\)](#) demonstrated that increased vascular sensitivity to angiotensin II clearly preceded the onset of pregnancy-induced hypertension. As shown in [Figure 24-11](#), nulliparas who remained normotensive were refractory to the pressor effect of infused angiotensin II, while women who subsequently became hypertensive lost this refractoriness weeks before the onset of hypertension. Of women who required more than 8 ng/kg/min of angiotensin II to provoke a standardized pressor response between 28 and 32 weeks, 90 percent remained normotensive throughout pregnancy. Conversely, among normotensive nulliparas who required less than 8 ng/kg/min at 28 to 32 weeks, 90 percent subsequently developed overt hypertension. Women with underlying chronic hypertension have almost identical responses ([Gant and colleagues, 1977](#)).

PROSTAGLANDINS. Based on the findings of a number of studies, it has been concluded that the blunted pressor response described earlier is due principally to decreased vascular responsiveness mediated in part by vascular endothelial synthesis of prostaglandins or prostaglandin-like substances ([Cunningham and associates, 1975](#); [Gant and co-workers, 1974a](#)). For example, refractoriness to angiotensin II in pregnant women is abolished by large doses of the prostaglandin synthase inhibitors ([Everett and colleagues, 1978](#)).

The exact mechanism by which prostaglandin(s) or related substances mediate vascular reactivity during pregnancy is unknown. From a number of observations, there is evidence that compared with normal pregnancy, prostacyclin production is decreased significantly and thromboxane A₂ significantly increased in preeclampsia ([Walsh, 1985](#)). Thus, in preeclamptic women, thromboxane is increased and prostacyclin and prostaglandin E₂ are decreased, resulting in vasoconstriction and sensitivity to infused angiotensin II.

[Spitz and colleagues \(1988\)](#) reported that 81 mg of aspirin given daily to future hypertensive women restored angiotensin II refractoriness by suppressing synthesis of thromboxane A₂ by about 75 percent; however, prostacyclin synthesis was decreased by only 20 percent and prostaglandin E₂ by 30 percent. These observations indicate that vessel reactivity may be mediated through a delicate balance of production and metabolism of these vasoactive prostaglandins. In this scheme, preeclampsia may follow inappropriately increased production or destruction of one prostaglandin, diminished synthesis or release of the other, or perhaps both. Unfortunately, these observations were not beneficial in clinical studies discussed subsequently.

NITRIC OXIDE. Previously termed *endothelium-derived relaxing factor (EDRF)*, nitric oxide is synthesized by endothelial cells from L-arginine ([Palmer and associates, 1988](#)). It is a potent vasodilator whose absence or decreased concentration might play a role in the etiology of hypertensive disorders due to pregnancy. Its production appears to be increased in severe preeclampsia ([Benedetto and associates, 2000](#)). Withdrawal of nitric oxide from some pregnant animals results in the development of a clinical picture similar to preeclampsia ([Conrad and Vernier, 1989](#); [Weiner and associates, 1989](#)). Inhibition of nitric oxide has been shown to increase mean arterial pressure, decrease heart rate, and reverse the pregnancy-induced refractoriness to vasopressors in some animals. Equally important, it appears to maintain the normal low-pressure vasodilated state characteristic of fetoplacental perfusion in the human ([Chang and colleagues, 1992](#); [Myatt and co-workers, 1992](#); [Weiner and associates, 1992](#)). Decreased nitric oxide release or production *has not been shown to develop prior to the onset of hypertension* ([Anumba and colleagues, 1999](#)). Thus, the changes in nitric oxide concentrations in women with hypertensive disorders due to pregnancy appear to be the consequence of hypertension and not the inciting event ([Morris and colleagues, 1996](#)).

ENDOTHELINS. These polypeptides are potent vasoconstrictors, and endothelin-1 is the only species produced by human endothelium ([Mastrogiannis and co-workers, 1991](#)). Plasma endothelin-1 is increased in normotensive laboring and nonlaboring women, and even higher levels have been reported in preeclamptic women ([Clark, 1992](#); [Nova, 1991](#); [Schiff, 1992](#), and their associates). [Otani and colleagues \(1991\)](#), however, did not observe increased plasma endothelin levels, and [Barton and associates \(1993\)](#) did not find increased urinary endothelin-1 levels in preeclamptic women.

VASCULAR ENDOTHELIAL GROWTH FACTOR. This is a glycosylated glycoprotein that is selectively mitogenic for endothelial cells. Vascular endothelial growth factor (VEGF) is important in vasculogenesis and control of microvascular permeability and has been identified in the human placenta. Serum levels of VEGF² increase in the first half of pregnancy concurrent with trophoblast and uterine vascular events characteristic of pregnancy. VEGF has been reported to be increased in serum from women with preeclampsia ([Baker and associates, 1995](#)). [Simmons and co-workers \(2000\)](#) studied uteroplacental vascular resistance, measured with Doppler ultrasound, and placental VEGF in pregnant women with and without preeclampsia. They found an increase in VEGF parallel to increased uteroplacental vessel resistance in women with preeclampsia. They concluded that increased placental VEGF may represent a compensatory mechanism attempting to restore uteroplacental blood flow toward normal.

GENETIC PREDISPOSITION. The tendency for preeclampsia-eclampsia is inherited. [Chesley and Cooper \(1986\)](#) studied the sisters, daughters, granddaughters, and daughters-in-law of eclamptic women delivered at the Margaret Hague Maternity Hospital from 1935 to 1984. They concluded that preeclampsia-eclampsia is highly heritable, and that the single-gene model, with a frequency of 0.25, best explained their observations. A multifactorial inheritance was also considered possible. [Kilpatrick and associates \(1989\)](#), but not [Hayward and co-workers \(1992\)](#), reported an association between the histocompatibility antigen HLA-DR4 and proteinuric hypertension. [Hoff and associates \(1992\)](#) concluded that a maternal humoral response directed against fetal anti-HLA-DR immunoglobulin antibody might influence the development of gestational hypertension.

[Cooper and Liston \(1979\)](#) examined the possibility that susceptibility to preeclampsia is dependent upon a single recessive gene. They calculated the expected first-pregnancy frequencies of daughters of women with eclampsia; daughters-in-law served as controls. The frequencies calculated by them and those actually observed by [Chesley and co-workers \(1968\)](#) in daughters and daughters-in-law of women with eclampsia are remarkably close. [Ward and associates \(1993\)](#) reported that women carrying the angiotensinogen gene variant T235 had a higher incidence of hypertensive disorders due to pregnancy. [Morgan and colleagues \(1995\)](#), however, could not confirm these findings. [Morgan and colleagues \(1999\)](#) subsequently showed that spiral arteries obtained at 8 weeks' gestation in women homozygous for the angiotensinogen gene failed to undergo the remodeling characteristic of normal implantation. They hypothesized that the failure to undergo such normal remodeling of the spiral arteries may predispose these women to preeclampsia. Inherited thrombophilias, discussed in [Chapter 49](#), predispose some women—either heterozygotes or homozygotes depending on the factor—to these syndromes.

IMMUNOLOGICAL FACTORS. The risk of hypertensive disorders due to pregnancy is appreciably enhanced in circumstances where formation of blocking antibodies to antigenic sites on the placenta *might* be impaired. This may arise where effective immunization by a previous pregnancy is lacking, as in first pregnancies; or where the number of antigenic sites provided by the placenta is unusually great compared with the amount of antibody, as with multiple fetuses ([Beer, 1978](#)). [Strickland and associates \(1986\)](#), however, provided data that do not support "immunization" by a previous pregnancy. They analyzed the outcomes of over 29,000 pregnancies at

Parkland Hospital and reported that hypertensive disorders were decreased only slightly (22 versus 25 percent) in women who previously had miscarried (and thus were "immunized") and were now having their first baby. The immunization concept is supported by the observation that preeclampsia develops more frequently in multiparous women impregnated by a new consort ([Trupin and colleagues, 1996](#)).

[Dekker and Sibai \(1998\)](#) have reviewed the possible role of immune maladaptation in the pathophysiology of preeclampsia. Beginning in the early second trimester, women destined to develop preeclampsia have a significantly lower proportion of T-helper cells compared with women who remain normotensive ([Bardequez and associates, 1991](#)). Antibodies against endothelial cells have been found in 50 percent of women with preeclampsia versus 15 percent of normotensive controls ([Rappaport and colleagues, 1990](#)). Immunological pathogenesis of acute atherosclerosis shown in [Figure 24-8](#) has also been suggested because of the morphological similarities to lesions seen in allograft rejection ([Labarrere, 1988](#)).

INFLAMMATORY FACTORS. [Redman and colleagues \(1999\)](#) have proposed that the endothelial cell dysfunction associated with preeclampsia can result from a "generalized perturbation of the normal, generalized maternal intravascular inflammatory adaptation to pregnancy" ([Fig. 24-10](#)). In this hypothesis, preeclampsia is considered a disease due to an extreme state of activated leukocytes in the maternal circulation ([Faas and colleagues, 2000](#); Gervasi and co-workers, 2001).

The decidua contains an abundance of cells that, when activated, can release noxious agents ([Staff and colleagues, 1999](#)). These then serve as mediators to provoke endothelial cell injury ([Fig. 24-10](#)). [Dekker and Sibai \(1998\)](#) have reviewed this aspect of the pathophysiology of hypertensive disorders due to pregnancy.

Briefly, cytokines, to include tumor necrosis factor-alpha (TNF- α) and the interleukins, may contribute to the oxidative stress associated with preeclampsia. In this scheme, oxygen-free radicals lead to the formation of self-propagating lipid peroxides that in turn propagate highly toxic radicals which, in turn, injure endothelial cells. Such injury modifies endothelial cell production of nitric oxide, as well as interfering with prostaglandin balance. Other consequences of oxidative stress include production of the lipid-laden macrophage foam cells characteristics of atherosclerosis ([Fig. 24-8](#)), activation of microvascular coagulation (thrombocytopenia), and increased capillary permeability (edema and proteinuria). These observations on the effects of oxidative stress in preeclampsia have given rise to increased interest in the potential benefit of antioxidant therapy given for the prevention of hypertensive disorders due to pregnancy. Antioxidants are a diverse family of components that function to prevent overproduction of and damage caused by noxious free radicals. Examples of antioxidants include vitamins E (a-tocopherol) and C (ascorbic acid) and β -carotene. Dietary supplementation with these antioxidants is discussed on page 590.

ENDOTHELIAL CELL ACTIVATION. Prevailing evidence is that endothelial cell activation is the centerpiece in the contemporary understanding of the pathogenesis of preeclampsia ([Fig. 24-10](#)). In this scheme, preeclampsia is an immunologically mediated deficiency in trophoblastic invasion of spiral arteries that leads to fetoplacental hypoperfusion. This results in the release of a factor(s) into the maternal circulation. These changes in turn provoke "activation" of the vascular endothelium, with the clinical syndrome of preeclampsia resulting from widespread changes in endothelial cell function ([Hayman and associates, 2000](#); [Ness and Roberts, 1996](#); [Roberts, 2000](#); [Walker, 2000](#)). Intact endothelium has anticoagulant properties and blunts the response of vascular smooth muscle to agonists. Damaged endothelium, on the other hand, activates endothelial cells to promote coagulation, and increases sensitivity to vasopressor agents.

Further evidence of endothelial activation in preeclampsia includes the characteristic changes in glomerular capillary endothelial morphology, increased capillary permeability, and elevated blood levels of substances associated with such activation (see preceding section). Serum from preeclamptic women stimulates cultured endothelial cells to produce greater amounts of prostacyclin than serum from normotensive controls. Hyperhomocysteinemia is of interest in preeclampsia because elevated levels in men and nonpregnant women are an independent risk factor for atherosclerosis, which is very similar to implantation-site atherosclerosis ([Rogers and colleagues, 1999](#)). [Cotter and colleagues \(2001\)](#) have presented preliminary data that elevated serum homocysteine levels in early pregnancy increase preeclampsia risk threefold. Conversely, [Laivuori and associates \(2000\)](#) found no increased risk in carriers of the T677 allele for methylenetetrahydrofolate reductase.

PREDICTION AND PREVENTION

PREDICTION

A variety of biochemical and biophysical markers, based primarily on rationales implicated in the pathology and pathophysiology of hypertensive disorders due to pregnancy, have been proposed for the purpose of predicting the development of preeclampsia later in pregnancy. Investigators have attempted to identify early markers of faulty placentation, reduced placental perfusion, endothelial cell dysfunction, and activation of coagulation. Virtually all these attempts have resulted in testing strategies with low sensitivity for the prediction of preeclampsia. [Friedman and Lindheimer \(1999\)](#) concluded in their review that, at the present time, there are no screening tests for preeclampsia that are reliable, valid, and economical. [Stamilio and colleagues \(2000\)](#) reached a similar conclusion. Selected tests for prediction of preeclampsia are discussed in the following section.

ANGIOTENSIN II INFUSION. In this test, angiotensin II is infused in a stepwise fashion until there is a 20 mm Hg rise in diastolic blood pressure. Women requiring less than 8 ng/kg/min of angiotensin II had a positive-predictive value (true positive) of developing preeclampsia of 20 to 40 percent ([Friedman and Lindheimer, 1999](#)). While quite good when compared with other tests for prediction, angiotensin II infusion is difficult to perform and is therefore not used clinically.

ROLL-OVER TEST. A hypertensive response induced by having the woman assume the supine position after lying laterally recumbent was demonstrated in some pregnant women by [Gant and colleagues \(1974b\)](#). The majority of nulliparous women at 28 to 32 weeks who had increased diastolic pressure of at least 20 mm Hg when the maneuver ("roll-over test") was performed, later developed hypertension due to pregnancy. Conversely, most women whose blood pressure did not become elevated when this was done remained normotensive. Women who demonstrated a positive roll-over test were also abnormally sensitive to infused angiotensin II. It is hypothesized that a positive test result is a manifestation of increased vascular reactivity or sympathetic overactivity in women who will develop hypertension later in pregnancy. Using preeclampsia, rather than gestational hypertension as the end point, the positive-predictive value (true positive) was 33 percent, which is similar to that of the angiotensin infusion test ([Dekker and colleagues, 1990](#)).

URIC ACID. Elevated uric acid levels in maternal blood, presumably due to decreased renal urate excretion, are frequently found in women with preeclampsia. [Jacobson and colleagues \(1990\)](#) studied 135 pregnant women to determine if plasma uric acid levels, determined at 24 weeks' gestation, might predict the subsequent development of preeclampsia. Values exceeding 5.9 mg/dL were considered predictive. The positive-predictive value (true positive) for this test was 33 percent. It is unlikely that uric acid levels will prove very useful in predicting development of preeclampsia later in pregnancy given the observation that such levels have not even proven to be useful in differentiating established gestational hypertension from preeclampsia ([Lim and co-authors, 1998](#)).

CALCIUM METABOLISM. Alterations in calcium metabolism as well as deficiencies in dietary intake of calcium have been implicated in the pathophysiology of preeclampsia. Hypocalciuria has been identified with preeclampsia ([Taufield and co-authors, 1987](#)). Several investigators have thus performed studies to determine if midpregnancy urinary calcium levels might predict the development of preeclampsia. [Sanchez-Ramos and colleagues \(1991\)](#) measured 24-hour urinary calcium excretion in 103 nulliparous women between 10 and 24 weeks. The sensitivity in predicting preeclampsia was 88 percent and the positive-predictive value was 32 percent.

URINARY KALLIKREIN EXCRETION. Kallikrein is an important regulator of blood pressure, and it has been hypothesized its diminished excretion might precede the development of preeclampsia. Although [Millar and colleagues \(1996\)](#) found the predictive value of this test to be very good (sensitivity 83 percent, 91 percent positive-predictive value), others have not confirmed these findings ([Kyle and associates, 1996](#)).

FIBRONECTIN. There are many reports describing plasma fibronectin levels in women with impending or established preeclampsia. Endothelial cell injury, a centerpiece in the hypothesized pathophysiology of preeclampsia discussed previously, is the presumed source of elevated cellular fibronectin levels found in women with established hypertensive disease ([Brubaker and associates, 1992](#)). For example, [Halligan and colleagues \(1994\)](#) reported that fibronectin levels were elevated in the first trimester in women destined to develop preeclampsia. [Paarlberg and colleagues \(1998\)](#) measured plasma fibronectin levels during the second trimester in 347 healthy nulliparous women to predict hypertensive disorders due to pregnancy. The sensitivity of this test was low (69 percent) as was the positive-predictive value (12 percent).

COAGULATION ACTIVATION. Thrombocytopenia and abnormalities of platelet function (aggregation) appear to be an integral feature of preeclampsia. Excessive platelet activation has been linked to maternal vasoconstriction, endothelial cell injury, placental infarction (atherosis and fetal growth restriction), and transient renal dysfunction. Platelet activation also leads to thromboxane A₂ release, which promotes vasospasm, further platelet aggregation, and endothelial cell injury. Thromboxane from platelets increases the thromboxane/prostacyclin ratio in women with preeclampsia ([Fitzgerald and colleagues, 1987](#)). This finding formed the basis for the concept that prophylactic administration of low-dose aspirin might prevent preeclampsia (see later discussion).

Clearly, the platelet count can be substantially decreased in women with severe preeclampsia. Platelet volume increases due to platelet consumption and resultant

production of relatively younger (and therefore larger) platelets. [Ahmed and associates \(1993\)](#) found that high platelet volumes may be a marker of impending preeclampsia. Similarly, fibrinolytic activity is normally decreased in pregnancy due to increased plasminogen activator inhibitors (PAI) 1 and 2. In preeclampsia, PAI³-1 is increased relative to PAI-2, and it may be a marker of endothelial cell dysfunction ([Caron and colleagues, 1991](#)).

MARKERS OF OXIDATIVE STRESS. Increased levels of lipid peroxides coupled with decreased activity of antioxidants in women with preeclampsia has raised the possibility that markers of oxidative stress might prove useful in the prediction of preeclampsia ([Walsh, 1994](#)). Possible markers include malondialdehyde lipid peroxidation ([Hubel and co-authors, 1989](#)); a variety of pro-oxidants or potentiators of pro-oxidants such as iron ([Herbert and colleagues, 1994](#)); homocysteine ([Cotter and associates, 2001](#); [Powers and colleagues, 2000](#)); blood lipids to include triglycerides, free fatty acids, and lipoproteins ([Hubel and colleagues, 1996](#)); and antioxidants to include ascorbic acid and vitamin E ([Mikhail and colleagues, 1994](#)).

The decrease in prostaglandin synthesis described earlier has been reported to be detectable as early as the first trimester in women destined to develop preeclampsia. However, measuring prostacyclin metabolites in urine presents significant technical problems. Other prostaglandin isomers, for example, 8-isoprostane, a potent vasoconstrictor and a result of lipid peroxidation, has been also studied as a potential marker of impending preeclampsia ([Regan and Fitzgerald, 1997](#)).

IMMUNOLOGICAL FACTORS. Cytokines are protein messengers released by immune cells that serve to regulate the function of other immune cells and are produced by macrophages and lymphocytes at the interface of trophoblast and decidua. There are at least 50 cytokines, to include interleukins, interferons, growth factors, and tumor necrosis factors. Several of these cytokines have been found to be elevated in women with preeclampsia and are of interest as possible markers for the development of preeclampsia ([Benyo, 2000](#); [Dudley, 1996](#); [Greer, 1994](#); [Kupferminc, 1994](#), and all their colleagues).

PLACENTAL PEPTIDES. A variety of peptides produced by the placenta are of interest as possible markers for the prediction of preeclampsia. Examples include corticotropin-releasing hormone ([Petraglia and colleagues, 1996](#)), chorionic gonadotropin ([Ashour and colleagues, 1997](#)), and activin A and inhibin A ([Aquilina and co-authors, 1999](#); [Cuckle and associates, 1998](#); [Muttukrishna and colleagues, 1997](#)). Inhibin A and activin A appear to be particularly promising in the search for early pregnancy markers for the development of preeclampsia ([Lindheimer and Woodruff, 1997](#)).

DOPPLER VELOCIMETRY OF THE UTERINE ARTERIES. Uteroplacental vascular resistance can be assessed by Doppler ultrasound ([Chap. 41, p. 1133](#)). This has prompted studies to use Doppler measurements of uterine artery impedance in the second trimester as an early screening test for preeclampsia ([Bewley and colleagues, 1991](#); [Chappell and Bewley, 1998](#)). The rationale for this is based upon the presumption that the pathophysiology of preeclampsia includes impaired trophoblastic invasion of the spiral arteries leading to obstruction in uteroplacental blood flow. [Bower and colleagues \(1993\)](#) screened 2026 pregnant women at 18 to 22 weeks using continuous-wave Doppler. Those women with increased uterine artery resistance (13 percent) underwent repeat testing using color Doppler at 24 weeks. The sensitivity of this two-stage test for prediction of preeclampsia was 78 percent, but the positive-predictive value was only 28 percent ([Friedman and Lindheimer, 1999](#)). [Irion and associates \(1998\)](#) found uterine artery Doppler velocimetry to be an unreliable screening test for preeclampsia in low-risk pregnancies. Clearly, none of the tests for prediction of preeclampsia described in this section are ideal.

PREVENTION

A variety of strategies have been used in attempts to prevent preeclampsia. Usually these strategies involve manipulation of diet and pharmacological attempts to modify the pathophysiological mechanisms thought to play a role in the development of preeclampsia. The latter includes use of low-dose aspirin and antioxidants.

DIETARY MANIPULATION. One of the earliest efforts aimed at preventing preeclampsia was salt restriction during pregnancy ([De Snoo, 1937](#)). The first randomized trial, however, was not published until [1998 \(Knuist and colleagues\)](#). In this study of 361 women, prescribing a sodium-restricted diet was proven to be ineffective in preventing hypertensive disorders due to pregnancy.

Based primarily upon studies outside the United States, women with low dietary calcium were found to be at significantly increased risk for developing hypertension due to pregnancy ([Belizan and Villar, 1980](#); [Lopez-Jaramillo and associates, 1989](#); [Marya and colleagues, 1987](#)). This has led to at least 14 randomized trials and resultant meta-analysis that showed calcium supplementation during pregnancy resulted in a significant reduction in blood pressure as well as prevention of preeclampsia ([Bucher and colleagues, 1996](#)). The apparently definitive study, however, was completed by [Levine and co-workers \(1997\)](#). This was a randomized trial sponsored by the National Institute of Child Health and Human Development. In this trial, using double-masking, 4589 healthy nulliparous women were randomly administered either 2 g per day of supplemental calcium or placebo. Supplemental calcium did not prevent any of the hypertensive disorders due to pregnancy, including gestational hypertension or preeclampsia.

Other dietary manipulations that have been tested for the purpose of preventing preeclampsia include administering four to nine capsules containing fish oil each day ([Olsen and colleagues, 2000](#)). This dietary supplement was chosen in an effort to modify the prostaglandin balance implicated in the pathophysiology of preeclampsia. Fish oil was ineffective in this study of 1474 pregnancies conducted at 19 hospitals in Europe.

LOW-DOSE ASPIRIN. In [1986, Wallenburg and co-workers](#) reported their experiences with either 60 mg of aspirin or placebo given to angiotensin-sensitive primigravid women at 28 weeks' gestation. The reduced incidence of preeclampsia in the treated group was attributed to selective suppression of thromboxane synthesis by platelets and sparing of endothelial prostacyclin production. As a result of this report and others with similar results, multicenter randomized trials have been completed in both low-risk and high-risk women in the United States as well as in other countries ([Caritis, 1998](#); [CLASP Collaborative Group, 1994](#); [Hauth, 1993](#); [Sibai, 1993a](#), and their many colleagues). These trials have consistently shown that low-dose aspirin was ineffective in preventing preeclampsia. [Hauth and colleagues \(1998\)](#) in a secondary analysis of the high-risk intervention trial by [Caritis and co-workers \(1998\)](#), showed that administration of low-dose aspirin significantly reduced maternal thromboxane B₂ levels, but that this was without benefit because the incidence of preeclampsia was not decreased compared with placebo.

ANTIOXIDANTS. Sera of normal pregnant women contain antioxidant mechanisms that function to control lipid peroxidation which have been implicated in endothelial cell dysfunction associated with preeclampsia. [Davidge and co-authors \(1992\)](#) have shown that sera of women with preeclampsia have markedly reduced antioxidant activity. [Schiff and colleagues \(1996\)](#) tested the hypothesis that diminished antioxidant activity is involved in preeclampsia by studying dietary consumption as well as plasma concentration of vitamin E in 42 pregnancies complicated by preeclampsia compared with 90 controls. They found high plasma vitamin E levels in women with preeclampsia, but that the dietary vitamin E consumption was unrelated to preeclampsia. They speculated that the high vitamin E levels they observed were a response to the oxidative stress of preeclampsia.

[Chappell and associates \(1999\)](#) performed the first systematic study designed to test the hypothesis that treatment of pregnant women with antioxidants would alter endothelial cell injury linked to preeclampsia. A total of 283 women at risk for preeclampsia were randomized at 18 to 22 weeks' gestation to treatment with antioxidants or placebo. Antioxidant therapy significantly reduced endothelial cell activation, suggesting that such therapy might indeed be beneficial in the prevention of preeclampsia. There was also a significant reduction in the incidence of preeclampsia in those women given vitamins C and E compared with the control group (17 versus 11 percent, $P < .02$). A larger trial must be performed before concluding that such antioxidant therapy prevents preeclampsia.

MANAGEMENT

Basic management objectives for any pregnancy complicated by preeclampsia are:

1. Termination of pregnancy with the least possible trauma to mother and fetus.
2. Birth of an infant who subsequently thrives.
3. Complete restoration of health to the mother.

In certain cases of preeclampsia, especially in women at or near term, all three objectives are served equally well by induction of labor. **Therefore, the most important information that the obstetrician has for successful management of pregnancy, and especially a pregnancy that becomes complicated by hypertension, is precise knowledge of the age of the fetus.**

EARLY PRENATAL DETECTION

Traditionally, the timing of prenatal examinations has been scheduled at intervals of 4 weeks until 28 weeks, and then every 2 weeks until 36 weeks, and weekly

thereafter. Increased prenatal visits during the third trimester facilitates early detection of preeclampsia. Women with overt hypertension (= 140/90 mm Hg) are frequently admitted to the hospital for 2 to 3 days to evaluate the severity of new-onset pregnancy hypertension. Those with persistent severe disease are observed closely and many are delivered. Conversely, women with mild disease are often managed as outpatients.

Management of women without overt hypertension, but in whom early preeclampsia is suspected during routine prenatal visits, is primarily based upon increased surveillance. The protocol used successfully for many years at Parkland Hospital in women during the third trimester and with new-onset diastolic blood pressure readings between 81 and 89 mm Hg or sudden abnormal weight gain (more than 2 pounds per week) includes return visits at 3 to 4 day intervals. Such outpatient surveillance is continued unless overt hypertension, proteinuria, visual disturbances, or epigastric discomfort supervene.

HOSPITAL MANAGEMENT

Hospitalization is considered at least initially for women with new-onset hypertension if there is persistent or worsening hypertension or development of proteinuria. A systematic evaluation is instituted to include the following:

1. Detailed examination followed by daily scrutiny for clinical findings such as headache, visual disturbances, epigastric pain, and rapid weight gain.
2. Weight on admittance and every day thereafter.
3. Analysis for proteinuria on admittance and at least every 2 days thereafter.
4. Blood pressure readings in sitting position with an appropriate-size cuff every 4 hours, except between midnight and morning.
5. Measurements of plasma or serum creatinine, hematocrit, platelets, and serum liver enzymes, the frequency to be determined by the severity of hypertension.
6. Frequent evaluation of fetal size and amniotic fluid volume either clinically or with sonography.

If these observations lead to a diagnosis of severe preeclampsia (Table 24-2), further management is the same as described subsequently for eclampsia.

Reduced physical activity throughout much of the day is beneficial. Absolute bed rest is not necessary, and sedatives and tranquilizers are not prescribed. Ample, but not excessive, protein and calories should be included in the diet. Sodium and fluid intakes should not be limited or forced. Further management depends upon:

1. Severity of preeclampsia, determined by presence or absence of conditions cited.
2. Duration of gestation.
3. Condition of the cervix.

Fortunately, many cases prove to be sufficiently mild and near enough to term that they can be managed conservatively until labor commences spontaneously or until the cervix becomes favorable for labor induction. Complete abatement of all signs and symptoms, however, is uncommon until after delivery. *Almost certainly, the underlying disease persists until after delivery!*

TERMINATION OF PREGNANCY

Delivery is the cure for preeclampsia. Headache, visual disturbances, or epigastric pain are indicative that convulsions are imminent, and oliguria is another ominous sign. Severe preeclampsia demands anticonvulsant and usually antihypertensive therapy followed by delivery. Treatment is identical to that described subsequently for eclampsia. The prime objectives are to forestall convulsions, to prevent intracranial hemorrhage and serious damage to other vital organs, and to deliver a healthy infant.

When the fetus is known or suspected to be preterm, however, the tendency is to temporize in the hope that a few more weeks in utero will reduce the risk of neonatal death or serious morbidity. As discussed, such a policy certainly is justified in milder cases. Assessments of fetal well-being and placental function have been attempted, especially when there is hesitation to deliver the fetus because of prematurity. Most investigators recommend frequent performance of various tests currently used to assess fetal well-being as described by the [American College of Obstetricians and Gynecologists \(1999\)](#). These include the nonstress test or the *biophysical profile*, which are discussed in [Chapter 40 \(p. 1104\)](#). Measurement of the lecithin-sphingomyelin ratio in amniotic fluid may provide evidence of lung maturity. Even when this ratio is less than 2.0, however, respiratory distress may not develop; and if it does, it is usually not fatal ([Chap. 39, p. 1006](#)).

With moderate or severe preeclampsia that does not improve after hospitalization, delivery is usually advisable for the welfare of both mother and fetus. Labor should be induced by intravenous oxytocin. Many clinicians favor preinduction cervical ripening with a prostaglandin or osmotic dilator (see [Chap. 20](#)). Whenever it appears that labor induction almost certainly will not succeed, or attempts at induction of labor have failed, cesarean delivery is indicated for more severe cases.

For a woman near term, with a soft, partially effaced cervix, even milder degrees of preeclampsia probably carry more risk to the mother and her fetus-infant than does induction of labor by carefully monitored oxytocin induction. This is not likely to be the case, however, if the preeclampsia is mild but the cervix is firm and closed, indicating that abdominal delivery might be necessary if pregnancy is to be terminated. The hazard of cesarean delivery may be greater than that of allowing the pregnancy to continue *under close observation* until the cervix is more suitable for induction.

ELECTIVE CESAREAN DELIVERY. Once severe preeclampsia is diagnosed, the obstetrical propensity is for prompt delivery. Induced labor to effect vaginal delivery has traditionally been considered to be in the best interest of the mother. Several concerns, including an unfavorable cervix precluding successful induction of labor, a perceived sense of urgency because of the severity of preeclampsia, and the need to coordinate neonatal intensive care have led some practitioners to advocate cesarean delivery. [Alexander and colleagues \(1999\)](#) reviewed 278 singleton liveborn infants weighing 750 to 1500 g delivered of women with severe preeclampsia at Parkland Hospital. Half of the women had labor induced and the remainder were delivered by cesarean without labor. Induction of labor was not successful in 35 percent of the women in the induced group, but was not harmful to their very low-birthweight infants. Similar results were reported by [Nassar and colleagues \(1998\)](#).

ANTIHYPERTENSIVE DRUG THERAPY

The use of antihypertensive drugs in attempts to prolong pregnancy or modify perinatal outcomes in pregnancies complicated by various types and severities of hypertensive disorders has been of considerable interest.

Drug treatment for early mild preeclampsia has been disappointing ([Table 24-8](#)). [Sibai and associates \(1987a\)](#) performed a well-designed randomized study to evaluate the effectiveness of labetalol and hospitalization compared with hospitalization alone. They evaluated 200 nulliparous women with preeclampsia diagnosed between 26 and 35 weeks. Although women given labetalol had significantly lower mean blood pressure, there were no differences between the groups for mean pregnancy prolongation, gestational age at delivery, or birthweight. The cesarean delivery rates were similar, as were the number of infants admitted to special-care nurseries. **Growth-restricted infants were twice as frequent in women given labetalol compared with those treated by hospitalization alone (19 versus 9 percent).**

At least three other studies have been done to compare either the β -blocking agent, labetalol, or calcium-channel blockers, nifedipine and isradipine, with placebo, and the results are shown in [Table 24-8](#). In none of these studies were any benefits of antihypertensive treatment shown. [Von Dadelszen and associates \(2000\)](#) performed a meta-analysis that included the aforementioned trials for the purpose of determining the relation between fetal growth and antihypertensive therapy. These investigators concluded that treatment-induced decreases in maternal blood pressure may adversely affect fetal growth.

In a somewhat unusual study, [Easterling and colleagues \(1999\)](#) identified 58 women at risk for preeclampsia because they had a high cardiac output at 24 weeks. Cardiac output was measured by Doppler technique and the women were randomized to either prophylactic atenolol or placebo. The incidence of preeclampsia was 18 percent in the control group compared with 4 percent in the atenolol group ($P = .04$).

The use of angiotensin-converting-enzyme (ACE) inhibitors during the second and third trimesters of pregnancy should be avoided ([Chap. 38, p. 1014](#)). Reported

complications include oligohydramnios, fetal growth restriction, bony malformations, limb contractures, persistent patent ductus arteriosus, pulmonary hypoplasia, respiratory distress syndrome, prolonged neonatal hypotension, and neonatal death ([Nightingale, 1992](#)). [Lip and colleagues \(1997\)](#) reported that ACE⁴ inhibitors taken during early pregnancy do not carry an adverse outlook as long as these drugs are discontinued as soon as possible.

DELAYED DELIVERY WITH SEVERE PREECLAMPSIA

Women with severe preeclampsia are usually delivered without delay. In recent years, a different approach in the treatment of women with severe preeclampsia remote from term has been advocated by several investigators worldwide ([Many and colleagues, 1999](#)). This approach advocates conservative or "expectant" management in a selected group of women with the aim of improving infant outcome without compromising the safety of the mother. Aspects of such conservative management always include careful daily and more frequent, monitoring of the pregnancy in the hospital with or without use of drugs to control hypertension.

Theoretically, antihypertensive therapy has potential usefulness when preeclampsia severe enough to warrant termination of pregnancy develops before neonatal survival is likely. Such management is controversial, and it may be catastrophic. [Sibai and colleagues \(1985b\)](#) from the University of Tennessee attempted to prolong pregnancy because of fetal immaturity in 60 women with severe preeclampsia diagnosed between 18 and 27 weeks. **The total perinatal mortality rate was 87 percent, and although no mothers died, 13 suffered placental abruption, 10 eclampsia, five consumptive coagulopathy, three renal failure, two hypertensive encephalopathy, one intracerebral hemorrhage, and one a ruptured hepatic hematoma.**

[Sibai and associates \(1994\)](#) subsequently performed a randomized controlled trial of expectant versus aggressive management of severe preeclampsia in 95 women at more advanced gestations of 28 to 32 weeks. Women with HELLP¹ syndrome were specifically excluded from this trial. Aggressive management included glucocorticoid administration for fetal lung maturation followed by delivery in 48 hours. Expectantly managed women were treated with bed rest and either labetalol or nifedipine given orally. Pregnancy was prolonged for a mean of 15.4 days in the expectant management group with an improvement in neonatal outcome. Importantly, 4 percent in each group sustained placental abruption.

In a follow-up nonrandomized study from Memphis, [Abramovici and colleagues \(1999\)](#) compared infant outcomes for deliveries between 24 and 36 weeks in 133 women with HELLP¹ syndrome to 136 women with severe preeclampsia. Women with HELLP syndrome were subdivided into those with hemolysis plus elevated liver enzymes plus low platelets and those with partial HELLP syndrome defined as either one or two, but not three, of these laboratory findings. It was concluded that women with partial HELLP syndrome, as well as those with severe preeclampsia, could be managed expectantly. They also concluded that infant outcomes were related to gestational age rather than the hypertensive disorder per se. As shown in [Table 24-9](#), these women were indeed severely hypertensive and had mean diastolic blood pressures of 110 mm Hg. The distinguishing feature between those with HELLP syndrome appears to be the platelet count: the mean value was 52,000/uL in women with complete HELLP syndrome compared with 113,000/uL in those with partial HELLP syndrome. Gestational age was about 2 weeks more advanced in women with severe preeclampsia compared with those with some degree of HELLP syndrome. Accordingly, neonatal outcomes, in terms of need for mechanical ventilation and neonatal death, were better in women with severe preeclampsia. Fetal growth restriction was not related to the severity of maternal disease and was prevalent in all three groups. Maternal morbidity was not described. However, [Witlin and associates \(2000\)](#) later reported that growth restriction adversely affected infant survival in such infants delivered in Memphis. Most importantly, the median elapsed time from admission to delivery was 0, 1 day, and 2 days for women with HELLP syndrome, partial HELLP syndrome, or severe preeclampsia, respectively.

Taken in toto, these three studies require comment about repeated claims that expectant management of severe preeclampsia and partial HELLP¹ syndrome is beneficial. First, with expectant management, the interval from admission to delivery is very short at their center, particularly in pregnancies managed subsequent to their report claiming efficacy and safety. Second, it seems possible, even likely, that the gestational age difference between severe preeclampsia and HELLP syndrome is related to the timing of onset of the disease itself. That is, HELLP syndrome may develop earlier in pregnancy than severe preeclampsia. Third, fetal growth restriction is prevalent in women with severe disease and it adversely affects infant survival, which is not improved by the severity of maternal disease. Lastly, and most importantly, the authors overlook that the overriding reason to terminate pregnancies with severe preeclampsia is maternal safety. Results in [Table 24-9](#) clearly confirm that severe preeclampsia is deleterious for fetal outcome. Conversely, these data in [Table 24-9](#) do not prove that expectant management is beneficial for the mother.

[Visser and Wallenburg \(1995\)](#) compared clinical outcomes of expectant management in 256 women with severe preeclampsia prior to 34 weeks. Half of these women had HELLP¹ syndrome and the other half had severe preeclampsia. They were able to prolong pregnancy in both groups for 10 to 14 days, but 5 percent had a placental abruption and three women developed eclampsia.

[Hall and colleagues \(2000b\)](#) managed 360 severely preeclamptic women with early-onset preeclampsia—before 34 weeks—by careful observation and blood pressure control. While these women gained a mean duration of 11 days, a fourth had major complications—20 percent had placental abruption, 2 percent pulmonary edema, and 1.2 percent had eclampsia. Reports such as these just cited serve to emphasize that it is prudent for clinicians to be concerned about maternal safety in women with severe hypertensive disorders due to pregnancy before term. We are reluctant to advise clinicians that it is safe to expectantly manage women with persistent severe hypertension or significant hematological, cerebral, or liver abnormalities due to preeclampsia. Such women are not managed expectantly at Parkland Hospital.

GLUCOCORTICOIDS

In attempts to enhance fetal lung maturation, glucocorticoids have been administered to severely hypertensive pregnant women remote from term. Treatment does not seem to worsen maternal hypertension, and a decrease in the incidence of respiratory distress and improved fetal survival has been cited ([Chap. 39, p. 1006](#)). [Thiagarajah and co-authors \(1984\)](#) were the first to suggest that glucocorticoids might also have a role in treatment of the laboratory abnormalities associated with the HELLP¹ syndrome. [Tompkins and Thiagarajah \(1999\)](#) more recently reported that glucocorticoids produced significant but transient improvement in the hematological abnormalities associated with the HELLP syndrome diagnosed upon admission in 52 women between 24 and 34 weeks. While platelet counts increased by an average of 23,000/uL, this salutary effect was short lived, and counts decreased by an average of 46,000/uL within 48 hours after completion of the glucocorticoid regimen. Importantly, few of the women studied had platelet counts less than 100,000/uL before glucocorticoid therapy, and hence, the efficacy of such treatment was not extensively tested in women with more severe hematological abnormalities.

One interpretation of these reports is that such use of glucocorticoids specifically administered as a therapy for the hematological abnormalities due to severe preeclampsia will not significantly delay the need for delivery. Most certainly, these reports should not be taken to imply that it is advisable to administer glucocorticoids to significantly delay delivery in women with severe laboratory abnormalities.

HIGH-RISK PREGNANCY UNIT

An inpatient High-Risk Pregnancy Unit was established at Parkland Hospital in 1973 in large part to provide care for women with hypertensive disorders. Initial results from this Unit were reported by [Hauth \(1976\)](#) and [Gilstrap \(1978\)](#) and their colleagues. The majority of women hospitalized have a salutary response characterized by disappearance or improvement of hypertension. **Importantly, these women are not "cured," because nearly 90 percent have recurrent hypertension before or during labor.** Through 2000, almost 8000 nulliparous women with mild to moderate early-onset hypertension during pregnancy have been successfully managed in the High-Risk Pregnancy Unit. The provider costs (as opposed to charges) for the relatively simple physical facility, modest nursing care, no drugs other than iron and folate supplements, and the very few laboratory tests that are essential, are slight compared with the cost of neonatal intensive care for a preterm infant.

HOME HEALTH CARE

Many clinicians feel that further hospitalization is not warranted if hypertension abates within a few days, and this has legitimized third-party payors in the United States to refuse hospital reimbursement. Thus, many women with mild to moderate hypertension, and without proteinuria, are consequently managed at home. Such management may continue as long as the disease does not worsen and if fetal jeopardy is not suspected. Sedentary activity throughout the greater part of the day is recommended. These women should be instructed in detail about reporting symptoms. Home blood pressure and urine protein monitoring or frequent evaluations by a visiting nurse may be necessary.

[Barton and colleagues \(1994\)](#) managed 592 predominately nulliparous women with mild hypertension in such a manner. They were 24 to 36 weeks at enrollment and a fourth had proteinuria. Gestation was prolonged for a mean of 4 weeks and 60 percent were delivered after 37 weeks. Importantly, half developed severe hypertension and 10 percent had fetal jeopardy. These investigators concluded that in highly motivated women such management produced results similar to inpatient care. [Helewa and associates \(1993\)](#) reached similar conclusions with a home-care program.

In a study from Parkland Hospital, [Horsager and associates \(1995\)](#) randomized 72 nulliparas with new-onset hypertension from 27 to 37 weeks to continued hospitalization or outpatient care. In all of these women, proteinuria had receded to less than 500 mg per day when randomized. Outpatient management included daily blood pressure monitoring by the patient or her family and weight and spot urine protein were determined three times weekly. A home health nurse visited twice weekly and the women were seen weekly in the clinic. Although perinatal outcomes were similar, recurrence of severe preeclampsia was significantly more common in the home group than in hospitalized women (40 versus 25 percent, respectively).

Another approach that has been evaluated on a limited basis is day-care. [Tuffnell and colleagues \(1992\)](#) randomized 54 women with gestational hypertension after 26 weeks to either day-care or routine management by their individual physicians. Hospitalizations, the development of preeclampsia, and labor inductions were significantly increased in the routine management group.

ECLAMPSIA

Preeclampsia that is complicated by generalized tonic-clonic convulsions is termed eclampsia. Fatal coma without convulsions has also been called eclampsia; however, it is better to limit the diagnosis to women with convulsions and to regard deaths in nonconvulsive cases as due to severe preeclampsia. Once eclampsia has ensued, the risk to both mother and fetus is appreciable.

Almost without exception, preeclampsia precedes the onset of eclamptic convulsions. Depending on whether convulsions appear before, during, or after labor, eclampsia is designated as antepartum, intrapartum, or postpartum. Eclampsia is most common in the last trimester and becomes increasingly more frequent as term approaches. In 254 eclamptic women cared for at the University of Mississippi Medical Center, about 3 percent first developed seizures more than 48 hours postpartum ([Miles and colleagues, 1990](#)). Other diagnoses should be considered in women with the onset of convulsions more than 48 hours postpartum.

The convulsive movements usually begin about the mouth in the form of facial twitchings. After a few seconds, the entire body becomes rigid in a generalized muscular contraction. This phase may persist for 15 to 20 seconds. Suddenly the jaws begin to open and close violently, and soon after, the eyelids as well. The other facial muscles and then all muscles alternately contract and relax in rapid succession. So forceful are the muscular movements that the woman may throw herself out of her bed, and, if not protected, her tongue is bitten by the violent action of the jaws ([Fig. 24-12](#)). This phase, in which the muscles alternately contract and relax, may last about a minute. Gradually, the muscular movements become smaller and less frequent, and finally the woman lies motionless. Throughout the seizure the diaphragm has been fixed, with respiration halted. For a few seconds the woman appears to be dying from respiratory arrest, but then she takes a long, deep, stertorous inhalation, and breathing is resumed. Coma then ensues. She will not remember the convulsion or, in all probability, events immediately before and afterward. Over time, these memories return.

The first convulsion is usually the forerunner of others, which may vary in number from one or two in mild cases to even 100 or more in untreated severe cases. In rare instances, convulsions follow one another so rapidly that the woman appears to be in a prolonged, almost continuous convulsion.

The duration of coma after a convulsion is variable. When the convulsions are infrequent, the woman usually recovers some degree of consciousness after each attack. As the woman arouses, a semiconscious combative state may ensue. In very severe cases, the coma persists from one convulsion to another, and death may result before she awakens. In rare instances, a single convulsion may be followed by coma from which the woman may never emerge, although, as a rule, death does not occur until after frequent convulsions.

Respirations after an eclamptic convulsion are usually increased in rate and may reach 50 or more per minute, in response presumably to hypercarbia from lactic acidemia, as well as to varying intensities of hypoxia. Cyanosis may be observed in severe cases. Fever of 39°C or more is a very grave sign, because it is probably the consequence of a central nervous system hemorrhage.

Proteinuria is almost always present and frequently pronounced. Urine output is likely diminished appreciably, and occasionally anuria develops. Hemoglobinuria is common, but hemoglobinemia is observed only rarely. Often, as shown in [Figure 24-13](#), the edema is pronounced—at times, massive—but it may also be absent.

As with severe preeclampsia, after delivery an increase in urinary output is usually an early sign of improvement. Proteinuria and edema ordinarily disappear within a week ([Fig. 24-13](#)). In most cases, blood pressure returns to normal within a few days to 2 weeks after delivery. The longer hypertension persists postpartum, the more likely that it is the consequence of chronic vascular or renal disease ([Table 24-1](#)).

In antepartum eclampsia, labor may begin spontaneously shortly after convulsions ensue and progress rapidly, sometimes before the attendants are aware that the unconscious or stuporous woman is having effective uterine contractions. If the convulsion occurs during labor, contractions may increase in frequency and intensity, and the duration of labor may be shortened. Because of maternal hypoxemia and lactic acidemia caused by convulsions, it is not unusual for fetal bradycardia to follow a seizure ([Fig. 24-14](#)). This usually recovers within 3 to 5 minutes; if it persists more than about 10 minutes, another cause must be considered, such as placental abruption or imminent delivery.

Pulmonary edema may follow eclamptic convulsions. There are at least two sources:

1. Aspiration pneumonitis may follow inhalation of gastric contents if simultaneous vomiting accompanies convulsions.
2. Cardiac failure may be the result of a combination of severe hypertension and vigorous intravenous fluid administration.

In some women with eclampsia, sudden death occurs synchronously with a convulsion or follows shortly thereafter, as the result of a massive cerebral hemorrhage ([Fig. 24-15](#)). Hemiplegia may result from sublethal hemorrhage. Cerebral hemorrhages are more likely in older women with underlying chronic hypertension. Rarely they may be due to a ruptured berry aneurysm or arteriovenous malformation ([Witlin and co-workers, 1997a](#)).

In about 10 percent of women, some degree of blindness will follow a seizure. Blindness may also develop spontaneously with preeclampsia. There are at least two causes:

1. Varying degrees of retinal detachment.
2. Occipital lobe ischemia, infarction, or edema.

Whether due to cerebral or retinal pathology, the prognosis for return of normal vision is good and usually complete within a week ([Cunningham and associates, 1995](#)). About 5 percent of women will have substantively altered consciousness, including persistent coma, following a seizure. This is due to extensive cerebral edema, and transtentorial uncal herniation may cause death ([Cunningham and Twickler, 2000](#)).

Rarely, eclampsia is followed by psychosis, and the woman becomes violent. This usually lasts for several days to 2 weeks, but the prognosis for return to normal is good, provided there was no preexisting mental illness. Chlorpromazine in carefully titrated doses has proved effective in the few cases of post-eclampsia psychosis treated at Parkland Hospital.

DIFFERENTIAL DIAGNOSIS. Generally, eclampsia is more likely to be diagnosed too frequently rather than overlooked, because epilepsy, encephalitis, meningitis, cerebral tumor, cysticercosis, and ruptured cerebral aneurysm during late pregnancy and the puerperium may simulate eclampsia. **Until other such causes are excluded, however, all pregnant women with convulsions should be considered to have eclampsia.**

PROGNOSIS. The prognosis for eclampsia is always serious; this is one of the most dangerous conditions that can afflict a pregnant woman and her fetus. Fortunately, maternal mortality due to eclampsia has decreased in the past three decades from 5 to 10 percent to less than 3 percent of cases ([Eclampsia Trial Collaborative Group, 1995](#); [Mattar and Sibai, 2000](#); [Pritchard and associates, 1984](#)). These experiences clearly underscore that eclampsia, as well as severe preeclampsia, are to be considered overt threats to maternal life. Indeed, 23 percent of maternal deaths recorded in the United States during 1997 were related to pregnancy hypertension and accounted for at least 64 deaths ([Hoyert and colleagues, 1999](#)).

TREATMENT. In 1955 Pritchard initiated a standardized treatment regimen at Parkland Hospital, and this was used through 1999 to manage over 400 women with eclampsia. The carefully analyzed results of treatment of 245 cases of eclampsia were reported by [Pritchard and associates \(1984\)](#). Most eclampsia regimens used in

the United States adhere to a similar philosophy, the tenets of which include:

1. Control of convulsions using an intravenously administered loading dose of magnesium sulfate. This is followed by either a continuous infusion of magnesium sulfate or by an intramuscular loading dose and periodic intramuscular injections.
2. Intermittent intravenous or oral administration of an antihypertensive medication to lower blood pressure whenever the diastolic pressure is considered dangerously high. Some clinicians treat at 100 mm Hg, some at 105 mm Hg, and some at 110 mm Hg.
3. Avoidance of diuretics and limitation of intravenous fluid administration unless fluid loss is excessive. Hyperosmotic agents are avoided.
4. Delivery.

MAGNESIUM SULFATE TO CONTROL CONVULSIONS. In more severe cases of preeclampsia, as well eclampsia, magnesium sulfate administered parenterally is the effective anticonvulsant agent without producing central nervous system depression in either the mother or the infant. It may be given intravenously by continuous infusion or intramuscularly by intermittent injection ([Table 24-10](#)). The dosage schedule for severe preeclampsia is the same as for eclampsia. Because labor and delivery is a more likely time for convulsions to develop, women with preeclampsia-eclampsia usually are given magnesium sulfate during labor and for 24 hours postpartum. **Magnesium sulfate is not given to treat hypertension.**

Based on a number of studies cited subsequently, as well as extensive clinical observations, magnesium most likely exerts a specific anticonvulsant action on the cerebral cortex. Typically, the mother stops convulsing after the initial administration of magnesium sulfate, and within an hour or two regains consciousness sufficiently to be oriented as to place and time.

The magnesium sulfate dosage schedules presented in [Table 24-10](#) usually result in plasma magnesium levels illustrated in [Figures 24-16](#) and [24-17](#). When magnesium sulfate is given to arrest and prevent recurrent eclamptic seizures, about 10 to 15 percent of women will have a subsequent convulsion. An additional 2-g dose of magnesium sulfate in a 20 percent solution is administered slowly intravenously. In a small woman, an additional 2-g dose may be used once, and twice if needed in a larger woman. In only 5 of 245 women with eclampsia at Parkland Hospital was it necessary to use supplementary medication to control convulsions ([Pritchard and associates, 1984](#)). Sodium amobarbital is given slowly intravenously in doses up to 250 mg in women who are excessively agitated in the postconvulsion phase. Thiopental is suitable also. Maintenance magnesium sulfate therapy for eclampsia is continued for 24 hours after delivery. For eclampsia that develops postpartum, magnesium sulfate is administered for 24 hours after the onset of convulsions.

PHARMACOLOGY AND TOXICOLOGY OF MAGNESIUM SULFATE. Magnesium sulfate USP is $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ and not MgSO_4 . Parenterally administered magnesium is cleared almost totally by renal excretion, and magnesium intoxication is avoided by ensuring that urine output is adequate, the patellar or biceps reflex is present, and there is no respiratory depression. Eclamptic convulsions are almost always prevented by plasma magnesium levels maintained at 4 to 7 mEq/L (4.8 to 8.4 mg/dL or 2.0 to 3.5 mmol/L).

When administered as described in [Table 24-10](#), the drug will practically always arrest eclamptic convulsions and prevent their recurrence. The initial intravenous infusion of 4 to 6 g is used to establish a prompt therapeutic level that is maintained by the nearly simultaneous intramuscular injection of 10 g of the compound, followed by 5 g intramuscularly every 4 hours, or by continuous infusion at 2 to 3 g per hour. With these dosage schedules, therapeutically effective plasma levels of 4 to 7 mEq/L are achieved compared with pretreatment plasma levels of less than 2.0 mEq/L.

[Sibai and co-workers \(1984\)](#) performed a prospective study in which they compared continuous intravenous magnesium sulfate and intramuscular magnesium sulfate. There was no significant difference between mean magnesium levels observed after intramuscular magnesium sulfate and those observed following a maintenance intravenous infusion of 2 g per hour ([Fig. 24-17](#)). In our experience many women will require 3-g-per-hour infusions to maintain effective plasma levels of magnesium.

Patellar reflexes disappear when the plasma magnesium level reaches 10 mEq per L (about 12 mg/dL), presumably because of a curariform action. This sign serves to warn of impending magnesium toxicity, because a further increase will lead to respiratory depression.

When plasma levels rise above 10 mEq/L, respiratory depression develops, and at 12 mEq/L or more, respiratory paralysis and arrest follow. [Somjen and co-workers \(1966\)](#) induced in themselves, by intravenous infusion, marked hypermagnesemia, achieving plasma levels up to 15 mEq/L. **Predictably, at such high plasma levels, respiratory depression developed that necessitated mechanical ventilation, but depression of the sensorium was not dramatic as long as hypoxia was prevented.** Treatment with calcium gluconate, 1 g intravenously, along with the withholding of magnesium sulfate usually reverses mild to moderate respiratory depression. Unfortunately, the effects of intravenously administered calcium may be short lived. For severe respiratory depression and arrest, prompt tracheal intubation and mechanical ventilation are life saving. Direct toxic effects on the myocardium from high levels of magnesium are uncommon. It appears that the cardiac dysfunction associated with magnesium is due to respiratory arrest and hypoxia. With appropriate ventilation, cardiac action is satisfactory even when plasma levels are exceedingly high ([McCubbin and colleagues, 1981](#)).

IMPAIRED RENAL FUNCTION. Because magnesium is cleared almost exclusively by renal excretion, plasma magnesium concentration, using the doses described previously, will be excessive if glomerular filtration is decreased substantively. The initial standard dose of magnesium sulfate can be safely administered without knowledge of renal function. Renal function is thereafter estimated by measuring plasma creatinine, and whenever it is 1.3 mg/dL or higher, we give only half of the maintenance intramuscular magnesium sulfate dose outlined in [Table 24-10](#). With this renal impairment dosage, plasma magnesium levels are usually within the desired range of 4 to 7 mEq/L. Whether magnesium sulfate is being given intravenously by continuous infusion, serum magnesium levels are used to adjust the infusion rate. **With either method, when there is renal insufficiency, plasma magnesium levels must be checked periodically.**

Acute cardiovascular effects of parenteral magnesium ion in women with severe preeclampsia have been studied by [Cotton and associates \(1986b\)](#), who obtained data using pulmonary and radial artery catheterization. Following a 4-g intravenous dose given over 15 minutes, mean arterial blood pressure fell slightly, and this was accompanied by a 13 percent increase in cardiac index. Thus, magnesium decreased systemic vascular resistance and mean arterial pressure, and at the same time increased cardiac output, without evidence of myocardial depression. These findings were coincidental with transient nausea and flushing, and the cardiovascular effects persisted for only 15 minutes despite continued infusion of magnesium sulfate at 1.5 g per hour.

[Thurnau and colleagues \(1987\)](#) showed that there was a small but highly significant increase in cerebrospinal fluid magnesium concentration after magnesium therapy for preeclampsia. The magnitude of the increase was directly proportional to the corresponding serum concentration. This increase cannot be due to the disease itself, because cerebrospinal fluid magnesium levels are unchanged in untreated severely preeclamptic women when compared with normotensive controls ([Fong and associates, 1995](#)).

[Lipton and Rosenberg \(1994\)](#) attribute anticonvulsant effects to blocked neuronal calcium influx through the glutamate channel. [Cotton and associates \(1992\)](#) induced seizure activity in the hippocampus region of rats because it is a region with a low seizure threshold and a high density of *N*-methyl-D-aspartate receptors. These receptors are linked to various models of epilepsy. Because hippocampal seizures can be blocked by magnesium, it is believed that this implicated the *N*-methyl-D-aspartate receptor in eclamptic convulsions ([Hallak and colleagues, 1998](#)). Importantly, results such as these suggest that magnesium has a central nervous system effect in blocking seizures.

UTERINE EFFECTS. Magnesium ions in relatively high concentration will depress myometrial contractility both in vivo and in vitro. With the regimen described earlier and the plasma levels that have resulted, no evidence of myometrial depression has been observed beyond a transient decrease in activity during and immediately after the initial intravenous loading dose. Indeed, [Leveno and colleagues \(1998\)](#) compared labor and delivery outcomes in 480 nulliparous women given phenytoin for preeclampsia with outcomes in 425 similar women given magnesium sulfate. Magnesium sulfate did not significantly alter oxytocin stimulation of labor, admission-to-delivery intervals, or route of delivery. Similar results have been reported by others ([Atkinson and associates, 1995](#); [Szal and co-workers, 1999](#); [Witlin and colleagues, 1997b](#)).

The mechanisms by which magnesium might inhibit uterine contractility is not established, but is generally assumed to depend on its effect on intracellular calcium ([Watt-Morse and associates, 1995](#)). The regulatory pathway leading to uterine contraction begins with an increase in the intracellular free Ca^{2+} concentration, which activates myosin light chain kinase ([Mizuki and associates, 1993](#)). High concentrations of extracellular magnesium have been reported not only to inhibit calcium entry into myometrial cells but to also lead to high intracellular magnesium levels.

This latter effect has been reported to inhibit calcium entry into the cell—presumably by blocking calcium channels ([Mizuki and associates, 1993](#)). These mechanisms

for inhibition of uterine contractility appear to be dose dependent because serum magnesium levels of at least 8 to 10 mEq/L are necessary to inhibit uterine contractions ([Watt-Morse and associates, 1995](#)). This likely explains why there is no uterine effect clinically when magnesium sulfate is given for eclampsia treatment or prophylaxis. Specifically, magnesium sulfate when given either intravenously or intramuscularly for preeclampsia or eclampsia, consistently results in serum magnesium levels less than the 8 to 10 mEq/L necessary to inhibit uterine contractility ([Fig. 24-16](#)).

FETAL EFFECTS. Magnesium administered parenterally to the mother promptly crosses the placenta to achieve equilibrium in fetal serum and less so in amniotic fluid ([Hallak and colleagues, 1993](#)). The neonate may be depressed only if there is severe hypermagnesemia at delivery. We have not observed neonatal compromise after therapy with magnesium sulfate ([Cunningham and Pritchard, 1984](#)), nor have [Green and associates \(1983\)](#). Whether magnesium sulfate affects the fetal heart rate pattern, specifically beat-to-beat variability ([Chap. 14, p. 336](#)), is controversial. [Hallak and colleagues \(1999b\)](#), in a randomized investigation comparing an infusion of magnesium sulfate to saline, found that magnesium sulfate was associated with a small but clinically insignificant decrease in variability of the fetal heart rate.

There is a suggestion of a possible protective effect of magnesium against cerebral palsy in very-low-birthweight infants ([Nelson and Grether, 1995](#); [Schendel and colleagues, 1996](#)). [Murphy and colleagues \(1995\)](#) found that preeclampsia, rather than magnesium sulfate, was protective against cerebral palsy in these infants. [Kimberlin and colleagues \(1996\)](#), however, found no advantage of maternal magnesium sulfate tocolysis in infants born weighing less than 1000 g.

CLINICAL EFFICACY OF MAGNESIUM SULFATE THERAPY. In 1995, results were reported from the multinational clinical trial of eclampsia therapy. The [Eclampsia Trial Collaborative Group \(1995\)](#) study was funded in part by the World Health Organization and coordination was provided by the National Perinatal Epidemiology Unit in Oxford, England. This study included 1687 women with eclampsia who were randomly allocated to different anticonvulsant regimens. The primary outcome measures were recurrence of convulsions and maternal deaths. In one study, 453 women were randomized to be given magnesium sulfate and compared with 452 given diazepam. Another 388 eclamptic women were randomized to be given magnesium sulfate and compared with 387 women given phenytoin.

As shown in [Figure 24-18](#), women allocated to magnesium sulfate therapy had a 50 percent reduction in incidence of recurrent seizures compared with those given diazepam. Importantly, as shown in [Table 24-11](#), maternal deaths were reduced in women given magnesium sulfate, and although these differences are clinically impressive, they are not statistically significant. Specifically, there were 3.8 percent deaths in 453 women randomized to magnesium sulfate compared with 5.1 percent of 452 given diazepam. Maternal and perinatal morbidity were not different between these two groups, and there was no difference in the number of labor inductions or cesarean deliveries.

In a second comparison, also shown in [Figure 24-18](#), women randomized to receive magnesium sulfate compared with phenytoin had a 67 percent reduction in recurrent convulsions. As shown in [Table 24-11](#), maternal mortality was lower in the magnesium compared with the phenytoin group (2.6 versus 5.2 percent). This clinically impressive decreased maternal mortality of 50 percent again was not significant statistically.

In other comparisons, women allocated to magnesium sulfate therapy were less likely to be artificially ventilated, to develop pneumonia, and to be admitted to intensive care units than those given phenytoin. Neonates of women given magnesium sulfate were significantly less likely to require intubation at delivery and to be admitted to the neonatal intensive care unit compared with infants whose mothers received phenytoin.

The Collaborative Group concluded: "There is now compelling evidence in favour of magnesium sulfate, rather than diazepam or phenytoin, for the treatment of eclampsia." These results are even more impressive when it is emphasized that women in this study who received intravenous magnesium sulfate received only 1 g per hour!

ANTIHYPERTENSIVE TREATMENT ALONE TO CONTROL SEIZURES. There continues to be a question of whether antihypertensive medications alone can be used to prevent recurrent seizures ([Duley and Johanson, 1994](#); [Ramsay and colleagues, 1994](#)). It is difficult and unwise to recommend withholding magnesium sulfate because even with the excellent results reported using both anticonvulsants and antihypertensive agents in the Collaborative Eclampsia Trial (1995), maternal mortality was still 4.1 percent of 1690 women.

PREVENTION OF ECLAMPSIA. Magnesium sulfate therapy also is superior to phenytoin in preventing eclamptic seizures. [Lucas and colleagues \(1995\)](#) reported results of a prospective study from Parkland Hospital in which women with gestational hypertension were randomized to receive magnesium sulfate or phenytoin during labor. The magnesium sulfate therapy consisted of the intramuscular regimen presented in [Table 24-10](#). The phenytoin regimen consisted of a 1000-mg loading dose infused over a 1-hour period, followed by a 500-mg oral dose 10 hours later. Anticonvulsant therapy in both groups was continued for 24 hours postpartum. Ten of the 1089 women randomly assigned to the phenytoin regimen had eclamptic convulsions. There were no convulsions in the 1049 women given magnesium sulfate ($P = .004$). There were no significant differences in any risk factors for eclampsia between the two groups of women studied. Maternal and neonatal outcomes were similar in the two study groups. Women given phenytoin, and who developed eclampsia, did so despite "therapeutic" serum levels (10 to 25 ug/mL).

Debate still ensues—mostly outside the United States—over whether magnesium sulfate prophylaxis should be given routinely to all women in labor who have hypertension ([Nelson and Grether, 1995](#); [Robson, 1996](#)). [Burrows and Burrows \(1995\)](#) described 467 women with preeclampsia in whom seizure prophylaxis was not given. A total of 3.9 percent developed eclamptic seizures. [Hall and colleagues \(2000a\)](#) reported this to be 1.5 percent in 318 preeclamptic women. This is in contrast to a failure rate of prophylaxis of 1 in 750 women treated with the regimen shown in [Table 24-10](#) and reported by [Cunningham and Leveno \(1988\)](#). The debate hinges primarily on the position of some clinicians that a convulsion due to eclampsia does no immediate great harm to most mothers and fetuses. Presumably, those who embrace this view would reserve magnesium sulfate therapy for only those women who develop eclampsia. There may be, however, other previously unmeasured fetal effects of maternal eclampsia that could justify attempts to prevent as well as treat eclampsia. For example, [Hallak and associates \(1999a\)](#) have reported in experimental animals that maternal seizures were associated with fetal brain injury due to maternal hypoxia during the convulsion. Magnesium sulfate prevented this fetal damage.

The debate currently centers around which preeclamptic women should be given prophylaxis. To assess this, [Coetzee and colleagues \(1998\)](#) randomized 699 South African women with severe preeclampsia to intravenous magnesium sulfate or to saline placebo. Eclampsia developed in 1 of 30 of the women given saline, and although the maternal and fetal outcomes were good, the study was stopped. Benefits of prophylactic magnesium sulfate for women with mild preeclampsia is disputable because the estimated risk of eclampsia is 1 in 100 or less ([Lucas and colleagues, 1995](#)). [Witlin and Sibai \(1998\)](#) recently reviewed the evidence for the efficacy of magnesium sulfate for treatment and prevention of convulsions resulting from hypertensive disorders due to pregnancy. They concluded that although there is little question about the benefits of magnesium sulfate in women with severe preeclampsia and eclampsia, the need for its prophylactic administration to women with mild disease is unclear. We certainly agree that it is prudent to prevent eclampsia in women at high risk for convulsions.

HYDRALAZINE TO CONTROL SEVERE HYPERTENSION. At Parkland Hospital, hydralazine is given intravenously whenever the diastolic blood pressure is 110 mm Hg or higher. Some recommend treatment of diastolic pressures higher than 100 mm Hg and some use 105 mm Hg as a limit ([Cunningham and Lindheimer, 1992](#); [Sibai, 1996](#)). Because precise data are lacking, the Working Group ([National High Blood Pressure Education Program, 2000](#)) recommended the compromise value of persistent systolic pressure greater than or equal to 160 mm Hg and/or diastolic pressure greater than 105 mm Hg.

A number of regimens have been used. Hydralazine is administered in 5- to 10-mg doses at 15- to 20-minute intervals until a satisfactory response is achieved. A satisfactory response antepartum or intrapartum is defined as a decrease in diastolic blood pressure to 90 to 100 mm Hg, but not lower lest placental perfusion be compromised. Hydralazine so administered has proven remarkably effective in the prevention of cerebral hemorrhage. At Parkland Hospital, approximately 8 percent of all women with hypertensive disorders are given hydralazine as described, and we estimate that more than 4000 women have been treated. Seldom was another antihypertensive agent needed because of poor response to hydralazine. In many European centers, hydralazine is also favored ([Redman and Roberts, 1993](#)).

The tendency to give a larger initial dose of hydralazine when the blood pressure is higher must be avoided. The response to even 5- to 10-mg doses cannot be predicted by the level of hypertension; thus we always give 5 mg as the initial dose. An example of very severe hypertension in a woman with chronic hypertension complicated by superimposed eclampsia that responded to repeated intravenous injections of hydralazine is shown in [Figure 24-19](#). Hydralazine was injected more frequently than recommended in the protocol, and blood pressure decreased in less than 1 hour from 240-270/130-150 mm Hg to 110/80 mm Hg. Uteroplacental insufficiency fetal heart rate decelerations were evident when the pressure fell to 110/80 mm Hg, and persisted until maternal blood pressure increased.

LABETALOL. Intravenous labetalol is also used to treat acute hypertension of pregnancy. In 1994, hydralazine was not always available in the United States and more experience was gained with this α_1 - and nonselective β -blocker. [Mabie and associates \(1987\)](#) compared intravenous hydralazine with labetalol for blood pressure control in 60 peripartum women. Labetalol lowered blood pressure more rapidly, and associated tachycardia was minimal, but hydralazine lowered mean arterial pressure to safe levels more effectively. We have evaluated labetalol given intravenously for women with severe preeclampsia and our results are very similar.

Our protocol calls for 10 mg intravenously initially. If the blood pressure has not decreased to the desirable level in 10 minutes, then 20 mg is given. The next 10-minute incremental dose is 40 mg followed by another 40 mg, and then 80 mg if a salutary response is not yet achieved.

The Working Group (2000) recommends starting with a 20-mg intravenous bolus. If not effective within 10 minutes, this is followed by 40 mg, then 80 mg every 10 minutes but not to exceed a 220-mg total dose.

OTHER ANTIHYPERTENSIVE AGENTS. The Working Group recommends **nifedipine** in a 10-mg oral dose to be repeated in 30 minutes if necessary. [Scardo and colleagues \(1996\)](#) gave 10-mg nifedipine orally to 10 women with preeclamptic hypertensive emergencies and reported no hypotension or fetal compromise. [Mabie and colleagues \(1988\)](#) administered nifedipine sublingually to 34 women with peripartum hypertension. Its antihypertensive effects were potent and rapid, and two women developed worrisome hypotension. Similar effects in nonpregnant patients have caused cerebrovascular ischemia, myocardial infarction, conduction disturbances, and death, leading [Grossman and colleagues \(1996\)](#) to call for a moratorium on its use in hypertensive emergencies. [Vermillion and colleagues \(1999\)](#) and [Scardo and co-workers \(1999\)](#) compared nifedipine with labetalol in randomized trials and found neither definitively superior to the other. [Belfort and associates \(1990\)](#) administered the calcium antagonist, **verapamil**, by intravenous infusion at 5 to 10 mg per hour. Mean arterial pressure was lowered by 20 percent. [Belfort and co-workers \(1996\)](#) reported that **nimodipine** given by continuous infusion as well as orally (1998) was effective to lower blood pressure in women with severe preeclampsia. [Bolte and colleagues \(1998\)](#) reported good results in 169 preeclamptic women treated with intravenous **ketanserin**, a selective serotonin₂ receptor blocker.

Nitroprusside is not recommended by the Working Group of the [National High Blood Pressure Education Program \(2000\)](#) unless there is no response to hydralazine, labetalol, or nifedipine. A continuous infusion is begun with a dose of 0.25 ug/kg/min increased as necessary to 5 ug/kg/min. Fetal cyanide toxicity may occur after 4 hours.

PERSISTENT IMMEDIATE SEVERE POSTPARTUM HYPERTENSION. The potential problem of antihypertensive agents causing serious compromise of placental perfusion and fetal well-being is obviated by delivery. If there is a problem after delivery in controlling severe hypertension and intravenous hydralazine or another agent is being used repeatedly early in the puerperium to control persistent severe hypertension, then other regimens can be used. We have had success with intramuscular hydralazine, usually in 10- to 25-mg doses at 4- to 6-hour intervals. Once repeated blood pressure readings remain near normal, hydralazine is stopped.

If hypertension of appreciable intensity persists or recurs *in these postpartum women*, oral labetalol or a thiazide diuretic are given for as long as necessary. A variety of other antihypertensive agents have been utilized for this purpose, including other β -blockers and calcium-channel antagonists. The persistence or refractoriness of hypertension is likely due to at least two mechanisms:

1. Underlying chronic hypertension.
2. Mobilization of edema fluid with redistribution into the intravenous compartment.

Labetalol and a diuretic are effective treatment for both mechanisms.

PLASMA EXCHANGE. Over the years, the group at the University of Mississippi Medical Center has described an atypical syndrome in which severe preeclampsia-eclampsia persists despite delivery. [Martin and associates \(1995\)](#) described 18 such women over a 10-year period during which time they delivered nearly 43,000 patients. They advocate single or multiple plasma exchange for these women and in some cases, 3 L of plasma (representing 12 to 15 donors) were exchanged three times before a response was forthcoming. In our experiences of over 50,000 hypertensive women in nearly 350,000 pregnancies, we have not encountered this syndrome. In a very few women, persistent hypertension, thrombocytopenia, and renal dysfunction was found to be due to thrombotic microangiopathy ([Dashe and colleagues, 1998](#)).

DIURETICS AND HYPEROSMOTIC AGENTS. Potent diuretics further compromise placental perfusion, because their immediate effects include intravascular volume depletion, which most often is already reduced compared with normal pregnancy. Therefore, diuretics are not used to lower blood pressure lest they enhance the intensity of the maternal hemoconcentration and its adverse effects on the mother and the fetus ([Zondervan and co-authors, 1988](#)).

Once delivery is accomplished, in almost all cases of severe preeclampsia and eclampsia there is a spontaneous diuresis that usually begins within 24 hours and results in the disappearance of excessive extravascular fluid over the next 3 to 4 days, as demonstrated in [Figure 24-13](#).

With infusion of hyperosmotic agents, the potential exists for an appreciable intravascular influx of fluid and, in turn, subsequent escape of intravascular fluid in the form of edema into vital organs, especially the lungs and brain. Moreover, an osmotically active agent that leaks through capillaries into lungs and brain promotes accumulation of edema at these sites. Most importantly, a sustained beneficial effect from their use has not been demonstrated. For all of these reasons, hyperosmotic agents have not been administered, and use of furosemide or similar drugs has been limited to the rare instances in which pulmonary edema was identified or strongly suspected.

FLUID THERAPY. Lactated Ringer solution is administered routinely at the rate of 60 mL to no more than 125 mL per hour unless there was unusual fluid loss from vomiting, diarrhea, or diaphoresis, or more likely, excessive blood loss at delivery. Oliguria, common in cases of severe preeclampsia and eclampsia, coupled with the knowledge that maternal blood volume is very likely constricted compared with normal pregnancy, makes it tempting to administer intravenous fluids more vigorously. The rationale for controlled, conservative fluid administration is that the typical eclamptic woman already has excessive extracellular fluid that is inappropriately distributed between the intravascular and extravascular spaces. Infusion of large fluid volumes could and does enhance the maldistribution of extravascular fluid and thereby appreciably increases the risk of pulmonary and cerebral edema ([Sibai and colleagues, 1987b](#)).

PULMONARY EDEMA. Women with severe preeclampsia-eclampsia who develop pulmonary edema most often do so postpartum ([Cunningham and colleagues, 1986](#)). Aspiration of gastric contents, the result of convulsions or perhaps from anesthesia, or oversedation, should be excluded; however, the majority of these women have cardiac failure. Some normal pregnancy changes, magnified by preeclampsia-eclampsia, predispose to pulmonary edema. Importantly, plasma oncotic pressure decreases appreciably in normal term pregnancy because of decreases in serum albumin, and oncotic pressure falls even more with preeclampsia ([Zinaman and associates, 1985](#)). Moreover, [Oian and colleagues \(1986\)](#) described increased extravascular fluid oncotic pressure in preeclamptic women, and this favors capillary fluid extravasation. [Brown and associates \(1989\)](#) verified increased capillary permeability in preeclamptic women. [Bhatia and associates \(1987\)](#) found a correlation between plasma colloid osmotic pressure and fibronectin concentration; this suggested to them that vascular protein loss was the result of increased vascular permeability caused by vessel injury.

The frequent findings of hemoconcentration, as well as the identification of reduced central venous and pulmonary capillary wedge pressures in women with severe preeclampsia, have tempted some investigators to infuse various fluids, starch polymers, or albumin concentrates, or all three, in attempts to expand blood volume and thereby somehow to relieve vasospasm and reverse organ deterioration. Thus far, clear-cut evidence of benefits from this approach is lacking; however, serious complications, especially pulmonary edema, have been reported. [Lopez-Llera \(1982\)](#) reported that vigorous volume expansion was associated with a high incidence of pulmonary edema in more than 700 eclamptic women. [Benedetti and colleagues \(1985\)](#) described pulmonary edema in 7 of 10 severely preeclamptic women who were given colloid therapy. [Sibai and colleagues \(1987b\)](#) cited excessive colloid and crystalloid infusions as causing most of their 37 cases of pulmonary edema associated with severe preeclampsia-eclampsia. Finally, [Lehmann and co-workers \(1987\)](#) reported that pulmonary edema caused nearly a third of maternal deaths due to hypertensive disorders at Charity Hospital in New Orleans.

For these reasons, until it is understood how to contain more fluid within the intravascular compartment and, at the same time, less fluid outside the intravascular compartment, we remain convinced that, in the absence of marked fluid loss, fluids can be administered safely only in moderation. To date, no serious adverse effects have been observed from such a policy. Importantly, dialysis for renal failure was not required for any of the more than 400 cases of eclampsia so managed.

INVASIVE HEMODYNAMIC MONITORING. Much of what has been learned within the past decade about cardiovascular and hemodynamic pathophysiological alterations associated with severe preeclampsia-eclampsia has been made possible by invasive hemodynamic monitoring using a flow-directed pulmonary artery catheter. The need for clinical implementation of such technology for the woman with preeclampsia-eclampsia, however, has not been established. [Gilbert and colleagues \(2000\)](#) recently described a retrospective review of pulmonary artery catheterization in 17 women with eclampsia. Although they found this procedure subjectively "helpful" in clinical management, all of these women had undergone "multiple interventions," including volume expansion, prior to catheterization.

Use of pulmonary-artery catheterization has been reviewed by [Nolan and colleagues \(1992\)](#), [Hankins and Cunningham \(1991\)](#), and [Clark and Cotton \(1988\)](#). Two

conditions frequently cited as indications for such monitoring are preeclampsia associated with oliguria and preeclampsia associated with pulmonary edema. Perhaps somewhat paradoxically, it is usually vigorous treatment of the former that results in most cases of the latter.

Because vigorous intravenous hydration and osmotically active agents are avoided at Parkland Hospital in women with severe preeclampsia and eclampsia, hemodynamic monitoring has not been used for the vast majority of these women. Such measures are usually reserved for women with accompanying severe cardiac disease and/or renal disease or in cases of refractory hypertension, oliguria, and pulmonary edema. Similar indications are used by [Clark and associates \(1997\)](#), [Clark and Cotton \(1988\)](#), [Cowles \(1994\)](#), and [Easterling and co-workers \(1989\)](#), as well as recommended by the [American College of Obstetricians and Gynecologists \(1988, 1996\)](#). The routine use of such monitoring even if pulmonary edema develops is questionable. Most of these women respond quickly to furosemide given intravenously. Afterload reduction with intermittent doses of intravenous hydralazine to lower blood pressure, as described earlier, may also be necessary, because women with chronic hypertension and severe superimposed preeclampsia are more likely to develop heart failure ([Cunningham and colleagues, 1986](#)). Obese women in these circumstances are even more likely to develop heart failure ([Mabie and associates, 1988](#)).

Invasive monitoring should be considered for those women with multiple clinical factors such as intrinsic heart disease and/or advanced renal disease that might cause pulmonary edema by more than one mechanism. This is particularly relevant if pulmonary edema is inexplicable or refractory to treatment. Still, in most of these cases it is not necessary to perform pulmonary artery catheterization for clinical management.

DELIVERY. To avoid maternal risks from cesarean delivery, steps to effect vaginal delivery are employed initially in women with eclampsia. After an eclamptic seizure, labor often ensues spontaneously or can be induced successfully even in women remote from term. An immediate cure does not immediately follow delivery by any route, but serious morbidity is less common during the puerperium in women delivered vaginally.

BLOOD LOSS AT DELIVERY. Hemoconcentration, or lack of normal pregnancy-induced hypervolemia, is an almost predictable feature of severe preeclampsia-eclampsia. **These women, who consequently lack normal pregnancy hypervolemia, are much less tolerant of blood loss than are normotensive pregnant woman.** It is of great importance to recognize that an appreciable fall in blood pressure very soon after delivery most often means excessive blood loss and not sudden dissolution of vasospasm. When oliguria follows delivery, the hematocrit should be evaluated frequently to help detect excessive blood loss that, if identified, should be treated appropriately by careful blood transfusion.

ANALGESIA AND ANESTHESIA

In the past, both spinal and epidural analgesia were avoided in women with severe preeclampsia and eclampsia. Physiological changes leading to these concerns centered on the hypotension induced by sympathetic blockade and, in turn, on dangers from pressor agents or large volumes of intravenous fluid used to correct iatrogenically induced hypotension. For example, rapid infusion of large volumes of crystalloid or colloid, given to counteract maternal hypovolemia caused by a variety of causes, including epidural analgesia, has been implicated as a cause of pulmonary edema ([Sibai and colleagues, 1987b](#)). There have also been concerns about fetal safety because sympathetic blockade-induced hypotension can dangerously lower uteroplacental perfusion ([Montan and Ingemorrsson, 1989](#)). Another concern is that attempts to restore blood pressure pharmacologically with vasopressors may be hazardous because women with preeclampsia are extremely sensitive to such agents.

As regional analgesia techniques were improved during the past decade, epidural analgesia was promoted by some proponents for women with severe preeclampsia to ameliorate vasospasm and lower blood pressure ([Gutsche and Creek, 1993](#)). Moreover, many who favored epidural blockade believed that general anesthesia was inadvisable because stimulation caused by tracheal intubation may result in sudden hypertension, which may cause pulmonary edema, cerebral edema, or intracranial hemorrhage ([Lavies and colleagues, 1989](#)). Others have also cited that tracheal intubation may be particularly hazardous in women with airway edema due to preeclampsia ([Chadwick and Easterling, 1991](#)).

These differing perspectives on the advantages, disadvantages, and safety of the anesthetic method used in the cesarean delivery of women with severe preeclampsia have evolved so that most authorities believe that epidural analgesia is the preferred method. [Wallace and colleagues \(1995\)](#) evaluated these important issues by conducting a randomized investigation in women with severe preeclampsia cared for at Parkland Hospital. There were 80 women with severe preeclampsia who were to be delivered by cesarean and who were randomized to general anesthesia or epidural or combined spinal-epidural analgesia. Their mean preoperative blood pressure was approximately 170/110 mm Hg, and all had proteinuria. Anesthetic and obstetrical management included antihypertensive drug therapy and limited intravenous fluids and other drug therapy. The infants, whose mean gestational age at delivery was 34.8 weeks, all were born in good condition as assessed by Apgar scores and umbilical arterial blood gas determinations. Maternal hypotension resulting from regional analgesia was managed without excessive intravenous fluid administration. Similarly, maternal blood pressure was managed without severe hypertensive effects in women undergoing general anesthesia ([Fig. 24-20](#)). There were no serious maternal or fetal complications attributable to any of the three anesthetic methods. It was concluded that general as well as regional anesthetic methods are equally acceptable for cesarean delivery in pregnancies complicated by severe preeclampsia if steps are taken to ensure a careful approach to either method.

The immense popularity and increasing availability of epidural analgesia for labor has led many anesthesiologists as well as obstetricians to develop the viewpoint that epidural analgesia is an important factor in the intrapartum *treatment* of women with preeclampsia ([Chadwick and Easterling, 1991](#); Ramanatham, 1991). Although epidural analgesia is widely used during labor in women with preeclampsia, the effects of such analgesia on the mother and fetus have not been extensively investigated. In a study by [Lucas and associates \(2001\)](#) from Parkland Hospital, 738 laboring women at 36 weeks or more who had gestational hypertension of varying severity were randomized to epidural analgesia or patient-controlled intravenous meperidine analgesia. Maternal and infant outcomes were similar in the two study groups. As shown in [Table 24-12](#), although epidural analgesia significantly lowered the maternal blood pressure compared with the meperidine-treated group, this provided no significant benefit in terms of preventing severe hypertension later in labor. It was concluded that epidural analgesia during labor was safe for women with pregnancy-associated hypertensive disorders; it should not be misconstrued to be a therapy for hypertension.

These results were similar to those published by the Maternal-Fetal Medicine Units Network of the National Institute of Child Health and Human Development. [Hogg and colleagues \(1999\)](#) performed a retrospective comparison of 327 women with severe hypertension, of whom 209 (65 percent) were given epidural analgesia during labor. There were no significant differences in the cesarean delivery rate or in neonatal outcomes in those given epidural analgesia compared with those not receiving such analgesia. Importantly, 4.3 percent of the women given epidural analgesia developed pulmonary edema, presumably due in part to the intravenous crystalloid required to alleviate epidural-induced hypotension.

[Newsome and colleagues \(1986\)](#) studied the lowered mean arterial pressure that follows epidural blockade in a group of women with severe preeclampsia. Despite decreased blood pressure, the cardiac index did not fall and intravenous fluid loading caused elevation of pulmonary capillary wedge pressures as compared with women in whom fluids were restricted. It is clear that aggressive volume replacement in these women increases their risk for pulmonary edema, especially in the first 72 hours postpartum ([Clark and colleagues, 1985](#); [Cotton and associates, 1986a](#)). When pulmonary edema develops there is also concern for development of cerebral edema. Finally, [Heller and co-workers \(1983\)](#) demonstrated that the majority of cases of pharyngolaryngeal edema seen in women with severe preeclampsia were related to aggressive volume therapy.

LONG-TERM CONSEQUENCES

Women who develop hypertension during pregnancy should be evaluated during the immediate postpartum months and counseled about future pregnancies and also their cardiovascular risk later in life (Working Group of the [National High Blood Pressure Education Program, 2000](#)). As mentioned earlier, the longer hypertension diagnosed during pregnancy persists postpartum, the greater the likelihood that the cause is underlying chronic hypertension. Indeed, the Working Group has taken the position that hypertension attributable to pregnancy must resolve within 12 weeks of delivery. Persistence of hypertension beyond this time is considered evidence of chronic hypertension ([Chap. 45](#)).

Although hypertension during pregnancy is common in occurrence, there are few reports concerning the long-term maternal consequences of hypertensive disorders during pregnancy. Most reports are focused on the risk of recurrence of hypertension during a subsequent pregnancy in women typically ascertained during the first months of such a pregnancy.

COUNSELING FOR FUTURE PREGNANCIES

Women who had preeclampsia are more prone to hypertensive complications in future pregnancies (Working Group of the [National High Blood Pressure Education Program, 2000](#)). Generally the earlier preeclampsia is diagnosed during the index pregnancy, the greater the likelihood of recurrence. For example, [Sibai and colleagues \(1986, 1991\)](#) found that nulliparous women diagnosed to have preeclampsia before 30 weeks have a recurrence risk as high as 40 percent during a

subsequent pregnancy. The recurrence rate for women with one episode of [HELLP¹](#) syndrome is approximately 5 percent ([Sibai and colleagues, 1995](#)). Multiparous women who develop preeclampsia are at increased risk for recurrence of preeclampsia in subsequent pregnancy compared with nulliparas who develop preeclampsia ([Trupin and associates, 1996](#)).

Women with early-onset severe preeclampsia may be at risk for underlying thrombophilias such as factor V Leiden, protein S and C deficiency, and antiphospholipid antibodies, ([Dekker and colleagues, 1995](#); [Kupferminc and associates, 1999](#); [Sibai, 1999](#); [van Pampus and co-workers, 1999](#)). These disorders, discussed in [Chapter 49 \(p. 1330\)](#), not only complicate subsequent pregnancies but also have an impact overall long-term health.

LONG-TERM PROGNOSIS

There is one truly remarkable and unparalleled effort to measure long-term maternal consequences of hypertension due to pregnancy. [Chesley and co-workers \(1976\)](#) identified 270 women with eclampsia delivered at the Margaret Hague Maternity Hospital between 1931 and 1951 and meticulously followed these women through 1974—entailing a follow-up period of up to 43 years in some of the women. As shown in [Table 24-13](#), the long-term cardiovascular prognosis depends on whether eclampsia occurred in nulliparous, compared with multiparous women. [Chesley and co-workers \(1976\)](#) also analyzed the long-term outcome in 54 nulliparous women with eclampsia in their index pregnancy and hypertension again during a subsequent pregnancy compared with 100 eclamptic nulliparous who were normotensive during all subsequent pregnancies. Those with recurrent pregnancy hypertension were at increased risk for chronic hypertension whereas those who remained normotensive during subsequent pregnancies were at decreased risk. Thus, normal blood pressure during subsequent pregnancies serves to define women not at risk for future chronic hypertension. According to the Working Group of the [National High Blood Pressure Education Program \(2000\)](#), women experiencing normotensive births have a reduced risk for remote hypertension. Thus, in some respects, repeated pregnancy serves as a screening test for future hypertension. Finally, and importantly, preeclampsia does not cause chronic hypertension ([Fisher and colleagues, 1981](#)).

TABLE 24-1. Diagnosis of Hypertensive Disorders Complicating Pregnancy

Gestational Hypertension

BP = 140/90 mm Hg for first time during pregnancy

No proteinuria

BP return to normal < 12 weeks' postpartum

Final diagnosis made only postpartum

May have other signs of preeclampsia, for example, epigastric discomfort or thrombocytopenia

Preeclampsia

Minimum criteria:

BP = 140/90 mm Hg after 20 weeks' gestation

Proteinuria = 300 mg/24 hours or = 1+ dipstick

Increased certainty of preeclampsia:

BP = 160/110 mm Hg

Proteinuria 2.0 g/24 hours or = 2+ dipstick

Serum creatinine > 1.2 mg/dL unless known to be previously elevated

Platelets < 100,000/mm³

Microangiopathic hemolysis (increased LDH)

Elevated ALT or AST

Persistent headache or other cerebral or visual disturbance

Persistent epigastric pain

Eclampsia

Seizures that cannot be attributed to other causes in a woman with preeclampsia

Superimposed Preeclampsia (on chronic hypertension)

New-onset proteinuria = 300 mg/24 hours in hypertensive women but no proteinuria before 20 weeks' gestation

A sudden increase in proteinuria or blood pressure or platelet count < 100,000/mm³ in women with hypertension and proteinuria before 20 weeks' gestation

Chronic Hypertension

BP = 140/90 mm Hg before pregnancy or diagnosed before 20 weeks' gestation

or

Hypertension first diagnosed after 20 weeks' gestation and persistent after 12 weeks' postpartum

ALT = alanine aminotransferase; AST = aspartate aminotransferase; BP = blood pressure; LDH = lactate dehydrogenase.

TABLE 24-10. Magnesium Sulfate Dosage Schedule for Severe Preeclampsia and Eclampsia

Continuous Intravenous Infusion

1. Give 4- to 6-g loading dose of magnesium sulfate diluted in 100 mL of IV fluid administered over 15-20 min.
2. Begin 2 g/h in 100 mL of IV maintenance infusion.
3. Measure serum magnesium level at 4-6 h and adjust infusion to maintain levels between 4 and 7 mEq/L (4.8-8.4 mg/dL).
4. Magnesium sulfate is discontinued 24 h after delivery.

Intermittent Intramuscular Injections

1. Give 4 g of magnesium sulfate ($MgSO_4 \cdot 7H_2O$ USP) as a 20% solution intravenously at a rate not to exceed 1 g/min.
2. Follow promptly with 10 g of 50% magnesium sulfate solution, one-half (5 g) injected deeply in the upper outer quadrant of both buttocks through a 3-inch-long, 20-gauge needle. (Addition of 1.0 mL of 2% lidocaine minimizes discomfort.) If convulsions persist after 15 min, give up to 2 g more intravenously as a 20% solution at a rate not to exceed 1 g/min. If the woman is large, up to 4 g may be given slowly.
3. Every 4 h thereafter give 5 g of a 50% solution of magnesium sulfate injected deeply in the upper outer quadrant of alternate buttocks, but only after assuring that:
 - a. the patellar reflex is present
 - b. respirations are not depressed
 - c. urine output during the previous 4 h exceeded 100 mL
4. Magnesium sulfate is discontinued 24 h after delivery.

FIGURE 24-1. Ventricular function in severe preeclampsia-eclampsia. Data plotted represent mean values obtained in five of six studies cited in [Table 24-5](#). Left ventricular stroke work index (LVSWI) and pulmonary artery capillary wedge pressure (PCWP) are plotted on a standard ventricular function curve. Points falling within the two solid lines represent normal function, while those below represent depressed function. Points above the solid lines represent hyperdynamic ventricular function. Each letter adjacent to the data points is the first initial of the last name of the investigator who reported this value. (From [Hauth and Cunningham, 1999](#)).

FIGURE 24-16. A. Plasma magnesium levels are plotted for a woman with antepartum eclampsia in whom 4 g of magnesium sulfate intravenously and 10 g intramuscularly were administered at the outset. When she soon convulsed again, 2 g more were injected slowly followed by 5 g intramuscularly every 4 hours, as described in [Table 24-10](#). She did not convulse again. **B.** The same woman as in **A.** Maternal magnesium levels during the first 28 hours postpartum and 4 days after magnesium sulfate was discontinued are plotted. Before and the day after delivery the renal clearance of magnesium remained relatively constant at about 35 percent of the somewhat depressed creatinine clearance. The mother recovered fully and the baby thrived. (From [Pritchard and associates, 1984.](#))

25. Obstetrical Hemorrhage

Obstetrics is "bloody business." Even though the maternal mortality rate has been reduced dramatically by hospitalization for delivery and the availability of blood for transfusion, death from hemorrhage remains prominent in the majority of mortality reports in advanced countries. In the United States from 1979 through 1992, the Centers for Disease Control and Prevention analyzed 4915 nonabortion-related maternal deaths from the Pregnancy Mortality Surveillance System ([Chichakli and colleagues, 1999](#)). They found that hemorrhage was a direct cause in about 30 percent of these deaths. According to [Bonnar \(2000\)](#), hemorrhage was the major factor in maternal deaths in the United Kingdom between 1985 and 1996. There undoubtedly has been great improvement in mortality from hemorrhage with modernization of American obstetrics. For example, [Sachs and associates \(1987\)](#) reported that maternal deaths from obstetrical hemorrhage in Massachusetts decreased tenfold from the mid-1950s to the mid-1980s.

Unfortunately, despite improved outcomes, poor and minority women continue to die from hemorrhage and its complications at a disparately high rate. In the report from the Centers for Disease Control cited above, there was threefold increased mortality from hemorrhage in African-American compared with Caucasian women. In a similar analysis of 3777 pregnancy-related deaths from states that include Hispanic origin on death certificates, [Hopkins and co-workers \(1999\)](#) reported that hemorrhage caused 20 percent of maternal deaths. They showed disparate mortality in African-American and Hispanic women compared with Caucasians.

Causes of maternal death from hemorrhage are shown in [Table 25-1](#). Obstetrical hemorrhage is most likely to be fatal in circumstances in which blood or components are not available immediately. The establishment and maintenance of facilities that allow prompt administration of blood are absolute requirements for acceptable obstetrical care. Hemorrhage may be **antepartum**—such as with placenta previa or placental abruption, or it more likely develops **postpartum**—from uterine atony or genital tract lacerations.

INCIDENCE AND PREDISPOSING CONDITIONS. Because of inexact definitions used, the incidence of obstetrical hemorrhage cannot be determined precisely. In one study of women delivered vaginally, [Combs and colleagues \(1991b\)](#) defined hemorrhage by a postpartum hematocrit drop of 10 volume percent or by need for transfusion. Using these criteria, the incidence was 3.9 percent. In women undergoing cesarean delivery it was 6 to 8 percent ([Combs and associates, 1991a](#); [Naef and co-workers, 1994](#)).

[Dickason and Dinsmoor \(1992\)](#) reported transfusions in 6.8 percent of women undergoing cesarean delivery. [Klapholz \(1990\)](#) reviewed over 30,000 deliveries at the Beth Israel Hospital from 1976 to 1986. As expected, the incidence of transfusion has decreased over the years; in 1976 it was 4.6 percent, but by 1986 it was 1.9 percent.

[Table 25-2](#) lists the many clinical circumstances in which risk of hemorrhage is appreciably increased. It is apparent that serious hemorrhage may occur at any time throughout pregnancy and the puerperium. The time of bleeding in pregnancy is widely used to classify obstetrical hemorrhage; however, the term *third-trimester* bleeding is imprecise and its use not recommended. One factor not generally considered as "predisposing" to hemorrhagic death is the lack of availability of obstetrical and anesthetic services. According to [Bonnar \(2000\)](#), the majority of deaths from hemorrhage in the United Kingdom cited earlier were associated with substandard care. Similarly, [Nagaya and associates \(2000\)](#) reviewed 197 maternal deaths in Japan in the 2-year period spanning 1991 and 1992. Hemorrhage caused 40 percent of these deaths, and they concluded that many of these were preventable because they were associated with inadequate obstetrical facilities. In Japan, 40 percent of deliveries take place in clinics with less than 20 beds, and frequently the physician functions both as obstetrician and anesthesiologist.

ANTEPARTUM HEMORRHAGE

Slight vaginal bleeding is common during active labor. This "bloody show" is the consequence of effacement and dilatation of the cervix, with tearing of small veins. Uterine bleeding from a site above the cervix before delivery is cause for concern. The bleeding may be the consequence of some separation of a placenta implanted in the immediate vicinity of the cervical canal—**placenta previa**. It may come from separation of a placenta located elsewhere in the uterine cavity—**abruptio placentae**. Rarely, the bleeding may be the consequence of velamentous insertion of the umbilical cord with rupture and hemorrhage from a fetal blood vessel at the time of rupture of the membranes—**vasa previa**.

The source of uterine bleeding that originates above the level of the cervix is not always identified. In that circumstance, the bleeding typically begins with little or no other symptomatology, and then stops, and at delivery no anatomical cause is identified. Almost always the bleeding must have been the consequence of slight marginal separation of the placenta that did not expand. **The pregnancy in which such bleeding occurs remains at increased risk for a poor outcome even though the bleeding soon stops and placenta previa appears to have been excluded by sonography.** [Lipitz and colleagues \(1991\)](#) studied 65 consecutive women—almost 1 percent of their patients—who had uterine bleeding between 14 and 26 weeks. Almost a fourth had placental abruption or previa. Total fetal loss including abortions and perinatal deaths was 32 percent. Even in pregnancies with hemorrhage after 26 weeks that are not explained by placental abruption or previa, [Ajayi and colleagues \(1992\)](#) reported adverse outcomes in a third. For this reason, delivery should be considered in any woman at term with unexplained vaginal bleeding.

PLACENTAL ABRUPTION

The separation of the placenta from its site of implantation before the delivery of the fetus has been variously called placental abruption, abruptio placentae, and in Great Britain, accidental hemorrhage. The term *premature separation of the normally implanted placenta* is most descriptive because it differentiates the placenta that separates prematurely but is implanted some distance beyond the cervical internal os, from one that is implanted over the cervical internal os—that is, placenta previa. It is cumbersome, however, and hence the shorter term **abruptio placentae**, or **placental abruption**, has been employed. The Latin *abruptio placentae*, which means "rending asunder of the placenta," denotes a sudden accident, a clinical characteristic of most cases of this complication.

Some of the bleeding of placental abruption usually insinuates itself between the membranes and uterus, and then escapes through the cervix, causing *external hemorrhage* ([Fig. 25-1](#)). Less often, the blood does not escape externally but is retained between the detached placenta and the uterus, leading to *concealed hemorrhage* ([Figs. 25-1](#) and [25-2](#)). Placental abruption may be *total* ([Figs. 25-1](#) and [25-2](#)) or *partial* ([Fig. 25-3](#)). Placental abruption with concealed hemorrhage carries with it much greater maternal hazards, not only because of the possibility of consumptive coagulopathy, but also because the extent of the hemorrhage is not appreciated.

FREQUENCY, INTENSITY, AND SIGNIFICANCE. The frequency with which abruptio placentae is diagnosed will vary because criteria employed for diagnosis differ. The intensity of the abruption will often vary depending on how quickly the woman seeks and receives care following the onset of symptoms. With delay, the likelihood of extensive separation causing death of the fetus is increased remarkably.

The reported frequency for placental abruption averages about 1 in 200 deliveries. [Karegard and Gennser \(1986\)](#) surveyed 849,619 births in Sweden and reported that 1 in 225 were complicated by abruptio placentae. [Ananth and colleagues \(1999a\)](#) reviewed 13 studies with nearly 1.6 million pregnancies and reported an incidence of 1 in 155.

At Parkland Hospital from 1988 through 1999, the incidence of abruption in over 169,000 deliveries has been 1 in 290. The incidence as well as severity have decreased over time. Applying the criterion of placental separation so extensive as to kill the fetus, the incidence was 1 in 420 deliveries from 1956 through 1967 ([Pritchard and Brekken, 1967](#)). As the number of high-parity women cared for decreased, and community-wide availability of prenatal care as well as emergency transportation improved, the frequency of abruption causing fetal death has dropped to about 1 in 830 deliveries from 1974 through 1989 ([Pritchard and colleagues, 1991](#)). From 1988 through 1999, it decreased to 1 in 1550.

PERINATAL MORBIDITY AND MORTALITY. In most reports, perinatal mortality with placental abruption is about 25 percent. In the large Swedish study by [Karegard and Gennser \(1986\)](#) cited earlier, it was 20 percent. [Krohn and associates \(1987\)](#) reported that perinatal mortality was 20 percent in 884 pregnancies complicated by placental abruption in Washington State. [Ananth and co-workers \(1999b\)](#) studied 530 women with placental abruption at Mt. Sinai Hospital in New York and reported that 40 percent were delivered preterm.

As stillbirths from other causes have decreased appreciably, those from abruptio placentae have become especially prominent. For example, of all third-trimester stillbirths in over 40,000 deliveries at Parkland Hospital during 1992 and 1994, 12 percent were the consequence of placental abruption ([Cunningham and Hollier, 1997](#)). This frequency is similar to that described by [Fretts and Usher \(1997\)](#), who studied almost 62,000 births at the Royal Victoria Hospital in Montreal between 1978 and 1995. Abruptio placentae had become the leading known cause and accounted for 15 percent of stillbirths.

Importantly, even if the infant survives, there may be adverse sequelae. Of the 182 survivors in the study by [Abdella and associates \(1984\)](#), 25 (14 percent) were identified to have significant neurological deficits within the first year of life.

ETIOLOGY. The primary cause of placental abruption is unknown, but there are several associated conditions. Some of these are listed in [Table 25-3](#). As shown in [Figure 25-4](#), the incidence increases with **maternal age**. While [Pritchard and colleagues \(1991\)](#) have also shown it to be higher in women of **great parity**, [Toohey and associates \(1995\)](#) did not find this in women para 5 or greater. Race or ethnicity appears to be important. In the 169,000-plus deliveries at Parkland Hospital, abruption was more common in African-American and Caucasian women (1 in 200) than in Asian (1 in 300) or Latin-American women (1 in 450).

By far the most commonly associated condition is some type of **hypertension**. This includes preeclampsia, gestational hypertension, or chronic hypertension. In the earlier Parkland Hospital study of 408 cases of placental abruption so severe as to kill the fetus, maternal hypertension was apparent in about half of the women once the depleted intravascular compartment was adequately refilled ([Pritchard and co-workers, 1991](#)). Half of these women had chronic hypertension and the remainder had either gestational hypertension or preeclampsia. [Morgan and colleagues \(1994\)](#) found that hypertensive women were more likely to suffer a more severe abruption. According to [Witlin and colleagues \(1999\)](#), however, the severity of preeclampsia did not correlate with the incidence of abruption in 445 women. From the Maternal-Fetal Medicine Network, [Sibai and co-workers \(1998\)](#) reported that 1.5 percent of women with chronic hypertension suffered placental abruption. [Ananth and associates \(1999b\)](#) reported a threefold increased incidence of abruption with chronic hypertension and fourfold with severe preeclampsia.

There is an increased incidence of abruption with **preterm prematurely ruptured membranes**. [Gonen and associates \(1989\)](#) reported an incidence of 5.6 percent in 143 pregnancies of less than 34 weeks in which the membranes were ruptured for more than 24 hours. [Major and colleagues \(1995\)](#) described an incidence of 5 percent in 756 women with ruptured membranes between 20 and 36 weeks. [Kramer and co-workers \(1997\)](#) found an incidence of 3.1 percent in all patients if membranes were ruptured for longer than 24 hours. In a meta-analysis of 54 studies, [Ananth and colleagues \(1996\)](#) found a threefold risk of abruption with prematurely ruptured membranes.

In the earliest studies, from the Collaborative Perinatal Project, **cigarette smoking** was linked to an increased risk for abruption ([Misra and Ananth, 1999](#); [Naeye, 1980](#)). In their meta-analysis of 1.6 million pregnancies, [Ananth and colleagues \(1999a, 1999b\)](#) found a twofold risk for abruption in smokers. This was increased to five- to eightfold if smokers had chronic hypertension and/or severe preeclampsia.

Cocaine abuse has been associated with an alarming frequency of placental abruption. In one report of 50 women who abused cocaine during pregnancy, there were eight stillbirths caused by placental abruption ([Bingol and associates, 1987](#)). [Hoskins and collaborators \(1991\)](#) reported a 13-percent rate of placental abruption in 112 women who were followed prospectively for cocaine abuse during pregnancy. [Slutsker \(1992\)](#) reviewed 10 studies of cocaine-using women and all showed that placental abruption was more common than in controls.

Over the past decade, a number of inherited or acquired **thrombophilias** have been described that are associated with thromboembolic disorders during pregnancy ([Chap. 46, p. 1234](#)). These clotting disorders also are associated with placental abruption and infarction ([Gherman and Goodwin, 2000](#)). Most of these are single-gene mutations that include genes for factor V Leiden, prothrombin, methylenetetrahydrofolate reductase, proteins S and C, and antithrombin III ([Chap. 49, p. 1330](#)). In addition, acquired antiphospholipid autoantibodies, including the lupus anticoagulant, are associated with placental abruption. For example, [Kupferminc and colleagues \(1999\)](#) found a sevenfold risk of abruption in women with a factor V, folate reductase, or prothrombin mutation.

As discussed in [Chapter 43 \(p. 1173\)](#), **external trauma** was implicated in only 3 of 207 cases of placental abruption causing fetal death at Parkland Hospital. Our experiences are similar to those of [Kettel \(1988\)](#) and [Stafford \(1988\)](#) and their co-workers, who stressed that abruption caused by relatively minor trauma may cause fetal jeopardy that is not always associated with immediate evidence for placental separation. In such cases, a period of monitoring for at least 4 hours is often necessary to exclude a subclinical abruption.

Uterine leiomyoma, especially if located behind the placental implantation site, predisposes to abruption ([Chap. 35, p. 926](#)). [Rice and associates \(1989\)](#) reported that 8 of 14 women with retroplacental myomas developed placental abruption; in four, fetal death ensued. By contrast, abruption developed in only 2 of 79 women whose myoma was not retroplacental.

RECURRENT ABRUPTION. [Pritchard and co-workers \(1970\)](#) identified a recurrence rate of severe abruption in 1 in 8 pregnancies. Importantly, of the 14 recurrent placental abruptions, eight caused fetal death for a second time. [Karegard and Gennser \(1986\)](#) reported that the recurrent placental abruption risk was increased tenfold, from 0.4 to 4 percent. Management of the subsequent pregnancy is made difficult in that the placental separation may suddenly occur at any time, even remote from term. In the majority of cases, fetal well-being was normal beforehand, and thus currently available methods of fetal evaluation are usually not predictive. In an extreme example, [Seski and Compton \(1976\)](#) documented both a normal nonstress test and a normal contraction stress test done 4 hours before the onset of placental abruption that promptly killed the fetus.

PATHOLOGY. Placental abruption is initiated by hemorrhage into the decidua basalis. The decidua then splits, leaving a thin layer adherent to the myometrium. Consequently, the process in its earliest stages consists of the development of a decidual hematoma that leads to separation, compression, and the ultimate destruction of the placenta adjacent to it. In its early stage, there may be no clinical symptoms. The condition is discovered only upon examination of the freshly delivered organ, which will present on its maternal surface a circumscribed depression measuring a few centimeters in diameter, and covered by dark, clotted blood. Undoubtedly, it takes at least several minutes for these anatomical changes to materialize. Thus, a very recently separated placenta may appear no different from a normal placenta at delivery. According to [Benirschke and Kaufmann \(2000\)](#), the "age" of the retroplacental clot cannot be determined exactly.

In some instances, a decidual spiral artery ruptures to cause a retroplacental hematoma, which as it expands disrupts more vessels to separate more placenta. The area of separation rapidly becomes more extensive and reaches the margin of the placenta. Because the uterus is still distended by the products of conception, it is unable to sufficiently contract to compress the torn vessels that supply the placental site. The escaping blood may dissect the membranes from the uterine wall and eventually appear externally, or may be completely retained within the uterus ([Figs. 25-1 and 25-2](#)).

CONCEALED HEMORRHAGE. Retained or concealed hemorrhage is likely when:

1. There is an effusion of blood behind the placenta but its margins still remain adherent.
2. The placenta is completely separated yet the membranes retain their attachment to the uterine wall.
3. Blood gains access to the amniotic cavity after breaking through the membranes.
4. The fetal head is so closely applied to the lower uterine segment that the blood cannot make its way past it.

In most cases, however, the membranes are gradually dissected off the uterine wall, and blood sooner or later escapes.

CHRONIC PLACENTAL ABRUPTION. In some women, hemorrhage with retroplacental hematoma formation is somehow arrested completely without delivery. We have been able to document this phenomenon by labeling maternal red cells with ⁵¹chromium. This technique served to demonstrate that red blood cells concealed as clot within the uterus at delivery 3 weeks later contained no chromium and therefore were shed before.

FETAL-TO-MATERNAL HEMORRHAGE. Bleeding with placental abruption is almost always maternal. In nontraumatic placental abruption, evidence for fetomaternal hemorrhage was found in 20 percent of 78 cases; however, in all instances it was less than 10 mL ([Stettler and colleagues, 1992](#)). Significant fetal bleeding is more likely to be seen with traumatic abruption ([Chap. 43, p. 1173](#)). [Pearlman and associates \(1990\)](#) found fetal bleeding that averaged 12 mL in a third of women with a traumatic abruption. [Stettler and colleagues \(1992\)](#) reported that there was fetomaternal hemorrhage of 80 to 100 mL in 3 of 8 cases of traumatic placental abruption.

CLINICAL DIAGNOSIS. It is emphasized that the signs and symptoms with abruption placenta can vary considerably. For example, external bleeding can be profuse, yet placental separation may not be so extensive as to compromise the fetus directly. Rarely, there may be no external bleeding but the placenta may be completely sheared off and the fetus dead as the direct consequence. In one very unusual case, a multiparous woman near term presented to the Parkland Hospital obstetrical emergency room because of nosebleed. There was no abdominal or uterine pain or tenderness and no vaginal bleeding but her fetus was dead. Her blood did not clot and the plasma fibrinogen level was 25 mg/dL. Labor was induced, and at delivery a total abruption with fresh clots was found.

[Hurd and co-workers \(1983\)](#), in a relatively small prospective study of abruptio placentae, identified the frequency of a variety of pertinent signs and symptoms ([Table 25-4](#)). Bleeding and abdominal pain are the most frequent findings. **In 22 percent of cases, idiopathic preterm labor was considered to be the diagnosis until subsequent fetal death or distress developed.** Other findings that developed were serious bleeding, back pain, uterine tenderness, frequent uterine contractions, or persistent uterine hypertonus. In older studies, ultrasound infrequently confirmed the diagnosis of abruption. For example, [Sholl \(1987\)](#) confirmed the clinical diagnosis sonographically in only 25 percent of women. Preliminary data from [Yeo and colleagues \(1999\)](#) indicated a 100-percent positive-predictive value and an 88-percent negative-predictive value in 25 women with preterm prematurely ruptured membranes and vaginal bleeding. In 48 women with vaginal bleeding and intact membranes, these corresponding numbers were 92 and 63 percent. **Importantly, negative findings with ultrasound examination do not exclude placental abruption.**

SHOCK. It was once held that the shock sometimes seen with placental abruption was out of proportion to the amount of hemorrhage. Supposedly, thromboplastin from decidua and placenta entered the maternal circulation and incited intravascular coagulation and other features of the amniotic fluid embolism syndrome, including hypotension. This sequence is rare, and the intensity of shock is seldom out of proportion to maternal blood loss. [Pritchard and Brekken \(1967\)](#) studied blood loss in 141 women with placental abruption so severe as to kill the fetus and found that it often amounted to at least half of the pregnant blood volume. Neither hypotension nor anemia is obligatory in cases of concealed hemorrhage, even when the acute hemorrhage has achieved considerable magnitude. Oliguria caused by inadequate renal perfusion but responsive to vigorous treatment of hypovolemia may also be observed in these circumstances.

DIFFERENTIAL DIAGNOSIS. In severe cases of placental abruption, the diagnosis is generally obvious. Milder and more common forms of abruption are difficult to recognize with certainty, and the diagnosis is often made by exclusion. Therefore, with vaginal bleeding complicating a viable pregnancy, it often becomes necessary to rule out placenta previa and other causes of bleeding by clinical inspection and ultrasound evaluation. It has long been taught, perhaps with some justification, that painful uterine bleeding means abruptio placentae, while painless uterine bleeding is indicative of placenta previa. Unfortunately, the differential diagnosis is not that simple. Labor accompanying placenta previa may cause pain suggestive of abruptio placentae. On the other hand, abruptio placentae may mimic normal labor, or it may cause no pain at all. The latter is more likely with a posteriorly implanted placenta.

There are neither laboratory tests nor diagnostic methods that accurately detect lesser degrees of placental separation. The cause of the vaginal bleeding at times remains obscure even after delivery. [Magriples and colleagues \(1999\)](#) found that **thrombomodulin**—an endothelial cell marker—was significantly elevated in eight women with placental abruption compared with 17 women without an abruption.

CONSUMPTIVE COAGULOPATHY. One of the most common causes of clinically significant consumptive coagulopathy in obstetrics is placental abruption. Overt *hypofibrinogenemia*—less than 150 mg/dL of plasma—along with elevated levels of fibrinogen-fibrin degradation products, D-dimer, and variable decreases in other coagulation factors is found in about 30 percent of women with placental abruption severe enough to kill the fetus. Such severe coagulation defects are seen less commonly in those cases in which the fetus survives. Our experience has been that serious coagulopathy, when it develops, is usually evident by the time the symptomatic woman seeks care.

The major mechanism is almost certainly the induction of coagulation intravascularly and, to a lesser degree, retroplacentally. Although an appreciable amount of fibrin is commonly deposited within the uterine cavity in cases of severe placental abruption and hypofibrinogenemia, the amounts are insufficient to account for all of the fibrinogen missing from the circulation ([Pritchard and Brekken, 1967](#)). Moreover, [Bonnar and co-workers \(1969\)](#) have observed, and we have confirmed, that the levels of fibrin degradation products are higher in serum from peripheral blood than in serum from blood contained in the uterine cavity. The reverse would be anticipated in the absence of significant intravascular coagulation.

An important consequence of intravascular coagulation is the activation of plasminogen to plasmin, which lyses fibrin microemboli, thereby maintaining patency of the microcirculation. In every instance of placental abruption severe enough to kill the fetus, we have identified clearly pathological levels—greater than 100 ug/mL—of fibrinogen-fibrin degradation products in maternal serum. At the outset, severe hypofibrinogenemia may or may not be accompanied by overt thrombocytopenia. After repeated blood transfusions, however, thrombocytopenia is common.

RENAL FAILURE. Acute renal failure that persists for any length of time is seen in severe forms of placental abruption. This includes those in which treatment of hypovolemia is delayed or incomplete ([Chap. 47, p. 1266](#)). Of 57 cases of acute renal failure in pregnant women described by [Grunfeld and Pertuiset \(1987\)](#), 23 percent were associated with placental abruption. Fortunately, reversible acute tubular necrosis accounts for three fourths of cases of renal failure ([Turney and colleagues, 1989](#)). According to [Lindheimer and associates \(2000\)](#), acute cortical necrosis in pregnancy is usually caused by abruptio placentae, and 7 of 19 women with this lesion indeed had a placental abruption in the report by [Grunfeld and Pertuiset \(1987\)](#).

Seriously impaired renal perfusion is the consequence of massive hemorrhage. Because preeclampsia frequently coexists with placental abruption, renal vasospasm is likely intensified ([Hauth and Cunningham, 1999](#)). Even when placental abruption is complicated by severe intravascular coagulation, prompt and vigorous treatment of hemorrhage with blood and crystalloid solution will often prevent clinically significant renal dysfunction. During nearly 45 years at Parkland Hospital, more than 500 cases of placental abruption so severe as to kill the fetus have received fluid replacement therapy consisting of blood and lactated Ringer solution. In only one instance has dialysis for renal failure been necessary.

For unknown reasons, *proteinuria* is common, especially with more severe forms of placental abruption. It usually clears soon after delivery.

COUVELAIRE UTERUS. There may be widespread extravasation of blood into the uterine musculature and beneath the uterine serosa ([Fig. 25-5](#)). This so-called *uteroplacental apoplexy*, first described by Couvelaire in the early 1900s, is now frequently called *Couvelaire uterus*. Such effusions of blood are also occasionally seen beneath the tubal serosa, in the connective tissue of the broad ligaments, and in the substance of the ovaries, as well as free in the peritoneal cavity. Its precise incidence is unknown because it can only be demonstrated conclusively at laparotomy. These myometrial hemorrhages seldom interfere with uterine contractions sufficiently to produce severe postpartum hemorrhage and are not an indication for hysterectomy.

MANAGEMENT. Treatment for placental abruption will vary depending upon gestational age and the status of the mother and fetus. With a live and mature fetus, and if vaginal delivery is not imminent, then emergent cesarean delivery is chosen by most. As discussed later in the section Hypovolemic Shock (p. 652), with massive external bleeding, intensive resuscitation with blood plus crystalloid and prompt delivery to control the hemorrhage are life saving for the mother and, it is hoped, for the fetus. If the diagnosis is uncertain and the fetus is alive but without evidence of fetal compromise, very close observation, with facilities for immediate intervention, can be practiced.

EXPECTANT MANAGEMENT IN PRETERM PREGNANCY. Delaying delivery may prove beneficial when the fetus is immature. [Sholl \(1987\)](#) described 72 women with pregnancies between 26 and 37 weeks who had clinically diagnosed placental abruption. About half were delivered within 3 days of admission because of progression to serious hemorrhage, fetal distress, or both. Interestingly, the cesarean rate was about 50 percent for those delivered soon after admission, as well as those in whom delivery was postponed for at least 3 days. In another study, [Bond and associates \(1989\)](#) expectantly managed 43 women with abruptio placentae before 35 weeks; 31 of these were given tocolytic therapy. The mean time to delivery in all 43 was about 12 days and there were no stillborns. Cesarean delivery was performed in 75 percent.

Women with evidence for very early abruption frequently develop oligohydramnios, either with or without premature membrane rupture. [Elliott and associates \(1998\)](#) described 24 women with abruptions who had a mean gestation of 20 weeks and who also developed oligohydramnios. They were delivered at a mean of 28 weeks.

Lack of ominous decelerations does not guarantee the safety of the intrauterine environment for any period of time. The placenta may further separate at any instant and seriously compromise or kill the fetus unless delivery is performed immediately. Some of the immediate causes of fetal distress from abruptio placentae are shown in [Figure 25-6](#). It is important for the welfare of the distressed fetus that steps be initiated immediately to correct maternal hypovolemia, anemia, and hypoxia so as to restore and maintain the function of any placenta that is still implanted. Little can be done to favorably modify the other causes that contribute to fetal distress except to deliver the fetus.

TOCOLYSIS. Some have advocated tocolysis for preterm pregnancy complicated by suspected abruption. [Hurd and associates \(1983\)](#) found that abruption went unrecognized for dangerously long periods if tocolysis was initiated. Conversely, [Sholl \(1987\)](#) as well as [Combs and co-workers \(1992\)](#), provided data that tocolysis improved outcome in a highly selected group of preterm pregnancies complicated by partial abruption. [Towers and co-workers \(1999\)](#) administered magnesium sulfate, terbutaline, or both to 95 of 131 women with abruptio placentae diagnosed before 36 weeks. The perinatal mortality was 5 percent and did not differ from the nontreated group. They concluded that a randomized clinical trial could be safely conducted. Until then, we are of the view that clinically evident placental abruption should be considered a contraindication to tocolytic therapy.

CESAREAN DELIVERY. Rapid delivery of the fetus who is alive but in distress practically always means cesarean delivery. An electrode applied directly to the fetus may rarely provide misleading information, as in the case illustrated in [Figure 25-7](#). At first impression at least, fetal bradycardia of 80 to 90 beats/min, with a degree of beat-to-beat variability, seemed evident. The fetus, however, was dead. There were no audible fetal heart sounds, and the maternal pulse rate was identical to that recorded through the fetal scalp electrode. Cesarean section at this time would likely have proved dangerous for the mother because she was profoundly hypovolemic and had severe consumptive coagulopathy.

VAGINAL DELIVERY. If placental separation is so severe that the fetus is dead, vaginal delivery is preferred unless hemorrhage is so brisk that it cannot be successfully managed even by vigorous blood replacement, or there are other obstetrical complications that prevent vaginal delivery. Serious coagulation defects are likely to prove especially troublesome with cesarean delivery. The abdominal and uterine incisions are prone to bleed excessively when coagulation is impaired. Hemostasis at the placental implantation site depends primarily upon myometrial contraction. Therefore, with vaginal delivery, stimulation of the myometrium pharmacologically and by uterine massage will cause these vessels to be constricted so that serious hemorrhage is avoided even though coagulation defects persist. Moreover, bleeding that does occur is shed through the vagina. An example of an indication for abdominal delivery despite documented fetal demise is now illustrated:

Although placental abruption was suspected, because rupture of a prior cesarean incision could not be excluded, repeat cesarean section was performed for a 26-week stillborn fetus. The patient had profound hypofibrinogenemia and serious bleeding was encountered from all surgical incisions. Persistent bleeding necessitated hysterectomy followed by internal iliac artery ligation. Lactated Ringer solution was given along with 17 units of blood, 8 units of plasma, and 10 units of platelets to maintain perfusion and treat the coagulopathy, which finally resolved intraoperatively.

AMNIOTOMY. Rupture of the membranes as early as possible has long been championed in the management of placental abruption. The rationale for amniotomy is that the escape of amniotic fluid might both decrease bleeding from the implantation site and reduce the entry into the maternal circulation of thromboplastin and perhaps activated coagulation factors from the retroplacental clot. There is no evidence, however, that either is accomplished by amniotomy. If the fetus is reasonably mature, rupture of the membranes may hasten delivery. If the fetus is immature, the intact sac may be more efficient in promoting cervical dilatation than will a small fetal part poorly applied to the cervix.

LABOR. With extensive placental abruption, the uterus will likely be persistently hypertonic. The baseline intra-amniotic pressure may be 50 mm Hg or higher, with rhythmic increases up to 75 to 100 mm Hg. Because of persistent hypertonus, it may be difficult at times to determine by palpation if the uterus is contracting and relaxing to any degree ([Fig. 25-8](#)).

OXYTOCIN. Although hypertonicity characterizes myometrial function in most cases of severe placental abruption, if no rhythmic uterine contractions are superimposed, then oxytocin is given in standard doses. Uterine stimulation to effect vaginal delivery provides benefits that override the risks. The use of oxytocin has been challenged on the basis that it might enhance the escape of thromboplastin into the maternal circulation and thereby initiate or enhance consumptive coagulopathy or amniotic fluid embolism syndrome. There is no evidence to support this fear ([Clark and colleagues, 1995](#); [Pritchard and Brekken, 1967](#)).

TIMING OF DELIVERY AFTER SEVERE PLACENTAL ABRUPTION. When the fetus is dead or pre-viable, there is no evidence that establishing an arbitrary time limit for delivery is necessary. Experiences at both the University of Virginia and Parkland Hospitals indicate that the maternal outcome depends upon the diligence with which adequate fluid and blood replacement therapy is pursued, rather than upon the interval to delivery ([Brame and associates, 1968](#); [Pritchard and Brekken, 1967](#)). At the University of Virginia Hospital, women with severe placental abruption who were transfused for 18 hours or more before delivery, experienced complications that were neither more numerous nor greater in severity than did the group in which delivery was accomplished sooner. Our observations are similar; [Figure 25-9](#) summarizes serial findings from one of the most severe cases in terms of the prolonged interval between the onset of symptoms and delivery and the necessity of transfusing a large volume of blood.

PLACENTA PREVIA

DEFINITION. In placenta previa, the placenta is located over or very near the internal os. Four degrees of this abnormality have been recognized:

1. **Total placenta previa.** The internal cervical os is covered completely by placenta ([Fig. 25-10](#)). BR>
2. **Partial placenta previa.** The internal os is partially covered by placenta ([Figs. 25-1](#) and [25-10](#)).
3. **Marginal placenta previa.** The edge of the placenta is at the margin of the internal os.
4. **Low-lying placenta.** The placenta is implanted in the lower uterine segment such that the placenta edge actually does not reach the internal os but is in close proximity to it.

Another condition, termed **vasa previa**, is where the fetal vessels course through membranes and present at the cervical os. This is an uncommon cause of antepartum hemorrhage and is associated with a high rate of fetal death. Prenatal diagnosis by ultrasonography improves perinatal salvage ([Lee and colleagues, 2000](#)). It is discussed in detail in [Chapter 32](#).

The degree of placenta previa will depend in large measure on the cervical dilatation at the time of examination. For example, a low-lying placenta at 2 cm dilatation may become a partial placenta previa at 8 cm dilatation because the dilating cervix has uncovered placenta. Conversely, a placenta previa that appears to be total before cervical dilatation may become partial at 4 cm dilatation because the cervix dilates beyond the edge of the placenta ([Fig. 25-11](#)). **Digital palpation to try to ascertain these changing relations between the edge of the placenta and the internal os as the cervix dilates can incite severe hemorrhage!**

In both the total and partial placenta previa, a certain degree of spontaneous placental separation is an inevitable consequence of the formation of the lower uterine segment and cervical dilatation. Such separation is associated with hemorrhage from blood vessels so disrupted.

INCIDENCE. [Iyasu and co-workers \(1993\)](#), in an analysis of the National Hospital Discharge Survey from 1979 to 1987, found that placenta previa complicated 0.5 percent (1 in 200) deliveries. At Prentice Women's Hospital, [Frederiksen and colleagues \(1999\)](#) reported that 0.55 percent (1 in 180) of nearly 93,500 deliveries were complicated by previa. [Crane and associates \(1999\)](#) found the incidence to be 0.33 percent (1 in 300) in almost 93,000 deliveries in the province of Nova Scotia. At Parkland Hospital, the incidence was 0.26 percent (1 in 390) for more than 169,000 deliveries over 12 years.

These statistics are remarkably similar considering the lack of precision in definition and identification for reasons already discussed. A question difficult to answer is whether painless bleeding from focal separation of a placenta implanted in the lower uterine segment but away from a partially dilated cervical os should be classified as placenta previa or placental abruption. Obviously, it is both.

ETIOLOGY. Advancing **maternal age** increases the risk of placenta previa. As shown in [Figure 25-4](#), in over 169,000 deliveries at Parkland Hospital from 1988 through 1999, the incidence of previa increased significantly with each age group. At the extremes, it is 1 in 1500 for women 19 or less and for women over 35 it is 1 in 100. [Frederiksen and colleagues \(1999\)](#) reported that the incidence of previa increased from 0.3 percent in 1976 to 0.7 percent in 1997. They attributed this to a shift to an older obstetrical population.

Multiparity is associated with previa. In a study of 314 women who were para 5 or greater, [Babinszki and collaborators \(1999\)](#) reported that the incidence of previa of 2.2 percent was increased significantly compared with women of lower parity. In the 169,000-plus women at Parkland Hospital the incidence was 1 in 175 in women para 3 or greater.

Prior cesarean delivery increases the likelihood of placenta previa. [Nielsen and colleagues \(1989\)](#) found a fivefold increased incidence of placenta previa in Swedish women with a prior cesarean delivery. At Parkland, the incidence was increased twofold from 1 in 400 to 1 in 200 with at least one prior cesarean section. [Miller and associates \(1996\)](#) cited a threefold increase of previa in women with prior cesarean delivery in over 150,000 deliveries at Los Angeles County Women's Hospital. The incidence increased with the number of previous cesarean deliveries—it was 1.9 percent with two prior cesareans and 4.1 percent with three or more. Certainly, a prior cesarean incision with a previa increases the incidence of hysterectomy. [Frederiksen and co-workers \(1999\)](#) reported a 25-percent hysterectomy rate in women with repeat cesarean for a previa compared with only 6 percent of those undergoing primary cesarean for placenta previa.

[Williams and colleagues \(1991b\)](#) found the relative risk of placenta previa to be increased twofold related to **smoking**. They theorized that carbon monoxide hypoxemia caused compensatory placental hypertrophy. These findings were confirmed by [Handler and colleagues \(1994\)](#). Perhaps related, defective decidual

vascularization, the possible result of inflammatory or atrophic changes, has been implicated in the development of previa.

PLACENTA ACCRETA, INCRETA, AND PERCRETA. Placenta previa may be associated with *placenta accreta* or one of its more advanced forms, *placenta increta* or *percreta*. Such abnormally firm attachment of the placenta might be anticipated because of poorly developed decidua in the lower uterine segment. Almost 7 percent of 514 cases of previa reported by [Frederiksen and collaborators \(1999\)](#) had an associated abnormal placental attachment. [Biswas and co-workers \(1999\)](#) performed placental bed biopsies at cesarean delivery in 50 women with previas and 50 control women. While about half of specimens from previas showed myometrial spiral arterioles with trophoblastic giant-cell infiltration, only 20 percent from those normally implanted had these changes.

CLINICAL FINDINGS. The most characteristic event in placenta previa is painless hemorrhage, which usually does not appear until near the end of the second trimester or after. Some abortions, however, may result from such an abnormal location of the developing placenta. Frequently, bleeding from placenta previa has its onset without warning, presenting without pain in a woman who has had an uneventful prenatal course. Fortunately, the initial bleeding is rarely so profuse as to prove fatal. Usually it ceases spontaneously, only to recur. In some cases, particularly those with a placenta implanted near but not over the cervical os, bleeding does not appear until the onset of labor, when it may vary from slight to profuse hemorrhage and may clinically mimic placental abruption.

The cause of hemorrhage is reemphasized. When the placenta is located over the internal os, the formation of the lower uterine segment and the dilatation of the internal os result inevitably in tearing of placental attachments. The bleeding is augmented by the inability of the myometrial fibers of the lower uterine segment to contract and thereby constrict the torn vessels.

Hemorrhage from the placental implantation site in the lower uterine segment may continue after delivery of the placenta, because the lower uterine segment is more prone to contract poorly than is the uterine body. Bleeding may also result from lacerations in the friable cervix and lower uterine segment, especially following manual removal of a somewhat adherent placenta.

COAGULATION DEFECTS. In our experiences, coagulopathy is rare with placenta previa, even when extensive separation from the implantation site has occurred. [Wing and colleagues \(1996b\)](#) studied 87 women with antepartum bleeding from placenta previa and found no evidence for coagulopathy. Presumably thromboplastin that incites intravascular coagulation that commonly characterizes abruptio placentae readily escapes through the cervical canal rather than being forced into the maternal circulation.

DIAGNOSIS. In women with uterine bleeding during the latter half of pregnancy, placenta previa or abruptio placentae should always be suspected. The possibility of placenta previa should not be dismissed until appropriate evaluation, including sonography, has clearly proved its absence. The diagnosis of placenta previa can seldom be established firmly by clinical examination unless a finger is passed through the cervix and the placenta is palpated. **Such examination of the cervix is never permissible unless the woman is in an operating room with all the preparations for immediate cesarean delivery, because even the gentlest examination of this sort can cause torrential hemorrhage.** Furthermore, such an examination should not be made unless delivery is planned, for it may cause bleeding of such a degree that immediate delivery becomes necessary even though the fetus is immature. Such a "double set-up" examination is rarely necessary as placental location can almost always be obtained by sonography.

LOCALIZATION BY SONOGRAPHY. The simplest, most precise, and safest method of placental localization is provided by *transabdominal sonography*, which is used to locate the placenta with considerable accuracy ([Figs. 25-12](#) and [25-13](#)). According to [Laing \(1996\)](#), the average accuracy is about 96 percent, and rates as high as 98 percent have been obtained. **False-positive results are often a result of bladder distention. Therefore, ultrasonic scans in apparently positive cases should be repeated after emptying the bladder.** An uncommon source of error has been identification of abundant placenta implanted in the uterine fundus but failure to appreciate that the placenta was large and extended downward all the way to the internal os of the cervix.

The use of *transvaginal ultrasonography* has substantively improved diagnostic accuracy of placenta previa. [Farine and associates \(1988\)](#) were able to visualize the internal cervical os in all cases with the transvaginal technique, in contrast to only 70 percent using transabdominal equipment. An example is shown in [Figure 25-14](#). [Leerentveld and colleagues \(1990\)](#) studied 100 women suspected of having placenta previa. They reported a 93-percent positive-predictive value and 98-percent negative-predictive value for transvaginal ultrasonography. [Tan and co-workers \(1995\)](#) reported less accuracy with the technique. In studies comparing abdominal ultrasound with transvaginal imaging, [Smith \(1997\)](#) and [Taipale \(1998\)](#) and their colleagues found the transvaginal technique to be superior. Most now agree that confirmatory transvaginal imaging is indicated if the placenta is low lying or appears to be covering the cervical os by transabdominal sonography.

[Hertzberg and associates \(1992\)](#) demonstrated that *transperineal sonography* allowed visualization of the internal os in all 164 cases examined because transabdominal sonography disclosed a previa or was inconclusive. Placenta previa was correctly excluded in 154 women, and in 10 in whom it was diagnosed sonographically, nine had a previa confirmed at delivery. The positive-predictive value was 90 percent and the negative-predictive value was 100 percent.

MAGNETIC RESONANCE IMAGING. A number of investigators have used magnetic resonance imaging to visualize placental abnormalities, including placenta previa. [Kay and Spritzer \(1991\)](#) discussed the many positive attributes of such technology ([Fig. 25-15](#)). It is unlikely that this will replace ultrasonic scanning for routine evaluation in the near future.

PLACENTAL "MIGRATION." Since the report by [King \(1973\)](#), the apparent peripatetic nature of the placenta has been well established. In earlier studies, "low-lying placentas" were evaluated and [McClure and Dornal \(1990\)](#) found these in 25 percent of 1490 routine scans at 18 weeks. At delivery, only seven of these 385 low-lying placentas persisted. [Sanderson and Milton \(1991\)](#) found that only 12 percent of placentas were "low lying" in 4300 women at 18 to 20 weeks. Of those not covering the internal os, previa did not persist and hemorrhage was not encountered. Conversely, of those covering the os at midpregnancy, about 40 percent persisted as a previa.

Thus, placentas that lie close to the internal os, but not over it, during the second trimester, or even early in the third trimester, are very unlikely to persist as previas by term. These data were amplified by [Taipale and co-workers \(1998\)](#), who found that 57 of 3696 (1.5 percent) unselected women had a placenta previa at 18 to 23 weeks. Only 20 percent of those with the placental edge extending less than 15 mm from the os had a previa at delivery. If the placental edge extended to 25 mm or more, however, 40 percent had a previa.

The low frequency with which placenta previa persists when it has been identified sonographically before 30 weeks is shown in [Table 25-5](#). It is apparent from these data that in the absence of any other abnormality, sonography need not be frequently repeated simply to follow placental position, and restriction of activity need not be practiced unless the previa persists beyond 30 weeks, or becomes clinically apparent before that time.

The mechanism of apparent placental movement is not completely understood. The term *migration* is clearly a misnomer, however, as invasion of chorionic villi into the decidua on either side of the cervical os will persist. The apparent movement of the low-lying placenta relative to the internal os probably results from inability to precisely define this relationship in a three-dimensional manner using two-dimensional sonography in early pregnancy. This difficulty is coupled with differential growth of lower and upper myometrial segments as pregnancy progresses. Thus, those placentas that "migrate" most likely never had actual circumferential villus invasion that reached the internal cervical os in the first place.

MANAGEMENT. Women with a placenta previa may be considered as follows:

1. Those in whom the fetus is preterm but there is no indication for delivery.
2. Those in whom the fetus is reasonably mature.
3. Those in labor.
4. Those in whom hemorrhage is so severe as to mandate delivery despite fetal immaturity.

Management with a preterm fetus, but with no active bleeding, consists of close observation. In some cases prolonged hospitalization may be ideal; however, the woman is usually discharged after bleeding has ceased and the fetus is judged to be healthy. The woman and her family must fully appreciate the problems of placenta previa and be prepared to transport her to the hospital immediately. In properly selected patients, there appears to be no benefit to inpatient versus outpatient management of placenta previa ([Mouer, 1994](#)). [Drost and Keil \(1994\)](#) demonstrated a 50 percent reduction in hospital days, a 50 percent reduction in maternal cost, and a 40 percent reduction in cost for mother-infant pairs, with no differences in maternal or fetal morbidity with outpatient compared with inpatient management. [Wing and colleagues \(1996a\)](#) reported preliminary results from their randomized clinical trial of inpatient versus home management of 53 women with

bleeding from a previa at 24 to 36 weeks. Maternal and perinatal morbidity was similar in each group, but home management saved \$15,000 per case. Importantly, 33 (62 percent) of these 53 women had recurrent bleeding and in 28 it required expeditious cesarean delivery.

DELIVERY. Cesarean delivery is necessary in practically all cases of placenta previa. In most cases a transverse uterine incision is made. Because fetal bleeding may result from an incision into an anterior placenta, a vertical incision is sometimes recommended in these circumstances. Even when the incision extends through the placenta, however, maternal or fetal outcome is rarely compromised.

Because of the poorly contractile nature of the lower uterine segment, there may be uncontrollable hemorrhage following placental removal. This can occur even without histological confirmation of placenta accreta. Under these circumstances, management appropriate for placenta accreta is indicated (see p. 632). When placenta previa is complicated by degrees of placenta accreta that render control of bleeding from the placental bed difficult by conservative means, other methods of hemostasis are necessary. Oversewing the implantation site with 0-chromic sutures may provide hemostasis. In some cases, bilateral uterine artery ligation is helpful, and in others, bleeding ceases with internal iliac artery ligation. [Cho and colleagues \(1991\)](#) have described placing circular interrupted 0-chromic sutures around the lower segment, above and below the transverse incision, which controlled hemorrhage in all eight women in whom this was employed. [Druzin \(1989\)](#) described four cases in which the lower uterine segment was tightly packed with gauze that successfully arrested hemorrhage. The pack was removed transvaginally 12 hours later.

If these conservative methods fail, and bleeding is brisk, then hysterectomy is necessary. In some cases, uterine or internal iliac artery ligation as described on page 652 may provide hemostasis. Pelvic artery embolization has gained acceptance also ([Hansch and colleagues, 1999](#); [Pelage and associates, 1999](#)). For women whose placenta previa is implanted anteriorly in the site of a prior cesarean section incision, there is an increased likelihood of associated placenta accreta and need for hysterectomy (see p. 632).

PROGNOSIS. A marked reduction in maternal mortality from placenta previa has been achieved, a trend that began in 1927 when Bill advocated adequate transfusion and cesarean delivery. Since 1945, when Macafee and Johnson independently suggested expectant therapy for patients remote from term, a similar trend has been evident in perinatal loss. Although half of women are near term when bleeding first develops, preterm delivery still poses a formidable problem for the remainder, because not all women with placenta previa and a preterm fetus can be treated expectantly.

PERINATAL MORBIDITY AND MORTALITY. Preterm delivery is a major cause of perinatal death even though expectant management of placenta previa is practiced. In their study of almost 93,000 deliveries, [Crane and co-investigators \(1999\)](#) reported a preterm delivery rate of 47 percent. Mortality from complications of preterm birth, however, was not increased when compared with infants of similar gestational age born to women without a previa. Although suggested earlier by some investigators that congenital malformations are increased with a previa, [Crane and co-workers \(1999\)](#) were the first to confirm this and to control for maternal age. For reasons that are unclear, fetal anomalies were increased 2.5-fold.

It is unclear if there is associated fetal growth restriction with a previa. [Brar and colleagues \(1988\)](#) reported that the incidence was nearly 20 percent. Conversely, [Crane and co-workers \(1999\)](#) found no increased incidence after controlling for gestational age. [Wolf and associates \(1991\)](#), in a case-control study of 179 women with placenta previa, found the incidence of growth restriction to be 5 percent for both groups.

POSTPARTUM HEMORRHAGE

Hemorrhage following delivery is the consequence of excessive bleeding from the placental implantation site, trauma to the genital tract and adjacent structures, or both ([Table 25-6](#)). Thus, postpartum hemorrhage is a description of an event, and not a diagnosis. In the United Kingdom, half of maternal deaths from hemorrhage are due to postpartum events ([Bonnar, 2000](#)). When excess bleeding is encountered, a specific etiology should be sought. Uterine atony, degrees of retained placenta—including placenta accreta and its variants, and genital tract lacerations account for most cases of postpartum hemorrhage. In the past 20 years, placenta accreta has overtaken uterine atony as the most common cause of postpartum hemorrhage of sufficient severity to mandate hysterectomy ([Chestnut and colleagues, 1985](#); [Clark and associates, 1984](#); [Zelop and co-workers, 1993](#)).

DEFINITION. Traditionally postpartum hemorrhage has been defined as the loss of 500 mL or more of blood after completion of the third stage of labor. Nonetheless, nearly a half of all women who are delivered vaginally shed that amount of blood or more, when measured quantitatively ([Fig. 25-16](#)). This compares with 1000 mL blood loss for cesarean section, 1400 mL for elective cesarean hysterectomy, and 3000 to 3500 mL for emergency cesarean hysterectomy ([Chestnut and associates, 1985](#); [Clark and colleagues, 1984](#)). The woman with normal pregnancy-induced hypervolemia usually increases her blood volume by 30 to 60 percent, which for an average-sized woman amounts to 1 to 2 L ([Pritchard, 1965](#)). Consequently, she will tolerate, without any remarkable decrease in postpartum hematocrit, blood loss at delivery that approaches the volume of blood she added during pregnancy. In one study, the mean postpartum hematocrit decline ranged from 2.6 to 4.3 volume percent; a third of women had no decline or had an actual increase ([Combs and colleagues, 1991b](#)). Women undergoing cesarean delivery had a mean drop in hematocrit of 4.2 volume percent, but 20 percent had no decline ([Combs and co-workers, 1991a](#)).

Therefore, blood loss somewhat in excess of 500 mL by accurate measurement is not necessarily an abnormal event for vaginal delivery. [Pritchard and associates \(1962\)](#) found that about 5 percent of women delivering vaginally lost more than 1000 mL of blood. **They also observed that estimated blood loss is commonly only about half the actual loss.** Based on an estimated blood loss greater than 500 mL, postpartum hemorrhage has been found in about 5 percent of deliveries. An estimated blood loss in excess of 500 mL in many institutions, therefore, should call attention to mothers who are bleeding excessively and warn the physician that dangerous hemorrhage is imminent. Hemorrhage after the first 24 hours is designated *late postpartum hemorrhage* and is discussed in [Chapter 17 \(p. 406\)](#).

HEMOSTASIS AT THE PLACENTAL SITE. Near term, it is estimated that approximately 600 mL/min of blood flows through the intervillous space. With separation of the placenta, the many uterine arteries and veins that carry blood to and from the placenta are severed abruptly. Elsewhere in the body, hemostasis in the absence of surgical ligation depends upon intrinsic vasospasm and formation of blood clot locally. At the placental implantation site, most important for achieving hemostasis are contraction and retraction of the myometrium to compress the vessels and obliterate their lumens. Adherent pieces of placenta or large blood clots will prevent effective contraction and retraction of the myometrium and thereby impair hemostasis at the implantation site. Fatal postpartum hemorrhage can occur from a hypotonic uterus while the maternal blood coagulation mechanism is quite normal. Conversely, if the myometrium at and adjacent to the denuded implantation site contracts and retracts vigorously, fatal hemorrhage *from the placental implantation site* is unlikely even though the coagulation mechanism is severely impaired.

PROLONGED THIRD STAGE. Occasionally, the placenta does not separate promptly. A question to which there is still no definite answer concerns the length of time that should elapse in the absence of bleeding before the placenta is removed manually. Management is discussed in [Chapter 13 \(p. 321\)](#). Obstetrical tradition has set somewhat arbitrary limits on third-stage duration in attempts to define *abnormally retained placenta*, and thus reduce blood loss due to excessively prolonged placental separation. [Combs and Laros \(1991\)](#) studied 12,275 singleton vaginal deliveries and reported the median third-stage duration to be 6 minutes, and 3.3 percent were more than 30 minutes. Several measures of hemorrhage, including curettage or transfusion, increased with third stages nearing 30 minutes or longer.

UTERINE ATONY

Failure of the uterus to contract properly following delivery is a common cause of obstetrical hemorrhage. In many cases, postpartum hemorrhage can be predicted well in advance of delivery ([Table 25-6](#)). Examples in which trauma may lead to postpartum hemorrhage include delivery of a large infant, midforceps delivery, forceps rotation, any intrauterine manipulation, and perhaps vaginal delivery after cesarean section or other uterine incisions. Uterine atony causing hemorrhage can be anticipated whenever excessive concentrations of halogenated anesthetic agents are used that will relax the uterus ([Gilstrap and colleagues, 1987](#)). The overdistended uterus is very likely to be hypotonic after delivery. Thus, the woman with a large fetus, multiple fetuses, or hydramnios is prone to hemorrhage from uterine atony. Blood loss with delivery of twins, for example, averages nearly 1000 mL and may be much greater ([Pritchard, 1965](#)). The woman whose labor is characterized by uterine activity that is either remarkably vigorous or barely effective is also likely to bleed excessively from uterine atony after delivery.

Similarly, labor either initiated or augmented with oxytocin is more likely to be followed by postdelivery uterine atony and hemorrhage. The woman of high parity may be at increased risk for uterine atony. [Fuchs and colleagues \(1985\)](#) described the outcomes of nearly 5800 women para 7 or greater. They reported that the 2.7 percent incidence of postpartum hemorrhage in these women was increased fourfold compared with the general obstetrical population. [Babinszki and colleagues \(1999\)](#) reported the incidence of postpartum hemorrhage to be 0.3 percent in women of low parity, but it was 1.9 percent in those para 4 or greater.

Another risk is if the woman has previously suffered postpartum hemorrhage. Finally, mismanagement of the third stage of labor involves an attempt to hasten delivery of the placenta short of manual removal. **Constant kneading and squeezing of the uterus that already is contracted likely will impede the physiological mechanism of placental detachment, causing incomplete placental separation and increased blood loss.**

CLINICAL CHARACTERISTICS. Postpartum hemorrhage before placental delivery is called **third-stage hemorrhage**. Contrary to general opinion, whether bleeding

begins before or after placental delivery, or at both times, there may be no sudden massive hemorrhage but rather steady bleeding that at any given instant appears to be moderate, but persists until serious hypovolemia develops. Especially with hemorrhage after placental delivery, the constant seepage may lead to enormous blood loss.

The effects of hemorrhage depend to a considerable degree upon the nonpregnant blood volume, magnitude of pregnancy-induced hypervolemia, and degree of anemia at the time of delivery. A treacherous feature of postpartum hemorrhage is the failure of the pulse and blood pressure to undergo more than moderate alterations until large amounts of blood have been lost. The normotensive woman may actually become somewhat hypertensive in response to hemorrhage, at least initially. Moreover, the already hypertensive woman may be interpreted to be normotensive although remarkably hypovolemic. Tragically, the hypovolemia may not be recognized until very late.

As emphasized in [Chapter 24](#), the woman with severe preeclampsia has usually lost her pregnancy-induced hypervolemia. Thus, she frequently is very sensitive or even intolerant of what may be considered normal blood loss. **Therefore, when excessive hemorrhage is even suspected in the woman with severe pregnancy-induced hypertension, efforts should be made immediately to identify those clinical and laboratory findings that would prompt vigorous crystalloid and blood replacement.**

In instances in which the fundus has not been adequately monitored after delivery, the blood may not escape vaginally but instead may collect within the uterus. The uterine cavity may thus become distended by 1000 mL or more of blood while an inattentive attendant fails to identify the large uterus or, having done so, erroneously massages a roll of abdominal fat. The care of the postpartum uterus, therefore, must not be left to an inexperienced person.

DIAGNOSIS. Except possibly when intrauterine and intravaginal accumulation of blood are not recognized, or in some instances of uterine rupture with intraperitoneal bleeding, the diagnosis of postpartum hemorrhage should be obvious. The differentiation between bleeding from uterine atony and from lacerations is tentatively made on the condition of the uterus. If bleeding persists despite a firm, well-contracted uterus, the cause of the hemorrhage most probably is from lacerations. Bright red blood also suggests lacerations. **To ascertain the role of lacerations as a cause of bleeding, careful inspection of the vagina, cervix, and uterus is essential.**

Sometimes bleeding may be caused by both atony and trauma, especially after major operative delivery. In general, inspection of the cervix and vagina should be performed after every delivery to identify hemorrhage from lacerations. Anesthesia should be adequate to prevent discomfort during such an examination. Examination of the uterine cavity, the cervix, and all of the vagina is essential after breech extraction, after internal podalic version, and following vaginal delivery in a woman who previously underwent cesarean section. The same is true when unusual bleeding is identified during the second stage of labor.

SHEEHAN SYNDROME. Severe intrapartum or early postpartum hemorrhage is on rare occasions followed by pituitary failure. In the classical case of Sheehan syndrome, this is characterized by failure of lactation, amenorrhea, breast atrophy, loss of pubic and axillary hair, hypothyroidism, and adrenal cortical insufficiency ([Chap. 50, p. 1354](#)). The exact pathogenesis is not well understood, because such endocrine abnormalities do not develop in most women who hemorrhage severely. In some but not all instances of Sheehan syndrome, varying degrees of anterior pituitary necrosis with impaired secretion of one or more trophic hormones account for endocrine abnormalities. The anterior pituitary of some women who develop hypopituitarism after puerperal hemorrhage does respond to various releasing hormones, which at the least implies impaired hypothalamic function. Moreover, [Whitehead \(1963\)](#) identified specific atrophic changes in hypothalamic nuclei histologically in some cases. Lactation after delivery usually, but not always, excludes extensive pituitary necrosis. In some women, failure to lactate may not be followed until many years later by other symptoms of pituitary insufficiency. In the series reported by [Ammi and Mathur \(1994\)](#), the average duration of onset of symptoms was 5 years.

The incidence of Sheehan syndrome was originally estimated to be 1 per 10,000 deliveries ([Sheehan and Murdoch, 1938](#)). It appears to be even more rare today in the United States. Application of tests of hypothalamic and pituitary function now available should identify milder forms of the syndrome and define their prevalence ([Grimes and Brooks, 1980](#)). [Bakiri and colleagues \(1991\)](#) used computed tomography to study 54 women with documented Sheehan syndrome. In all of these, the appearance of the pituitary was abnormal; the sella turcica was either totally or partially empty.

MANAGEMENT OF THIRD-STAGE BLEEDING. Some bleeding is inevitable during the third stage as the result of transient partial separation of the placenta. As the placenta separates, the blood from the implantation site may escape into the vagina immediately (*Duncan mechanism*) or it may be concealed behind the placenta and membranes (*Schultze mechanism*) until the placenta is delivered.

In the presence of any external hemorrhage during the third stage, the uterus should be massaged if it is not contracted firmly. If the signs of placental separation have appeared, expression of the placenta should be attempted by manual fundal pressure as described in [Chapter 13 \(p. 321\)](#). Descent of the placenta is indicated by the cord becoming slack. If bleeding continues, manual removal of the placenta is mandatory.

TECHNIQUE OF MANUAL REMOVAL. Adequate analgesia or anesthesia is mandatory. Aseptic surgical technique should be employed. After grasping the fundus through the abdominal wall with one hand, the other hand is introduced into the vagina and passed into the uterus, along the umbilical cord. As soon as the placenta is reached, its margin is located and the ulnar border of the hand insinuated between it and the uterine wall ([Fig. 25-17](#)). Then with the back of the hand in contact with the uterus, the placenta is peeled off its uterine attachment by a motion similar to that employed in separating the leaves of a book. After its complete separation, the placenta should be grasped with the entire hand, which is then gradually withdrawn. Membranes are removed at the same time by carefully teasing them from the decidua, using ring forceps to grasp them as necessary. Some clinicians prefer to wipe out the uterine cavity with a sponge. If this is done, it is imperative that a sponge not be left in the uterus or vagina.

MANAGEMENT AFTER DELIVERY OF PLACENTA. The fundus should always be palpated following placental delivery to make certain that the uterus is well contracted. If it is not firm, vigorous fundal massage is indicated. Most often, 20 U of oxytocin in 1000 mL of lactated Ringer or normal saline proves effective when administered intravenously at approximately 10 mL/min (200 mU of oxytocin per minute) simultaneously with effective uterine massage. Oxytocin should never be given as an undiluted bolus dose as serious hypotension or cardiac arrhythmias may follow ([Chap. 13, p. 323](#)).

ERGOT DERIVATIVES. If oxytocin given by rapid infusion does not prove effective, some administer methylergonovine, 0.2 mg intramuscularly or intravenously. This may stimulate the uterus to contract sufficiently to control hemorrhage. Any superior therapeutic effects of ergot derivatives over oxytocin are speculative, and if intravenously administered they may cause dangerous hypertension, especially in the woman with preeclampsia.

PROSTAGLANDINS. The 15-methyl derivative of prostaglandin F_{2a} (carboprost tromethamine) was approved in the mid-1980s by the Food and Drug Administration for treatment of uterine atony. The initial recommended dose is 250 ug (0.25 mg) given intramuscularly, and this is repeated if necessary at 15- to 90-minute intervals up to a maximum of eight doses. [Oleen and Mariano \(1990\)](#) studied use of carboprost for postpartum hemorrhage at 12 cooperating obstetrical units. Arrest of bleeding was considered successful in 208 of 237 (88 percent) women treated. An additional 17 women required other oxytocics for control of hemorrhage. The remaining 12 women in whom drug treatment failed required surgical intervention.

Carboprost is associated with side effects in about 20 percent of women ([Oleen and Mariano, 1990](#)). In descending order of frequency, these include diarrhea, hypertension, vomiting, fever, flushing, and tachycardia. We have encountered serious hypertension in a few women so treated. In addition, [Hankins and colleagues \(1988\)](#) observed that intramuscular carboprost was followed by arterial oxygen desaturation that averaged 10 percent and developed within 15 minutes. They concluded that this was due to pulmonary airway and vascular constriction.

Rectally administered prostaglandin E₂ 20-mg suppositories have been used for uterine atony, but not studied in clinical trials. [O'Brien and colleagues \(1998\)](#) reported that misoprostol, 1000 ug given rectally, was effective in 14 women unresponsive to usual oxytocics.

BLEEDING UNRESPONSIVE TO OXYTOCICS. Continued bleeding after multiple oxytocic administrations may be from unrecognized genital tract lacerations, including in some cases uterine rupture. Thus, if bleeding persists, no time should be lost in haphazard efforts to control hemorrhage, but the following management should be initiated immediately:

1. Employ bimanual uterine compression ([Fig. 25-18](#)). The technique consists simply of massage of the posterior aspect of the uterus with the abdominal hand and massage through the vagina of the anterior uterine aspect with the other fist. This procedure will control most hemorrhage.
2. Obtain help!
3. Begin blood transfusions. The blood group of every obstetrical patient should be known, if possible, before labor, and an indirect Coombs test done to detect

erythrocyte antibodies. If the latter is negative, then cross-matching of blood is not necessary (see p. 655). In an extreme emergency, type O D-negative "universal donor" blood is given.

4. Explore the uterine cavity manually for retained placental fragments or lacerations.
5. Thoroughly inspect the cervix and vagina after adequate exposure.
6. Add a second large-bore intravenous catheter so that crystalloid with oxytocin is continued at the same time as blood is given.
7. A Foley catheter is inserted to monitor urine output, which is a good measure of renal perfusion.

Resuscitation is then carried out as described subsequently (see p. 652). Blood transfusion should be considered in any case of postpartum hemorrhage in which abdominal uterine massage and oxytocic agents fail to control the bleeding. With transfusion and simultaneous manual uterine compression and intravenous oxytocin, additional measures are rarely required. Intractable atony may mandate hysterectomy as a lifesaving measure ([Chap. 23, p. 553](#)). Alternatively, uterine artery ligation, internal iliac artery ligation, or angiographic embolization as described on page 647 may prove successful.

HEMORRHAGE FROM RETAINED PLACENTAL FRAGMENTS

Immediate postpartum hemorrhage is seldom caused by retained small placental fragments, but a remaining piece of placenta is a common cause of bleeding late in the puerperium. Inspection of the placenta after delivery must be routine. If a portion of placenta is missing, the uterus should be explored and the fragment removed, particularly with continuing postpartum bleeding. Retention of a succenturiate lobe (see [Fig. 5-15](#)) is an occasional cause of postpartum hemorrhage. The late bleeding that may result from a placental polyp is discussed in [Chapter 17 \(p. 406\)](#).

PLACENTA ACCRETA, INCRETA, AND PERCRETA

In most instances, the placenta separates spontaneously from its implantation site during the first few minutes after delivery of the infant. The precise reason for delay in detachment beyond this time is not always obvious, but quite often it seems to be due to inadequate uterine contraction. Very infrequently, the placenta is unusually adherent to the implantation site, with scanty or absent decidua, so that the physiological line of cleavage through the decidual spongy layer is lacking. As a consequence, one or more cotyledons are firmly bound to the defective decidua basalis or even to the myometrium. When the placenta is densely anchored in this fashion, the condition is called placenta accreta.

DEFINITIONS. The term *placenta accreta* is used to describe any placental implantation in which there is abnormally firm adherence to the uterine wall. As the consequence of partial or total absence of the decidua basalis and imperfect development of the fibrinoid layer (*Nitabuch layer*), placental villi are attached to the myometrium in **placenta accreta**, actually invade the myometrium in **placenta increta**, or penetrate through the myometrium in **placenta percreta** ([Figs. 25-19](#) and [25-20](#)). The abnormal adherence may involve all of the cotyledons (total placenta accreta), a few to several cotyledons (partial placenta accreta), or a single cotyledon (focal placenta accreta). According to [Benirschke and Kaufmann \(2000\)](#), histological diagnosis of accreta cannot be made from the placenta alone and the entire uterus or curettings with myometrium are necessary.

SIGNIFICANCE. An abnormally adherent placenta, although an uncommon condition, assumes considerable significance clinically because of morbidity and, at times, mortality from severe hemorrhage, uterine perforation, and infection. The incidence of placenta accreta, increta, and percreta have increased because of the increased cesarean delivery rate. In earlier reports, [Breen and associates \(1977\)](#) reviewed studies published since 1891 and found an average incidence of about 1 in 7000. [Read and co-workers \(1980\)](#) reported an incidence of about 1 per 2500 deliveries. [Zelop and colleagues \(1993\)](#) reported that abnormally adherent placentation caused 65 percent of cases of intractable postpartum hemorrhage requiring emergency peripartum hysterectomy at Brigham and Women's Hospital. [Zaki and associates \(1998\)](#) found an incidence of 1 in 1900 from 1990 to 1996 during which time there were over 23,000 deliveries at their hospital.

ETIOLOGICAL FACTORS. Abnormal placental adherence is found when decidual formation is defective. Associated conditions include implantation in the lower uterine segment; over a previous cesarean section scar or other previous uterine incisions; or after uterine curettage. In his review of 622 cases collected between 1945 and 1969, [Fox \(1972\)](#) noted the following characteristics:

1. Placenta previa was identified in a third of affected pregnancies.
2. A fourth of the women had been previously delivered by cesarean section.
3. Nearly a fourth had previously undergone curettage.
4. A fourth were gravida 6 or more.

[Zaki and associates \(1998\)](#) found that 10 percent of 112 consecutive cases of placenta previa had associated accreta. [Hardardottir and colleagues \(1996\)](#) observed that almost half of placentas in women with a prior cesarean delivery had adherent myometrial fibers detected microscopically.

Other risk factors for placenta accreta were analyzed by [Hung and co-workers \(1999\)](#) in their study of over 9300 women screened for Down syndrome at 14 to 22 weeks. Compared with the normal population, they found a 54-fold increased risk for accreta with placenta previa; an 8.3-fold risk when maternal serum alpha-fetoprotein levels exceeded 2.5 multiples of the median (MOM); or a 3.9-fold risk when maternal free β -hCG levels were greater than 2.5 MOM; and a 3.2-fold risk with maternal age of 35 or older.

CLINICAL COURSE AND DIAGNOSIS. Early in pregnancy, the maternal serum alpha-fetoprotein level may be increased ([Chap. 37, p. 983](#)). Antepartum hemorrhage is common, but in the great majority of cases, bleeding before delivery is the consequence of coexisting placenta previa. Myometrial invasion by placental villi at the site of a previous cesarean section scar may lead to uterine rupture before labor ([Berchuck and Sokol, 1983](#)). We have seen this as early as 12 weeks in a woman explored for an ectopic pregnancy. [Archer and Furlong \(1987\)](#) described massive hemoperitoneum caused by placenta percreta at 21 weeks. In women whose pregnancies go to term, however, labor will most likely be normal in the absence of an associated placenta previa or an involved uterine scar.

The possibility exists that placenta increta might be diagnosed antepartum. [Cox and associates \(1988\)](#) described a case of placenta previa in which they also were able to identify placenta increta ultrasonically from *the lack of the usual subplacental sonolucent space*. They hypothesize that the presence of this normal subplacental sonolucent area represents the decidua basalis and the underlying myometrial tissue. The absence of this sonolucent area is consistent with the presence of a placenta increta. [Pasto and associates \(1983\)](#) confirmed that the *absence* of a subplacental sonolucent or "hypoechoic retroplacental zone" is consistent with placenta increta.

More recently, magnetic resonance imaging has been used to diagnose placenta accreta ([Maldjian and co-workers, 1999](#)).

MANAGEMENT. The problems associated with delivery of the placenta and subsequent developments vary appreciably, depending upon the site of implantation, depth of myometrial penetration, and number of cotyledons involved. It is likely that focal placenta accreta with implantation in the upper uterine segment develops much more often than is recognized. The involved cotyledon is either pulled off the myometrium with perhaps somewhat excessive bleeding, or the cotyledon is torn from the placenta and adheres to the implantation site with increased bleeding, immediately or later. According to [Benirschke and Kaufmann \(2000\)](#), this may be one mechanism for formation of so-called placental polyps ([Chap. 17, p. 406](#)).

With more extensive involvement, hemorrhage becomes profuse as delivery of the placenta is attempted. In some cases, the placenta invades the broad ligament and entire cervix ([Lin and co-workers, 1998](#)). Such a case is shown in [Figure 25-19](#). Successful treatment depends upon immediate blood replacement therapy as described on page 652 and nearly always prompt hysterectomy. Alternative measures are discussed subsequently (p. 647), and include uterine or internal iliac artery ligation or angiographic embolization. [Scarantino and associates \(1999\)](#) described use of argon beam coagulation for hemostasis in the lower uterine segment.

With total placenta accreta, there may be very little or no bleeding, at least until manual placental removal is attempted. At times, traction on the umbilical cord will invert the uterus, as described in the next section. Moreover, usual attempts at manual removal will not succeed because a cleavage plane between the maternal placental surface and the uterine wall cannot be developed. In the past, the most common form of "conservative" management was manual removal of as much

placenta as possible and then packing of the uterus. In the review by [Fox \(1972\)](#), 25 percent of women managed conservatively died. Thus, the safest treatment in this circumstance is prompt hysterectomy.

INVERSION OF THE UTERUS

Complete uterine inversion after delivery of the infant is almost always the consequence of strong traction on an umbilical cord attached to a placenta implanted in the fundus ([Fig. 25-21](#)). Incomplete uterine inversion may also occur ([Fig. 25-22](#)). Contributing to uterine inversion is a tough cord that does not readily break away from the placenta, combined with fundal pressure and a relaxed uterus, including the lower segment and cervix. Placenta accreta may be implicated, although uterine inversion can occur without the placenta being so firmly adherent.

[Shah-Hosseini and Evrard \(1989\)](#) reported an incidence of about 1 in 6400 deliveries at the Women and Infants Hospital of Rhode Island. Of the 11 inversions identified, most were in primiparous women; immediate vaginal replacement of the inverted uterus was successful in nine instances. [Platt and Druzin \(1981\)](#) reported 28 cases in over 60,000 deliveries, for an incidence of about 1 in 2100. On the busy obstetrical service at Parkland Hospital, we encounter several cases annually and the vast majority are in "low-risk" deliveries.

CLINICAL COURSE. Uterine inversion is most often associated with immediate life-threatening hemorrhage, and without prompt treatment it may be fatal ([Fig. 25-23](#)). In the past it was stated that shock tends to be disproportionate to blood loss. Careful evaluation of the effects from transfusion of large volumes of blood in such cases does not support this concept, but instead makes it very apparent that blood loss in such circumstances was often massive but greatly underestimated ([Watson and associates, 1980](#)).

TREATMENT. Delay in treatment increases the mortality rate appreciably. It is imperative that a number of steps be taken immediately and simultaneously:

1. Assistance, including an anesthesiologist, is summoned immediately.
2. The freshly inverted uterus with placenta already separated from it may often be replaced simply by immediately pushing up on the fundus with the palm of the hand and fingers in the direction of the long axis of the vagina.
3. Preferably two intravenous infusion systems are made operational, and lactated Ringer solution and blood are given to treat hypovolemia.
4. If attached, the placenta is not removed until the infusion systems are operational, fluids are being given, and anesthesia, preferably halothane or enflurane, has been administered. Tocolytic drugs such as terbutaline, ritodrine, or magnesium sulfate have been used successfully for uterine relaxation and repositioning ([Catanzarite and associates, 1986](#); [Kovacs and DeVore, 1984](#); [Thiery and Delbeke, 1985](#)). In the meantime, the inverted uterus, if prolapsed beyond the vagina, is replaced within the vagina.
5. After removing the placenta, the palm of the hand is placed on the center of the fundus with the fingers extended to identify the margins of the cervix. Pressure is then applied with the hand so as to push the fundus upward through the cervix.
6. As soon as the uterus is restored to its normal configuration, the agent used to provide relaxation is stopped and simultaneously oxytocin is started to contract the uterus while the operator maintains the fundus in normal relationship.

Initially, bimanual compression ([Fig. 25-18](#)) will aid in control of further hemorrhage until uterine tone is recovered. After the uterus is well contracted, the operator continues to monitor the uterus transvaginally for any evidence of subsequent inversion.

SURGICAL INTERVENTION. Most often, the inverted uterus can be restored to its normal position by the techniques described. If the uterus cannot be reinverted by vaginal manipulation because of a dense constriction ring ([Fig. 25-24](#)), laparotomy is imperative. The fundus then may be simultaneously pushed upward from below and pulled from above. A traction suture well placed in the inverted fundus may be of aid. If the constriction ring still prohibits reposition, it is carefully incised posteriorly to expose the fundus. This surgical technique was described by [Van Vuqt and associates \(1981\)](#). After replacement of the fundus, the anesthetic agent used to relax the myometrium is stopped, oxytocin infusion is begun, and the uterine incision repaired.

GENITAL TRACT LACERATIONS

PERINEAL LACERATIONS. All except the most superficial perineal lacerations are accompanied by varying degrees of injury to the lower portion of the vagina. Such tears may reach sufficient depth to involve the anal sphincter and may extend to varying depths through the walls of the vagina. Bilateral lacerations into the vagina are usually unequal in length and separated by a tongue-shaped portion of vaginal mucosa (see [Fig. 13-17](#)). Their repair should form part of every operation for the restoration of a lacerated perineum. If the underlying perineal and vaginal fascia and muscle are not sutured, this may lead to relaxation of the vaginal outlet and may contribute to rectocele and cystocele formation.

VAGINAL LACERATIONS. Isolated lacerations involving the middle or upper third of the vagina but unassociated with lacerations of the perineum or cervix are observed less commonly. These are usually longitudinal and frequently result from injuries sustained during a forceps or vacuum operation, but they may even develop with spontaneous delivery. Such lacerations frequently extend deep into the underlying tissues and may give rise to significant hemorrhage, which usually is controlled by appropriate suturing. They may be overlooked unless thorough inspection of the upper vagina is performed. **Bleeding while the uterus is firmly contracted is strong evidence of genital tract laceration, retained placental fragments, or both.**

Lacerations of the anterior vaginal wall in close proximity to the urethra are relatively common. They are often superficial with little to no bleeding, and repair is usually not indicated. If such lacerations are large enough to require extensive repair, difficulty in voiding can be anticipated and an indwelling catheter placed.

INJURIES TO LEVATOR ANI. These are the result of overdistention of the birth canal. Muscle fibers are separated and diminution in their tonicity may be sufficient to interfere with the function of the pelvic diaphragm. In such cases, the woman may develop pelvic relaxation. If these injuries involve the pubococcygeus muscle, urinary incontinence also may develop ([Chap. 13, p. 325](#)).

INJURIES TO THE CERVIX. The cervix is lacerated in over half of vaginal deliveries ([Fahmy and associates, 1991](#)). Most of these are less than 0.5 cm. Deep cervical tears may extend to the upper third of the vagina. In rare instances, however, the cervix may be entirely or partially avulsed from the vagina, with colporrhesis in the anterior, posterior, or lateral fornices. Such injuries sometimes follow difficult forceps rotations or deliveries performed through an incompletely dilated cervix with the forceps blades applied over the cervix. Rarely, cervical tears may extend to involve the lower uterine segment and uterine artery and its major branches, and even through the peritoneum. They may be totally unsuspected, but much more often they become manifest by excessive external hemorrhage or by hematoma formation. Extensive tears of the vaginal vault should be explored carefully. If there is question of peritoneal perforation, or of retroperitoneal or intraperitoneal hemorrhage, laparotomy should be considered. With damage of this severity, intrauterine exploration for possible rupture is also mandatory. Surgical repair is usually required, and effective anesthesia, vigorous blood replacement, and capable assistance are mandatory.

Cervical lacerations up to 2 cm must be regarded as inevitable in childbirth. Such tears heal rapidly and are rarely the source of any difficulty. In healing, they cause a significant change in the round shape of the external os before cervical effacement and dilatation to that of appreciable lateral elongation after delivery. As the consequence of such tears, there may be eversion of the cervix with exposure of the delicate mucus-producing endocervical glands.

Occasionally, during labor the edematous anterior lip of the cervix may be caught and compressed between the head and the symphysis pubis. If ischemia is severe, the cervical lip may undergo necrosis and separation. More rarely, the entire vaginal portion may be avulsed from the rest of the cervix. Such *annular or circular detachment of the cervix* is uncommon in modern obstetrics.

DIAGNOSIS. A deep cervical tear should always be suspected in cases of profuse hemorrhage during and after third-stage labor, particularly if the uterus is firmly contracted. Thorough examination is necessary, and the flabby cervix often makes digital examination alone unsatisfactory. Thus, the extent of the injury can be fully appreciated only after adequate exposure and visual inspection of the cervix. The best exposure is gained by the use of right-angle vaginal retractors by an assistant while the operator grasps the patulous cervix with a ring forceps ([Fig. 25-25](#)).

In view of the frequency with which deep tears follow major operative procedures, the cervix should be inspected routinely at the conclusion of the third stage after all

difficult deliveries, even if there is no bleeding.

TREATMENT. Deep cervical tears require surgical repair. When the laceration is limited to the cervix, or even when it extends somewhat into the vaginal fornix, satisfactory results are obtained by suturing the cervix after bringing it into view at the vulva. Visualization is best accomplished when an *assistant* makes firm downward pressure on the uterus while the operator exerts traction on the lips of the cervix with fenestrated ovum or sponge forceps. Right-angle vaginal wall retractors are often helpful ([Fig. 25-25](#)). Because the hemorrhage usually comes from the upper angle of the wound, the first suture is applied just above the angle and sutured outward toward the operator. Associated vaginal lacerations may be tamponaded with gauze packs to retard hemorrhage while cervical lacerations are repaired. Either interrupted or running absorbable sutures are suitable. Overzealous suturing in an attempt to restore the normal cervical appearance may lead to subsequent stenosis during uterine involution.

PUERPERAL HEMATOMAS

From a review of six series, the incidence of puerperal hematomas was found to vary from 1 in 300 to 1 in 1000 deliveries ([Gilstrap and colleagues, 2001](#)). Nulliparity, episiotomy, and forceps delivery are the most commonly associated risk factors ([Propst and Thorp, 1998](#); [Ridgway, 1995](#)). In many other cases, however, hematomas develop following injury to a blood vessel without laceration of the superficial tissues. These may develop with spontaneous or operative delivery. Occasionally, the hemorrhage is delayed.

Puerperal hematomas may be classified as vulvar, vulvovaginal, paravaginal, or retroperitoneal. Vulvar hematomas most often involve branches of the pudendal artery, including the posterior rectal, transverse perineal, or posterior labial artery, whereas paravaginal hematomas may involve the descending branch of the uterine artery ([Zahn and Yeomans, 1990](#)). Infrequently, the torn vessel lies above the pelvic fascia. In that event, the hematoma develops above it. In its early stages, the hematoma forms a rounded swelling that projects into the upper portion of the vaginal canal and may almost occlude its lumen. If the bleeding continues, it dissects retroperitoneally, and thus may form a tumor palpable above the Poupart ligament, or it may dissect upward, eventually reaching the lower margin of the diaphragm. Branches of the uterine artery may be involved with these types of hematomas.

VULVAR HEMATOMAS. These hematomas, such as the one shown in [Figure 25-26](#), particularly those that develop rapidly, may cause excruciating pain, which often is the first symptom noticed. Hematomas of moderate size may be absorbed spontaneously. The tissues overlying the hematoma may give way as a result of necrosis caused by pressure, and profuse hemorrhage may follow. In other cases, the contents of the hematoma may be discharged in the form of large clots. In the subperitoneal variety, extravasation of blood beneath the peritoneum may be massive and occasionally fatal.

DIAGNOSIS. A vulvar hematoma is readily diagnosed by severe perineal pain and the sudden appearance of a tense, fluctuant, and sensitive tumor of varying size covered by discolored skin. When the mass develops adjacent to the vagina, it may escape detection temporarily; but symptoms of pressure, if not pain, or inability to void should prompt a vaginal examination with discovery of a round, fluctuant tumor encroaching on the lumen. When the hematoma extends upward between the folds of the broad ligament, it may escape detection unless a portion of the tumor can be felt on abdominal palpation or unless hypovolemia develops. These are worrisome because large hematomas have led to death.

TREATMENT. Smaller vulvar hematomas identified after leaving the delivery room may be treated expectantly ([Propst and Thorp, 1998](#)). If, however, the pain is severe, or if the hematoma continues to enlarge, the best treatment is prompt incision. This is done at the point of maximal distention along with evacuation of blood and clots and ligation of bleeding points. The cavity may then be obliterated with mattress sutures. Often, no sites of bleeding are identified after the hematoma has been drained. In such cases, the vagina—and not the hematoma cavity—is packed for 12 to 24 hours. **With hematomas of the genital tract, blood loss is nearly always considerably more than the clinical estimate.** Hypovolemia and severe anemia should be prevented by adequate blood replacement. In about half of women with hematomas requiring surgical repair, transfusions are necessary ([Zahn and Yeomans, 1990](#)).

Subperitoneal and supravaginal hematomas are more difficult to treat. They can be evacuated by incision of the perineum; but unless there is complete hemostasis, which is difficult to achieve by this route, laparotomy is advisable.

ANGIOGRAPHIC EMBOLIZATION. This technique has become popular for management of intractable puerperal hematomas. It can be used primarily, or usually when hemostasis is not obtained by surgical methods. A case in which embolization was carried out with occlusion of the internal pudendal artery and its vaginal branch as well as the uterine artery is shown in [Figure 25-27](#). [Alvarez and co-workers \(1992\)](#) and [Hsu and Wan \(1998\)](#) have reviewed indications for angiographic embolization and described cases in which it was employed.

RUPTURE OF THE UTERUS

The incidence of uterine rupture may vary appreciably among institutions. According to the [Centers for Disease Control and Prevention \(2000\)](#), use of hospital discharge data is inaccurate for surveillance purposes. Although the frequency of uterine rupture from all causes has probably not decreased remarkably during the past several decades, the etiology of rupture has changed appreciably and the outcome has improved significantly. Still, maternal mortality is reported ([Ripley, 1999](#)). Indeed, 20 percent of maternal deaths from hemorrhage were due to ruptured uterus ([Nagaya and colleagues, 2000](#)).

[Eden and associates \(1986\)](#) reviewed experiences with uterine rupture over a 53-year period at Duke University. From 1931 to 1950 the incidence was 1 in 1280 deliveries compared with 1 in 2250 from 1973 to 1983. [Rachagan and colleagues \(1991\)](#) reported a similar incidence of about 1 in 3000 over a 21-year period. [Miller and Paul \(1996\)](#) reported an incidence of about 1 in 1235 in nearly 190,000 deliveries from Los Angeles County-University of Southern California Women's Hospital. More than 90 percent of these were associated with a prior cesarean delivery. In our experiences, true uterine rupture, as will be defined, has become exceedingly rare. For the 5-year period from 1990 through 1994, during which time nearly 74,000 women were delivered at Parkland Hospital, there were only four uterine ruptures for an incidence of 1 in 18,500 deliveries. This low rate is related to our policy of not inducing or augmenting labor with oxytocin in women with a prior cesarean delivery ([Chap. 23, p. 540](#)).

ETIOLOGY. Uterine rupture may develop as a result of preexisting injury or anomaly, it may be associated with trauma, or it may complicate labor in a previously unscarred uterus. A classification of the etiology of uterine rupture is presented in [Table 25-7](#).

The most common cause of uterine rupture is separation of a previous cesarean section scar. As discussed in [Chapter 23 \(p. 542\)](#), this is increasing with the developing trend of allowing a trial of labor following prior transverse cesarean section(s). [Farmer and colleagues \(1991\)](#) reported that two thirds of over 11,000 women with a prior cesarean delivery underwent a trial of labor with an incidence of overt uterine rupture of 0.8 percent. In the study cited above by [Miller and Paul \(1996\)](#), only 11 of 153 cases of uterine rupture were not associated with prior cesarean section. Midtrimester uterine rupture is rare ([Levrant and Wingate, 1996](#)). However, women undergoing midpregnancy terminations following a prior cesarean were found to have a 3.8 percent risk of rupture ([Chapman and associates, 1996](#)).

Other common predisposing factors to uterine rupture are previous traumatizing operations or manipulations such as curettage, perforation, or myomectomy ([Fedorkow and colleagues, 1987](#); [Pelosi and Pelosi, 1997](#)). Excessive or inappropriate uterine stimulation with oxytocin, a previously common cause, has become very uncommon. [Mishra and colleagues \(1995\)](#) described a 43-year-old woman who suffered a ruptured vertical cesarean incision associated with inhaled crack cocaine.

DEFINITIONS. Rupture of the uterus may communicate directly with the peritoneal cavity (*complete*) or may be separated from it by the visceral peritoneum over the uterus or that of the broad ligament (*incomplete*).

It is important to differentiate between *rupture versus dehiscence of a cesarean section scar*. Rupture refers to separation of the old uterine incision throughout most of its length, with rupture of the fetal membranes so that the uterine cavity and the peritoneal cavity communicate. In these circumstances, all or part of the fetus is usually extruded into the peritoneal cavity. In addition, there is usually significant bleeding from the edges of the scar or from an extension of the rent into previously uninvolved uterus. By contrast, with dehiscence of a cesarean section scar, the fetal membranes are not ruptured and the fetus is not extruded into the peritoneal cavity. Typically, with dehiscence, the separation does not involve all of the previous uterine scar, the peritoneum overlying the defect is intact, and bleeding is absent or minimal.

CLASSICAL VERSUS LOWER-SEGMENT CESAREAN SECTION SCARS. With prior cesarean delivery, the [American College of Obstetricians and Gynecologists \(1999\)](#) cite the following figures for a trial of labor and uterine rupture: 1 to 7 percent with a prior low-vertical cesarean incision, 4 to 9 percent with a T-shaped incision, and 4 to 9 percent with a classical scar. Importantly, in about a third of cases the classical scar ruptures before labor, and not infrequently, it takes place several weeks before term. We recently encountered a term abdominal pregnancy in a woman whose prior classical incision had separated weeks to months before

she was delivered by repeat cesarean.

RUPTURE OF A CESAREAN SECTION SCAR. As discussed in detail in [Chapter 23 \(p. 540\)](#), the current trend is to offer and even encourage a trial of labor for women who had one previous transverse cesarean delivery ([American College of Obstetricians and Gynecologists, 1999](#)). The main drawback is that separation of the previous scar complicates about 1 in 200 trials of labor. This is higher in women with two or more prior operations who have a trial of labor, either spontaneous or with oxytocin stimulation.

The experience at Parkland Hospital has been that separation of the transverse uterine incision that develops antepartum or during early labor usually is limited to dehiscence without an appreciable increase in maternal or perinatal morbidity. From 1986 through 1990, there were a total of 7049 women at Parkland Hospital with prior cesarean sections, and 2044, or almost 30 percent, were allowed a trial of labor. Of the women undergoing such a trial, 1482 (73 percent) delivered vaginally. Uterine rupture with part of the fetus extruded outside of the uterus developed in three women, for a rate of 1.5 per 1000. In the entire group, there were two stillbirths (1 per 1000) and four women required hysterectomy (2 per 1000). In another 307 women undergoing a trial of labor who were given oxytocin, there were three uterine ruptures (10 per 1000). **Since 1990, when we discontinued the use of oxytocin for labor induction or augmentation for women with prior cesarean deliveries, there have been no uterine ruptures in these women.**

Separation of a vertical (classical) scar is more likely to result in severe hemorrhage with increased perinatal morbidity and mortality. It also more likely will require hysterectomy ([Fig. 25-28](#)).

MORBIDITY AND MORTALITY. Maternal risks are related to whether there is rupture of an intact uterus versus a prior cesarean scar. Scar separation following a trial of labor in a woman with a prior transverse incision has not been associated with maternal deaths ([Flamm and colleagues, 1988](#); [Rachagan and associates, 1991](#)). Conversely, in the 24 cases of uterine rupture principally unassociated with prior incisions, [Eden and associates \(1986\)](#) reported one maternal death and a 46 percent perinatal loss. Likewise, [Rachagan and colleagues \(1991\)](#) reported fetal mortality to be almost 70 percent with either spontaneous or traumatic uterine rupture. As discussed in [Chapter 23 \(p. 542\)](#), perinatal morbidity and mortality can be substantive with rupture during labor of a prior uterine incision.

HEALING OF THE CESAREAN SECTION SCAR. There is little information that deals with healing of cesarean section scars. [Williams \(1921\)](#) believed that the uterus heals by regeneration of the muscular fibers and not by scar tissue formation. For example, upon inspection of the unopened uterus at repeat cesarean delivery, there is usually no trace of the former incision, or at most, an almost invisible linear scar. Also, when the uterus is removed and fixed in formalin, often no scar is visible, or only a shallow vertical furrow in the external and internal surfaces of the anterior uterine wall is seen, with no trace of scar tissue between them.

[Schwarz and co-workers \(1938\)](#) concluded that healing occurs mainly by fibroblast proliferation. They studied the uterine incision site some days after cesarean incision and observed that as the scar shrinks, connective tissue proliferation becomes less obvious. If the cut surfaces of the uterus are closely apposed, the proliferation of connective tissue is minimal, and the normal relation of smooth muscle to connective tissue is gradually reestablished. Even when the healing is so poor that marked thinning has resulted, the remaining tissue often is entirely muscular.

RUPTURE OF THE UNSCARRED UTERUS

TRAUMATIC RUPTURE. Although the uterus is surprisingly resistant to blunt trauma, pregnant women sustaining blunt trauma to the abdomen should be watched carefully for signs of a ruptured uterus ([Chap. 43, p. 1173](#)). [Miller and Paul \(1996\)](#) described only three cases due to trauma in over 150 women with a ruptured uterus. The likelihood of placental abruption with blunt trauma is greater. Conversely, penetrating abdominal wounds are much more likely to involve the large pregnant uterus.

In the past, traumatic rupture during delivery often was caused by internal podalic version and extraction. Other causes of traumatic rupture include difficult forceps delivery, breech extraction ([Fig. 25-29](#)), and unusual fetal enlargement, such as hydrocephaly.

SPONTANEOUS RUPTURE. In the study cited earlier by [Miller and Paul \(1996\)](#), the incidence of spontaneous uterine rupture was only about 1 in 15,000 deliveries. They also found that rupture is more likely in women of high parity ([Miller and colleagues, 1997](#)). Oxytocin stimulation of labor has been rather commonly associated with uterine rupture, especially in women of high parity ([Fuchs and co-workers, 1985](#); [Rachagan and associates, 1991](#)). [Maymon and associates \(1991\)](#) as well as [Bennett \(1997\)](#) have reported uterine rupture with labor induction using prostaglandin E₂ gel or E₁ vaginal tablets. For these reasons, oxytocin should be given with great caution to stimulate labor in women of high parity. Similarly, in women of high parity, a trial of labor in the presence of suspected cephalopelvic disproportion, or abnormal presentation such as a brow, must be undertaken with caution.

PATHOLOGICAL ANATOMY. The role in uterine rupture of excessive stretching of the lower uterine segment with the development of a pathological retraction ring is described in [Chapter 18](#). Rupture of the previously intact uterus at the time of labor most often involves the thinned-out lower uterine segment. The rent, when it is in the immediate vicinity of the cervix, frequently extends transversely or obliquely. Usually the tear is longitudinal when it occurs in the portion of the uterus adjacent to the broad ligament ([Fig. 25-29](#)). Although developing primarily in the lower uterine segment, it is not unusual for the laceration to extend further upward into the body of the uterus or downward through the cervix into the vagina. At times, the bladder may also be lacerated ([Rachagan and colleagues, 1991](#)). After complete rupture, the uterine contents escape into the peritoneal cavity, unless the presenting part is firmly engaged, when only a portion of the fetus may be extruded from the uterus.

With uterine rupture in which the peritoneum remains intact, hemorrhage frequently extends into the broad ligament. In such circumstances, hemorrhage tends to be less severe than with intraperitoneal rupture. Such bleeding results in a large retroperitoneal hematoma that may involve sufficient blood loss to cause death. Fatal exsanguination may also supervene after rupture of the hematoma relieves the tamponading effect of the intact broad ligament.

CLINICAL COURSE. Prior to circulatory collapse from hemorrhage, the symptoms and physical findings may appear bizarre unless the possibility of uterine rupture is kept in mind. For example, hemoperitoneum from a ruptured uterus may result in irritation of the diaphragm and pain referred to the chest—leading one to a diagnosis of pulmonary or amniotic fluid embolus instead of uterine rupture.

Although once taught, it appears that few women experience cessation of contractions following uterine rupture. [Rodriguez and colleagues \(1989\)](#) described data from 39 of 76 women with uterine rupture in whom there was an intrauterine pressure catheter. In none of these was there a loss of intrauterine pressure or cessation of labor. Four women had increased baseline pressure associated with severe variable decelerations ([Fig. 25-30](#)). The most common finding in all of these 76 cases was sudden, severe fetal heart rate decelerations, seen in almost 80 percent of cases. They concluded that intrauterine pressure monitoring added little to the diagnosis of uterine rupture.

In other women, the appearance is identical to that of placental abruption. In still others, rupture is unaccompanied by appreciable pain and tenderness. Also, because most women in labor are given something for discomfort (either narcotics or lumbar epidural analgesia), pain and tenderness may not be readily apparent and the condition becomes evident because of signs of fetal distress, maternal hypovolemia from concealed hemorrhage, or both.

In some cases in which the fetal presenting part had entered the pelvis with labor, there is *loss of station* detected by pelvic examination. If the fetus is partly or totally extruded, abdominal palpation or vaginal examination is helpful to identify the presenting part, which has moved away from the pelvic inlet. A firm contracted uterus may at times be felt alongside the fetus. Often fetal parts are more easily palpated than usual. On vaginal examination, it is sometimes possible to palpate a tear in the uterine wall through which the fingers can be passed into the peritoneal cavity. **Failure to detect the tear by no means proves its absence.** In suspected cases, it is imperative that thorough examination be performed by an experienced examiner before the suspicion is abandoned. Sonography, performed on site, may be useful.

PROGNOSIS. With rupture and expulsion of the fetus into the peritoneal cavity, the chances for intact fetal survival are dismal, and mortality rates reported in various studies range from 50 to 75 percent. If the fetus is alive at the time of the rupture, the only chance of continued survival is afforded by immediate delivery, most often by laparotomy. Otherwise, hypoxia from both placental separation and maternal hypovolemia is inevitable. If untreated, most of the women die from hemorrhage or, less often, later from infection. Prompt diagnosis, immediate operation, the availability of large amounts of blood, and antimicrobial therapy have greatly improved the prognosis. Conversely, [Nkata \(1996\)](#) reported 44 percent maternal deaths in 32 women with a ruptured uterus in Zambia.

HYSTERECTOMY VERSUS REPAIR. In cases of scar separation without bleeding following vaginal birth after cesarean section, exploratory laparotomy is not indicated. With spontaneous uterine rupture, or frank rupture during a trial of labor after cesarean delivery, hysterectomy is frequently required. In two recent reports by [McMahon \(1996\)](#) and [Miller \(1997\)](#) and their colleagues, 10 to 20 percent of these women required hysterectomy for hemostasis. In selected cases, suture of the wound with uterine preservation may be performed. [Sheth \(1968\)](#) described outcomes from a series of 66 cases in which repair of a uterine rupture was elected rather

than hysterectomy. In 25 instances, the repair was accompanied by tubal sterilization. Thirteen of the 41 mothers who did not have tubal sterilization had a total of 21 subsequent pregnancies, but uterine rupture recurred in four instances. [Martin and colleagues \(1990\)](#) described a woman in whom recurrent uterine lateral fundal separation at 19 weeks was repaired using a Gore-Tex soft tissue patch. When delivered by cesarean section at 33 weeks, the patch was intact and epithelialized.

In the presence of a large hematoma in the broad ligament, identification and ligation of the uterine vessels can be extremely difficult. In general, efforts to control hemorrhage by clamping indiscriminately at the site of rupture involving the lower segment should be avoided. To do otherwise often leads to clamping and ligation of the ureter, bladder, or both. With uterine ruptures involving the lower uterine segment, bleeding vessels must be visualized free of surrounding tissue before clamping, or the ureter and bladder must be demonstrated to be remote from the tissue that is clamped. In some cases, the transected uterine artery has retracted laterally and is displaced to the pelvic sidewall by the hematoma that resulted. Placement of clamps to control bleeding carries little risk when rupture involves the body of the uterus remote from the ureters and bladder. The broad ligament may be entered and the ascending uterine artery and veins safely clamped. Usually, the ovarian vessels should be promptly clamped adjacent to the uterus.

INTERNAL ILIAC ARTERY LIGATION. Ligation of the internal iliac arteries at times reduces the hemorrhage appreciably ([Allahbadia, 1993](#); [Clark and colleagues, 1985](#)). This operation is more easily performed if the midline abdominal incision is extended upward above the umbilicus. With adequate exposure, ligation is accomplished by opening the peritoneum over the common iliac artery and dissecting down to the bifurcation of the external and internal iliac arteries. The areolar sheath covering the internal iliac artery is incised longitudinally, and a right-angle clamp is carefully passed just beneath the artery. Care must be taken not to perforate contiguous large veins, especially the internal iliac vein. Suture, usually nonabsorbable, is then inserted into the open clamp, the jaws are locked, the suture is carried around the vessel, and the vessel is securely ligated ([Figs. 25-31](#) and [25-32](#)). Pulsations in the external iliac artery, if present before tying the ligature, should be present afterward as well. If not, pulsations must be identified after arterial hypotension has been successfully treated, in order to assure that the blood flow through the external iliac vessel has not been compromised by the ligature. The most important mechanism of action with internal iliac artery ligation is an 85 percent reduction in pulse pressure in those arteries distal to the ligation ([Burchell, 1968](#)), thus turning an arterial pressure system into one with pressures approaching those in the venous circulation and more amenable to hemostasis via simple clot formation. Bilateral ligation of these arteries does not appear to interfere seriously with subsequent reproduction. [Mengert and associates \(1969\)](#) documented successful pregnancies in five women after bilateral internal iliac artery ligation. In three, the ovarian arteries were also ligated.

In some women, pelvic vessel bleeding may continue even after internal iliac artery ligation. Angiographically directed arterial embolization has been reported to successfully arrest hemorrhage. This was described on page 647 and in [Figure 25-27](#).

HYPOVOLEMIC SHOCK

Shock from hemorrhage evolves through several stages. Early in the course of massive bleeding, there are decreases in mean arterial pressure, stroke volume, cardiac output, central venous pressure, and pulmonary capillary wedge pressure. Increases in arteriovenous oxygen content difference reflect a relative increase in tissue oxygen extraction, although overall oxygen consumption falls ([Bland and colleagues, 1985](#)).

Blood flow to capillary beds in various organs is controlled by arterioles, which are resistance vessels that in turn are controlled by the central nervous system. At least 70 percent of total blood volume is contained in venules, which are passive resistance vessels controlled by humoral factors. Catecholamine release during hemorrhage causes a generalized increase in venular tone, resulting in an autotransfusion from this capacitance reservoir ([Barber and colleagues, 1999](#)). These changes are accompanied by compensatory increases in heart rate, systemic and pulmonary vascular resistance, and myocardial contractility. In addition, there is redistribution of cardiac output and blood volume by selective centrally mediated arteriolar constriction. This results in diminished perfusion to the kidneys, splanchnic beds, skin, and uterus with relative maintenance of blood flow to the heart, brain, and adrenal glands, organs that auto-regulate their own flow ([Barber and associates, 1999](#)).

As blood volume deficit exceeds 25 percent, compensatory mechanisms usually are inadequate to maintain cardiac output and blood pressure. At this point, additional small losses of blood result in rapid clinical deterioration. Despite an initial increase in *total oxygen extraction* by maternal tissue, maldistribution of blood flow results in *local* tissue hypoxia and metabolic acidosis, producing a vicious cycle of vasoconstriction, organ is-chemia, and cellular death. Hemorrhage also activates the CD-18 locus of lymphocytes and monocytes, which mediates leukocyte-endothelial cell interactions. These events lead to loss of capillary membrane integrity and additional loss of intravascular volume. A number of these adverse effects appear to be mediated by peptide leukotrienes and cytokines and may be experimentally improved by their pharmacological antagonism mediators ([Bitterman and colleagues, 1988](#)). There is also increased platelet aggregation in hypovolemic shock, resulting in the release of a number of vasoactive mediators that cause small vessel occlusion and further impairment of microcirculatory perfusion.

Often overlooked is the importance of extracellular fluid and electrolyte shifts in both pathophysiology and successful treatment of hypovolemic shock. This involves changes in the cellular transport of various ions, in which sodium and water enter skeletal muscles and cellular potassium is lost to the extracellular fluid ([Chiao and colleagues, 1990](#)). Replacement of extracellular fluid is thus an important component of therapy in hypovolemic shock. Indeed, survival appears to be reduced in acute hemorrhagic shock when blood alone—compared with blood and lactated Ringer solution—is administered ([Barber and co-workers, 1999](#)).

ESTIMATION OF BLOOD LOSS

Visual inspection is most often used but is notoriously inaccurate. In some reports, the amount of blood estimated to have been lost by inspection was on average about half the measured loss. Importantly, in obstetrics, part or all of the hemorrhage may be concealed. It is important to realize that in a situation of acute hemorrhage, the immediate hematocrit may not reflect actual blood loss. After the loss of 1000 mL, the hematocrit typically falls only 3 volumes percent in the first hour. However, rapid infusion of intravenous crystalloids will allow for more rapid equilibration.

Urine output is one of the most important parameters to follow in the bleeding patient. **When carefully measured, the rate of urine formation, in the absence of diuretics, reflects the adequacy of renal perfusion and, in turn, perfusion of other vital organs, because renal blood flow is especially sensitive to blood volume changes.** Urine flow of at least 30 mL and preferably 60 mL per hour should be maintained. With potentially serious hemorrhage, an indwelling catheter should be inserted promptly to measure urine flow. Potent diuretics such as furosemide invalidate the relationship between urine flow and renal perfusion. This need not be a problem in the management of the woman who is hemorrhaging, however, because the use of diuretics is contraindicated. Further intravascular volume reduction with diuretics is harmful in a hypovolemic patient. Another effect of furosemide is venodilation, which further reduces cardiac venous return, thereby further compromising cardiac output.

RESUSCITATION AND ACUTE MANAGEMENT

Whenever there is any suggestion of excessive blood loss, it is essential that steps be immediately taken to identify the presence of uterine atony, retained placental fragments, or genital tract lacerations. It is imperative that at least one or two intravenous infusion systems of large caliber be established immediately to allow rapid administration of crystalloid solutions and blood. An operating room, surgical team, and anesthesiologist should always be immediately available. The management of specific causes of postpartum hemorrhage were discussed earlier in this chapter.

FLUID AND BLOOD REPLACEMENT. Treatment of serious hemorrhage demands prompt and adequate refilling of the intravascular compartment. Crystalloid solutions typically are used for initial volume resuscitation. Such solutions rapidly equilibrate into the extravascular space and only 20 percent of crystalloid remains in the circulation of critically ill patients after 1 hour ([Shoemaker and co-workers, 1991](#)). Because of such equilibration, initial fluid infusion should involve about three times as much crystalloid as the estimated blood loss.

There is debate concerning fluid resuscitation of hypovolemic shock with colloid versus crystalloid solutions. According to their review, [Schierhout and Roberts \(1998\)](#) found a 4-percent excessive mortality in nonpregnant patients resuscitated with colloid compared with crystalloid. The [Cochrane Injuries Group Albumin Reviewers \(1998\)](#) found a 6-percent excess mortality in albumin-treated nonpregnant patients with shock. We concur with [Bonnar \(2000\)](#) that fluid resuscitation preferably should be with crystalloid and blood.

Considerable debate also surrounds the hematocrit level or hemoglobin concentration that mandates blood transfusion. According to deliberations of a [Consensus Development Conference \(1988\)](#), cardiac output does not substantively increase until the hemoglobin concentration falls to about 7 g/dL. Although the committee reported that otherwise healthy anesthetized animals survived isovolemic anemia with hematocrit decreases down to 5 volume percent, they further cited that there was significant functional deterioration well before that point. It is difficult to define a universal hematocrit or hemoglobin value below or above which transfusion is either mandatory or contraindicated. However, the recommendations of the Consensus Development Conference should be considered in clinical decision making.

According to these guidelines, red blood cells are not infused for moderate anemia in stable women.

For the woman acutely bleeding, we recommend rapid blood infusion if the hematocrit is less than 25 volume percent. Similarly, [Morrison and colleagues \(1993\)](#) recommend transfusion if the hematocrit is less than 24 volume percent or if hemoglobin is less than 8 g/dL if there is imminent surgery, acute operative blood loss, acute hypoxia, vascular collapse, or other factors present. Further support for these recommendations was provided by [Czer and Shoemaker \(1978\)](#). In 94 critically ill postoperative patients, mortality rates were lowest when hematocrit values were maintained between 27 and 33 volume percent.

[Hebert and associates \(1999\)](#) reported results from the Canadian Critical Care Trials Group. A total of 838 critically ill nonpregnant patients were randomized to restrictive red cell transfusions to maintain hemoglobin concentration over 7 g/dL, or to liberal transfusions to maintain the hemoglobin 10 to 12 g/dL. The 30-day mortality rate was similar (19 versus 23 percent, restrictive versus liberal), however, in the less ill patients (APACHE score 20 or less) the 30-day mortality was significantly lower in the restrictive group (9 versus 26 percent). [Morrison and colleagues \(1991\)](#) reported no benefits of red cell transfusions given to women who had suffered postpartum hemorrhage and who were *isovolemic but anemic* with a hematocrit between 18 and 25 volume percent. **Clearly, the level to which a woman is transfused depends not only on the present red cell mass, but also on the likelihood of additional blood loss.**

BLOOD AND COMPONENT REPLACEMENT. Contents and effects of transfusion of various blood components are shown in [Table 25-8](#). **Compatible whole blood is ideal for treatment of hypovolemia from catastrophic acute hemorrhage.** It has a shelf life of 40 days, and 70 percent of the transfused red cells remain viable for at least 24 hours following transfusion. It replaces many coagulation factors, and especially fibrinogen, and its plasma expands the hypovolemia from hemorrhage. Overall, the bleeding patient is resuscitated with fewer blood donor exposures with whole blood. One unit of whole blood will raise the hematocrit by 3 to 4 volume percent. For two decades, in most cases of obstetrical hemorrhage, as well as most every other field of medicine, red cell replacement has been used and usually proves to be sufficient. The exception is the woman with torrential bleeding.

Autotransfusion has been used for many years in surgical procedures and is becoming more popular ([Schwartz, 1999](#)). The safety of intraoperative autologous blood salvage and autotransfusion was evaluated in a multicenter historical cohort study by [Rebarber and colleagues \(1998\)](#). When 139 women undergoing cesarean delivery and given autotransfusion were compared with 87 control women, there were no differences in adverse outcomes. Specifically, there was no evidence for respiratory distress or amniotic fluid embolism.

Fractionation of whole blood makes available specific components—clotting factors and platelets—that otherwise would be scarce and thus unavailable for specific deficiencies. According to the [National Institutes of Health \(1993\)](#), component therapy provides better treatment because only the specific component needed is given. It also conserves blood resources because components from one unit of blood can be used for several patients. For these reasons, the infusion of whole banked blood is usually not necessary and rarely, available ([Barber and colleagues, 1999](#); [Bonnar, 2000](#); [Klein, 1994](#)).

DILUTIONAL COAGULOPATHY. When blood loss is massive, replacement with crystalloid solutions and packed red blood cells usually results in a depletion of platelets and soluble clotting factors, leading to a functional coagulopathy that clinically is indistinguishable from disseminated intravascular coagulopathy (p. 657). This impairs hemostasis and further contributes to blood loss. The most frequent coagulation defect found in women with blood loss and multiple transfusions is thrombocytopenia ([Counts and associates, 1979](#); [Wilson and associates, 1971](#)). Because stored whole blood is deficient in factors V, VIII, XI, and platelets, and all soluble clotting factors are absent from packed red blood cells, severe hemorrhage without factor replacement may also cause hypofibrinogenemia and prolongation of the prothrombin and partial thromboplastin times. In some cases, frank consumptive coagulopathy may accompany shock and confuse the distinction between dilutional and consumptive coagulopathy. Fortunately, in most situations encountered in obstetrics, treatment of both is the same.

Although various algorithms have been proposed to guide the replacement of platelets and clotting factors according to the volume of blood loss, there is great patient variability. Thus, component replacement is rarely necessary with acute replacement of 5 to 10 units of packed red blood cells or less. However, when blood loss exceeds this amount, consideration should be given to laboratory evaluation of platelet count, clotting studies, and fibrinogen levels. Fortunately, in practice the level of various clotting factors required for adequate hemostasis is quite minimal.

In the bleeding woman, the platelet count should be maintained above 50,000/uL with the infusion of platelet concentrates. A fibrinogen level of less than 100 mg/dL or sufficiently prolonged prothrombin or partial thromboplastin times in a patient with surgical bleeding is an indication for fresh-frozen plasma administration in doses of 10 to 15 mL/kg. If fibrinogen is severely depleted and the woman is bleeding, 15 units of cryoprecipitate given rapidly will result in plasma levels above 100 mg/dL.

TYPE AND SCREEN VERSUS CROSS-MATCH. Blood transfusion is usually not needed in most women delivered vaginally, and even with cesarean section, only 2 to 5 percent will require transfusion ([Dickason and Dinsmoor, 1992](#); [Klapholtz, 1990](#)). In any women at significant risk for hemorrhage, typing and screening or cross-matching is essential. The screening procedure involves mixing the maternal serum with standard reagent red cells that contain the antigens with which most of the common clinically significant antibodies will react. A cross-match, on the other hand, involves the use of actual donor erythrocytes rather than standard red cells. Only 0.03 to 0.07 percent of patients who are determined not to have antibodies in a type and screen procedure subsequently will have antibodies as determined by cross-match ([Boral and colleagues, 1979](#)). Thus, in an emergency, administration of screened blood very rarely results in adverse clinical sequelae. Not testing for a cross-match also decreases blood bank costs. Further, blood that is cross-matched is held exclusively for a single potential recipient, whereas with screening, blood is available for more than one potential recipient and wastage of banked blood is reduced. For these reasons, type and screen is preferred in most obstetrical situations.

PACKED RED BLOOD CELLS. Cells packed from a unit of whole blood have a hematocrit of 60 to 70 volumes percent, depending upon the method used for preparation and storage. A unit of packed red blood cells contains the same volume of erythrocytes as whole blood, and will also raise the hematocrit by 3 to 4 volume percent. Packed red blood cell and crystalloid infusion are the mainstays of transfusion therapy for most cases of obstetrical hemorrhage.

PLATELETS. When transfusion is needed, it is preferable to give platelets obtained by apheresis from one donor. In this scheme, the equivalent of platelets from six individual donors is given as a one-unit one-donor transfusion. Such units generally cannot be stored more than 5 days. The donor plasma must be compatible with recipient erythrocytes. Further, because some red blood cells are invariably transfused along with the platelets, only platelets from D-negative donors should be given to D-negative recipients. Platelet transfusion is considered in a bleeding patient with a platelet count below 50,000/uL. In the **nonsurgical patient**, bleeding is rarely encountered if the platelet count exceeds 5000 to 10,000/uL ([Sachs, 1991](#)).

If single-donor platelets are not available, random donor platelet packs are used. These are prepared from individual units of whole blood by centrifugation, then resuspended in 50 to 70 mL of plasma. One unit of random donor platelets contains about 5.5×10^{10} platelets; 6 to 10 such units are generally transfused. Each unit transfused should raise the platelet count by 5000/uL ([National Institutes of Health, 1993](#)).

FRESH-FROZEN PLASMA. This component is prepared by separating plasma from whole blood and then freezing it. It is a source of all stable and labile clotting factors, including fibrinogen. It is often used in the acute treatment of women with consumptive or dilutional coagulopathy. Fresh-frozen plasma is not appropriate for use as a volume expander in the absence of specific clotting factor deficiency. It should be considered in a bleeding woman with a fibrinogen level below 100 mg/dL and abnormal prothrombin and partial thromboplastin times.

CRYOPRECIPITATE. This component is prepared from fresh-frozen plasma. It contains factor VIII: C, factor VIII: von Willebrand factor, fibrinogen (at least 150 mg), factor XIII, and fibronectin in less than 15 mL of plasma from which it was derived ([American Association of Blood Banks, 1994](#)). There is no advantage to the use of cryoprecipitate for general clotting factor replacement in the bleeding woman instead of fresh-frozen plasma. Cryoprecipitate is only indicated in states of general factor deficiency where potential volume overload is a problem, and in a few conditions involving deficiency of specific factors. A major indication for this fraction is with severe hypofibrinogenemia caused by placental abruption in a woman with surgical incisions.

AUTOLOGOUS TRANSFUSIONS. Under some circumstances, autologous blood storage for transfusion may be considered. [McVay and colleagues \(1989\)](#) reported observations from 273 pregnant women in whom blood was drawn in the third trimester. Minimal requirements were a hemoglobin concentration 11 g/dL or a hematocrit of 34 volume percent. However, almost three fourths of these women donated only one unit, a volume of questionable value. They reported no complications. Further, the need for transfusion generally cannot be predicted. [Sherman and colleagues \(1992\)](#) studied 27 women given two or more transfusions in over 16,000 deliveries. In only 40 percent was an antepartum risk factor identified. [Andres and co-workers \(1990\)](#) and [Etchason and associates \(1995\)](#) concluded that autologous transfusions were not cost effective.

TRANSFUSION-RELATED INFECTIONS. With each unit of blood or any component thereof, the recipient is exposed to the risk of blood-borne infections. In a multihospital prospective follow-up done in London, [Regan and colleagues \(2000\)](#) tested almost 5600 recipients of nearly 22,000 units of blood. All were seronegative when tested 9 months after transfusion for hepatitis B and C, human immunodeficiency virus (HIV) infection, and human T-cell leukemia/lymphoma virus (HTLV) types I and II.

Fortunately, the most feared infection—**human immunodeficiency virus (HIV)**—is the least common. Earlier estimates with donor screening for viral antibody placed the risk of infection at 1 in 40,000 to 1 in 310,000 ([National Institutes of Health, 1993](#)). Unfortunately, more than 60 percent of recipients of HIV-positive blood become seropositive, and half develop acquired immunodeficiency syndrome (AIDS) within 7 years ([Ward and associates, 1988](#)). Because of improved sensitivity of enzyme immunosorbent assays, the risk of HIV transmission in screened blood is currently computed to be 1 in 500,000 to 1 million donations ([Cohn, 2000](#); [Lackritz and associates, 1995](#); [Schreiber and co-workers, 1996](#)).

The likelihood of **HIV-2** infection is even less. After implementation of a combined HIV-1/HIV-2 screening of blood donors in 1992, only three units of 74 million tested through 1995 were positive for HIV-2 ([Centers for Disease Control and Prevention, 1995](#)).

Until relatively recently, the transmission of **non-A, non-B hepatitis virus** was much more likely to complicate transfusions. The prevalence of hepatitis C is 1 to 2 percent of donors. In the past, most cases were undetected because they caused anicteric infection, although chronic hepatitis was common ([Chap. 48, p. 1289](#)). Serological testing for hepatitis C antibody became available in 1990 and the American Association of Blood Banks mandated hepatitis C testing for all donors. With current testing techniques, the risk of hepatitis C transmission is approximately 1 in 3300 to 1 in 103,000 ([Schreiber and associates, 1996](#); [Sloand and colleagues, 1995](#)). The risk of transmitting other infectious disease with transfusion, such as malaria and cytomegalovirus, is estimated to be less than 1 in 1 million ([National Institutes of Health, 1993](#)).

RED-CELL SUBSTITUTES. These are of three varieties: perfluorochemicals, liposome-encapsulated hemoglobin, and hemoglobin-based oxygen carriers. Their history and development was recently reviewed by [Cohn \(2000\)](#). Fluorinated hydrocarbons are biologically inert liquids with relatively high oxygen solubility. The use of such emulsions allows oxygen to be transported and delivered to tissues by simple diffusion. The most commonly used emulsion, Fluosol, must be stored frozen and thawed within 24 hours of use. Clinical benefits of these emulsions are not well established, but they may decrease the need for blood with extensive hemorrhage ([Klein, 2000](#)). Liposome-encapsulated hemoglobin has not proved promising. One formulation of a hemoglobin-based oxygen carrier, diaspirin cross-linked hemoglobin (DCLHb), proved to be dangerous ([Sloan and colleagues, 1999](#)). More recently, [Mullon and co-workers \(2000\)](#) have described successful use of polymerized bovine hemoglobin, HBOC-201, as a blood substitute for a nonpregnant woman with severe autoimmune hemolytic anemia.

CONSUMPTIVE COAGULOPATHY

In 1901, DeLee reported that "temporary hemophilia" developed in a woman with a placental abruption and another with a long-dead macerated fetus. Observations that extensive placental abruption, as well as other accidents of pregnancy, were frequently associated with hypofibrinogenemia, stimulated interest in causes of intense intravascular coagulation. Although these observations were initially almost totally confined to obstetrical cases, subsequently they were made for almost all areas of medicine ([Baglin, 1996](#)). These syndromes are commonly termed **consumptive coagulopathy or disseminated intravascular coagulation**.

PREGNANCY HYPERCOAGULABILITY. Pregnancy normally induces appreciable increases in the concentrations of coagulation factors I (fibrinogen), VII, VIII, IX, and X. Other plasma factors and platelets do not change so remarkably. Plasminogen levels are increased considerably, yet plasmin activity antepartum is normally decreased compared with the nonpregnant state. Various stimuli act to incite the conversion of plasminogen to plasmin, and one of the most potent is activation of coagulation.

PATHOLOGICAL ACTIVATION OF COAGULATION. In normal circumstances, there is no appreciable continuous physiological intravascular coagulation. During pregnancy, there does appear to be increased activation of platelet, clotting, and fibrinolytic mechanisms in vivo. [Gerbasi and colleagues \(1990\)](#) found significant increases in fibrinopeptide A, β -thromboglobulin, platelet factor 4, and fibrinogen-fibrin degradation products. They concluded that this compensated, accelerated intravascular coagulation may serve for maintenance of the uteroplacental interface.

In pathological states, coagulation may be activated via the extrinsic pathway by thromboplastin from tissue destruction and perhaps via the intrinsic pathway by collagen and other tissue components when there is loss of endothelial integrity ([Fig. 25-33](#)). Tissue factor is released and complexes with factor VII. This in turn activates tenase (factor IX) and prothrombinase (factor X) complexes ([Fig. 25-34](#)). Common inciting factors in obstetrics include thromboplastin from placental abruption as well as endotoxin and exotoxins. Another mechanism is by direct activation of factor X by proteases, for example, as present in mucin or produced by neoplasms. Amniotic fluid contains abundant mucin from fetal squames, and this likely causes rapid defibrination with amniotic fluid embolism.

Consumptive coagulopathy is almost always seen as a complication of an identifiable, underlying pathological process against which treatment must be directed to reverse defibrination. Thus identification and prompt elimination of the source of the coagulopathy is the first priority in dealing with it. With pathological activation of procoagulants that triggers disseminated intravascular coagulation, there is consumption of platelets and coagulation factors in variable quantities. As a consequence, fibrin may be deposited in small vessels of virtually every organ system. Fortunately, this seldom causes organ failure. Small vessels are protected because coagulation releases fibrin monomers that combine with tissue plasminogen activator (t-PA) and plasminogen, which releases plasmin. In turn, plasmin lyses fibrinogen, fibrin monomer, and fibrin polymers to form a series of fibrinogen-fibrin derivatives. These share immunological determinants known as fibrin degradation products or split products.

SIGNIFICANCE. In addition to bleeding and circulatory obstruction, which may cause ischemia from hypoperfusion, consumptive coagulopathy may be associated with microangiopathic hemolysis. This is caused by mechanical disruption of the erythrocyte membrane within small vessels in which fibrin has been deposited. Varying degrees of hemolysis with anemia, hemoglobinemia, hemoglobinuria, and erythrocyte morphological changes are produced. This process likely causes or contributes to the hemolysis encountered with the so-called **HELLP syndrome** ([Pritchard and colleagues, 1976](#)).

In obstetrical syndromes involving consumptive coagulopathy, the importance of vigorous restoration and maintenance of the circulation to treat hypovolemia and persistent intravascular coagulation cannot be overemphasized. With adequate perfusion of vital organs, activated coagulation factors and circulating fibrin and fibrin degradation products are promptly removed by the reticuloendothelial system. At the same time, hepatic and endothelial synthesis of procoagulants is promoted.

The likelihood of life-threatening hemorrhage in obstetrical situations complicated by defective coagulation will depend not only on the extent of the coagulation defects but—of great importance—on whether or not the vasculature is intact or disrupted. With gross derangement of blood coagulation, there may be fatal hemorrhage when vascular integrity is disrupted, yet no hemorrhage as long as all blood vessels remain intact.

CLINICAL AND LABORATORY EVIDENCE OF DEFECTIVE HEMOSTASIS. Bioassay is an excellent method to clinically detect or suspect significant coagulopathy. **Excessive bleeding at sites of modest trauma characterizes defective hemostasis.** Persistent bleeding from venipuncture sites, nicks from shaving the perineum or abdomen, trauma from insertion of a catheter, and spontaneous bleeding from the gums or nose are signs of possible coagulation defects. Purpuric areas at pressure sites may indicate incoagulable blood, or more commonly, clinically significant thrombocytopenia. A surgical procedure provides the ultimate bioassay for coagulation. Continuous generalized oozing from the skin, subcutaneous and fascial tissues, and vascular retroperitoneal space, should at least suggest coagulopathy. Such evidence also may be gained by observing continuous oozing from episiotomy incisions or perineal lacerations.

HYPOFIBRINOGENEMIA. In late pregnancy, plasma fibrinogen levels typically are 300 to 600 mg/dL. With activation of coagulation, these high levels may sometimes serve to protect against clinically significant hypofibrinogenemia. To promote clinical coagulation, fibrinogen levels must be around 150 mg/dL. If serious *hypofibrinogenemia* is present, the clot formed from whole blood in a glass tube may initially be soft but not necessarily remarkably reduced in volume. Then, over the next half hour or so, it becomes quite small, so that many of the erythrocytes are extruded and the volume of liquid clearly exceeds that of the clot.

FIBRIN AND FIBRINOGEN DERIVATIVES. Fibrin degradation products in serum may be detected by a number of sensitive test systems. Monoclonal antibodies to detect the D-dimer are commonly used. With clinically significant consumption coagulopathy, these measurements are always abnormally high.

THROMBOCYTOPENIA. Serious thrombocytopenia is likely if petechiae are abundant, clotted blood fails to retract over a period of an hour or so, or if platelets are rare in a stained blood smear. Confirmation is provided by platelet count.

PROTHROMBIN AND PARTIAL THROMBOPLASTIN TIMES. Prolongation of these coagulation tests may be the consequence of appreciable reductions in those coagulants essential for generating thrombin, a fibrinogen concentration below a critical level of about 100 mg/dL, or appreciable amounts of circulating fibrinogen-fibrin degradation products. Prolongation of the prothrombin time and partial thromboplastin time need not be the consequence of disseminated intravascular coagulation.

HEPARIN. The infusion of heparin to try to block disseminated intravascular coagulation associated with placental abruption or other situations in which

the integrity of the vascular system is compromised is mentioned only to condemn its use.

EPSILON-AMINOCAPROIC ACID. Epsilon-aminocaproic acid has been administered to try to control fibrinolysis by inhibiting the conversion of plasminogen to plasmin and the proteolytic action of plasmin on fibrinogen, fibrin monomer, and fibrin polymer (clot). Failure to clear fibrin polymer from the microcirculation could result in organ ischemia and infarction, such as renal cortical necrosis. Its use in most types of obstetrical coagulopathy is **not** recommended.

ABRUPTIO PLACENTAE

Abruptio placentae is the most common cause of severe consumptive coagulopathy in obstetrics. It is discussed on page 621.

FETAL DEATH AND DELAYED DELIVERY

Although in most women with fetal death, spontaneous labor eventually ensues—most often within 2 weeks—the psychological stress imposed by carrying a dead fetus usually prompts induction of labor at the time of discovery. This also obviates the dangers of coagulation defects that may develop. Undoubtedly, the advent of more effective methods of labor induction have enhanced the desirability of early delivery ([Chap. 20](#)).

COAGULATION CHANGES. Weiner and associates reported in 1950 that some isoimmunized D-negative women who carried a dead fetus developed coagulation defects. Prospective studies indicated that gross disruption of the maternal coagulation mechanism rarely developed before less than 1 month after fetal death ([Pritchard, 1959, 1973](#)). If the fetus was retained longer, however, about 25 percent of the women developed a coagulopathy.

Typically the fibrinogen concentration falls to levels that are normal for the nonpregnant state, and in some cases it falls to potentially dangerous concentrations of 100 mg/dL or less ([Pritchard, 1973](#)). The rate of decrease commonly found is demonstrated in [Figure 25-35](#). Simultaneously, fibrin degradation products are elevated in serum. The platelet count tends to decrease in these instances, but severe thrombocytopenia is uncommon even if the fibrinogen level is quite low. Although coagulation defects may correct spontaneously before evacuation, this is unusual and happens quite slowly ([Pritchard, 1959](#)).

PATHOGENESIS. It was clearly established that consumptive coagulopathy, presumably mediated by thromboplastin from the dead products of conception, is operational in these cases ([Jimenez and Pritchard, 1968](#); [Lerner and associates, 1967](#)). Heparin infused alone over a few days corrected the coagulation defects, but e-aminocaproic acid did not.

HEPARIN. Correction of coagulation defects has been accomplished using low doses of heparin—5000 U two to three times daily—under carefully controlled conditions *in women with an intact circulation* ([Weiner, 1991](#)). Heparin appropriately administered can block further pathological consumption of fibrinogen and other clotting factors, thereby slowing or temporarily reversing the cycle of consumption and fibrinolysis. Such correction should be undertaken only if the patient is not actively bleeding, and with simultaneous steps to effect delivery.

FETAL DEATH IN MULTIFETAL PREGNANCY. It is uncommon that an obvious coagulation derangement develops in multifetal pregnancy complicated by death of at least one fetus and survival of another ([Landy and Weingold, 1989](#)). [Carlson and Towers \(1989\)](#) described 642 multifetal gestations of which 3 percent were complicated by death of only one fetus. [Fusi and Gordon \(1990\)](#) reported 11 of 485 twin pairs in which one fetus died. [Santerna and associates \(1995\)](#) followed 29 consecutive pregnancies in which one twin died after 20 weeks. [Chitkara and colleagues \(1989\)](#) performed selective termination in 17 twin pairs between 20 and 24 weeks. [Petersen and Nyholm \(1999\)](#) followed 22 multifetal pregnancies with one fetal death after the first trimester. In none of these almost 100 cases was a coagulopathy detected.

[Chescheir and Seeds \(1988\)](#) reported a woman in whom, following death of one of twin fetuses, there was progressive but transient fall in plasma fibrinogen concentration and rise in fibrin split products. We have encountered only a few such cases at Parkland Hospital, and one is shown in [Figure 25-36](#). Coagulation changes ceased spontaneously, and the surviving fetus, when delivered near term, was healthy. The placenta of the long-dead fetus was filled with fibrin. Most cases are in monochorionic twins with vascular anastomoses ([Chap. 30, p. 784](#)). The survivor-twin has an extremely high risk of cerebral palsy and other cerebral impairment ([Pharoah and Adi, 2000](#)). Although perfusion abnormalities seem the likely cause of these problems, some investigators attribute cerebral hemorrhage to disseminated intravascular coagulation and have recommended heparin administration for women with one dead twin ([Romero and colleagues, 1984](#)).

AMNIONIC FLUID EMBOLISM

This is a complex disorder classically characterized by the abrupt onset of hypotension, hypoxia, and consumptive coagulopathy. There is great individual variation in its clinical manifestation and women will be encountered in whom one of these three clinical hallmarks dominates, or is entirely absent. The syndrome is uncommon in an absolute sense; however, it is a common cause of maternal death ([Berg and associates, 1996](#); [Koonin and colleagues, 1997](#)). Using data from 1.1 million deliveries in California, [Gilbert and Danielsen \(1999\)](#) estimated a frequency of about 1 case per 20,000 deliveries.

In obvious cases, the clinical picture frequently is dramatic. Classically, a woman in the late stages of labor or immediately postpartum begins gasping for air, and then rapidly suffers seizure or cardiorespiratory arrest complicated by disseminated intravascular coagulation, massive hemorrhage, and death. There appears to be great variation in clinical presentations of this condition. We have managed a number of women in whom otherwise uncomplicated vaginal delivery was followed by severe acute disseminated intravascular coagulation without cardiorespiratory symptoms. Thus, in some women, consumptive coagulopathy appears to be the *forme fruste* of amniotic fluid embolism ([Davies, 1999](#); [Porter and colleagues, 1996](#)).

PATHOGENESIS. Amniotic fluid embolism was originally described in 1941 by Steiner and Luschbaugh, who found evidence of fetal debris in the pulmonary circulation of a group of women dying during labor. Subsequent studies by [Adamsons and associates \(1971\)](#) and [Stolte and co-workers \(1967\)](#), however, clearly demonstrated that amniotic fluid itself is innocuous, even when infused in large amounts. Cumulative data from the National Amniotic Fluid Embolism Registry suggested a clinical picture similar to that seen in human anaphylaxis and unlike an embolic phenomenon as commonly understood ([Clark and co-workers, 1995](#)).

Amniotic fluid enters the circulation as a result of a breach in the physiological barrier that normally exists between maternal and fetal compartments. Such events appear to be common, if not universal, with both squames of presumed fetal origin and trophoblasts being commonly found in the maternal circulation ([Clark and colleagues, 1986](#); [Lee and co-workers, 1986](#)). There may be maternal exposure to various fetal elements during pregnancy termination, following amniocentesis or trauma, or more commonly during labor or delivery as small lacerations develop in the lower uterine segment or cervix. Alternately, cesarean section affords ample opportunity for mixture of maternal blood and fetal tissue.

In most cases, these events are innocuous. In certain women, however, such exposure initiates a complex series of physiological reactions mimicking those seen in human anaphylaxis and sepsis ([Table 25-9](#)). A similar process has been shown for traumatic fat embolism, a process once felt to involve simple vascular obstruction following trauma ([Peltier, 1984](#)). The pathophysiological cascade likely is caused by a number of chemokines and cytokines. For example, [Khong \(1998\)](#) found intense expression of endothelin-1 in fetal squames recovered from the lungs of two fatal cases.

PATHOPHYSIOLOGY. Studies in primates using homologous amniotic fluid injection, as well as a carefully performed study in the goat model, have provided important insights into central hemodynamic aberrations ([Adamsons and co-workers, 1971](#); [Hankins and colleagues, 1993](#); [Stolte and colleagues, 1967](#)). After a brief initial phase of pulmonary and systemic hypertension, there is decreased systemic vascular resistance and left ventricular stroke work index ([Clark and colleagues, 1988](#)). Transient but profound oxygen desaturation is often seen in the initial phase, resulting in neurological injury in most survivors ([Harvey and associates, 1996](#)). In women who live beyond the initial cardiovascular collapse, a secondary phase of lung injury and coagulopathy often ensues.

The association of uterine hypertonus with cardiovascular collapse appears to be the effect of amniotic fluid embolism rather than the cause ([Clark and co-workers, 1995](#)). Indeed, uterine blood flow ceases completely when intrauterine pressures exceed 35 to 40 mm Hg ([Towell, 1976](#)), thus, a hypertonic contraction is the *least* likely time for fetal-maternal exchange to take place. Similarly, there is no causal association between oxytocin use and amniotic fluid embolism, and the frequency of oxytocin use is not increased in these women ([American College of Obstetricians and Gynecologists, 1993](#)).

DIAGNOSIS. In the past, the detection of squamous cells or other debris of fetal origin in the central pulmonary circulation was felt to be pathognomonic for amniotic fluid embolism. Indeed, in fatal cases, histopathological findings may be dramatic, especially in those involving meconium-stained amniotic fluid ([Fig. 25-37](#)). The detection of such debris, however, may require extensive special staining and even then it is often not seen. In the National Registry, fetal elements were detected in 75 percent of autopsies and 50 percent of specimens prepared from concentrated buffy coat aspirates from a pulmonary artery catheter before death. Further, several studies have demonstrated that squamous cells, trophoblasts, and other debris of fetal origin may commonly be found in the central circulation of women with

conditions other than amniotic fluid embolism. Thus, this finding is neither sensitive nor specific, and the diagnosis is generally made by identifying clinically characteristic signs and symptoms. In less typical cases, diagnosis is contingent upon careful exclusion of other causes.

MANAGEMENT. Although an initial period of systemic and pulmonary hypertension appears to be involved in amniotic fluid embolism, this phase is transient. Women who survive long enough to receive any treatment other than cardiopulmonary resuscitation should receive therapy directed at oxygenation and support of the failing myocardium. Circulatory support and blood and component replacement are paramount. **There are no data that any type of intervention improves maternal prognosis with amniotic fluid embolism.** In undelivered women suffering cardiac arrest, consideration should be given to emergency perimortem cesarean delivery in an effort to improve newborn outcome. However, for the mother who is hemodynamically unstable, but who has not suffered arrest, such decision making becomes more complex.

PROGNOSIS. The dismal outcomes with amniotic fluid embolism are undoubtedly related to reporting biases. Also, the syndrome likely is underdiagnosed in all but the most severe cases. In the National Registry series, there was a 60 percent maternal mortality rate. In the California database of 1.1 million deliveries by [Gilbert and Danielson \(1999\)](#), only a fourth of reported cases were fatal. [Weiwen \(2000\)](#) has provided preliminary data from 38 cases in the Suzhou region of China. Almost 90 percent of these women died. Death can be amazingly rapid, and of the 34 women who died in the series from China, 12 died within 30 minutes.

Profound neurological impairment is common in survivors. Of women reported to the National Registry who had cardiac arrest in conjunction with initial symptoms, only 8 percent survived neurologically intact. Outcome is also poor for fetuses of these latter women and is related to arrest-to-delivery interval. Overall neonatal survival is 70 percent, but almost half suffer residual neurological impairment.

SEPTICEMIA

Infections that lead to bacteremia and septic shock in obstetrics are most commonly due to septic abortion, antepartum pyelonephritis, or puerperal sepsis. Other aspects of septic shock are discussed in [Chapter 43 \(p. 1167\)](#).

COAGULOPATHY. The lethal properties of bacterial toxins, and especially endotoxins, are undoubtedly mediated largely by disruption of vascular endothelium. It is unclear, however, whether this is the major mechanism that initiates consumptive coagulopathy. For example, in experimental animals, endothelial damage is greatest 24 hours after endotoxin is given, but intravascular coagulation can usually be identified during the first few hours. More likely, as shown in [Figure 25-34](#), endotoxin activates the extrinsic clotting mechanism through cytokine-induced tissue factor expression on the surface of activated monocytes ([Levi and colleagues, 1993](#)). The intrinsic route seems unimportant in this role.

MANAGEMENT. Therapy for women with septicemia from any cause is outlined in [Chapter 43 \(p. 1167\)](#). In general, treatment of the inciting cause will be followed by reversal of the coagulopathy. In some cases, especially if surgical procedures are performed before sepsis is controlled and the coagulopathy is reversed, treatment with fresh-frozen plasma and platelet packs usually will arrest such bleeding. **Heparin therapy is dangerous and should not be given.**

ABORTION

Remarkable blood loss may occur as the consequence of abortion. Hemorrhage during early pregnancy is less likely to be severe unless abortion was induced and the procedure was traumatic. When pregnancy is more advanced, the mechanisms responsible for hemorrhage are most often the same as those described for placental abruption and placenta previa—that is, the disruption of a large number of maternal blood vessels at the site of placental implantation.

COAGULATION DEFECTS. Serious disruption of the coagulation mechanism as the consequence of abortion may develop in the following circumstances:

1. Prolonged retention of a dead fetus, as already described.
2. Sepsis, a notorious cause.
3. Intrauterine instillation of hypertonic saline or urea solutions.
4. Medical induction with a prostaglandin.
5. During instrumental termination of the pregnancy.

The kinds of changes in coagulation that have been identified with abortion induced with *hypertonic solutions* imply at least that thromboplastin is released from placenta, fetus, decidua, or all three by the necrobiotic effect of the hypertonic solutions, which then initiates coagulation within the maternal circulation ([Burkman and associates, 1977](#)). Coagulation defects have been observed to develop rarely during induction of abortion with prostaglandin. [Saraiya and colleagues \(1999\)](#) reported 62 spontaneous-abortion related deaths reported to the Pregnancy Mortality Surveillance System. Almost 60 percent of deaths were caused by infection and half of these women had consumptive coagulopathy.

Consumptive coagulopathy has been an uncommon but serious complication among women with **septic abortion**. The incidence of coagulation defects in the past at Parkland Hospital was highest in those with *Clostridium perfringens* sepsis and intense intravascular hemolysis ([Pritchard and Whalley, 1971](#)). Management consists of prompt restoration and maintenance of the circulation, and appropriate steps to control the infection, including evacuation of the infected products ([Chap. 33, p. 877](#)).

TABLE 25-2. Conditions That Predispose to or Worsen Obstetrical Hemorrhage

Abnormal Placentation

Placenta previa
Placental abruption
Placenta accreta/increta/percreta
Ectopic pregnancy
Hydatidiform mole

Trauma During Labor and Delivery

Episiotomy
Complicated vaginal delivery
Low- or mid-forceps delivery
Cesarean delivery or hysterectomy
Uterine rupture—risk increased by
Previously scarred uterus
High parity
Hyperstimulation
Obstructed labor
Intrauterine manipulation
Midforceps rotation

Small Maternal Blood Volume

Small women
Pregnancy hypervolemia not yet maximal
Pregnancy hypervolemia constricted
Severe preeclampsia
Eclampsia

Other Factors

Obesity
Native American ethnicity
Previous postpartum hemorrhage

Uterine Atony

Overdistended uterus
Large fetus
Multiple fetuses
Hydramnios
Distention with clots
Anesthesia or analgesia
Halogenated agents
Conduction analgesia with hypotension
Exhausted myometrium
Rapid labor
Prolonged labor
Oxytocin or prostaglandin stimulation
Chorioamnionitis
Previous uterine atony

Coagulation Defects—Intensify Other Causes

Placental abruption
Prolonged retention of dead fetus
Amnionic fluid embolism
Saline-induced abortion
Sepsis with endotoxemia
Severe intravascular hemolysis
Massive transfusions
Severe preeclampsia and eclampsia
Congenital coagulopathies
Anticoagulant treatment

TABLE 25-3. Risk Factors for Abruption Placentae

Risk Factor	Relative Risk (%)
Increased age and parity	NA
Preeclampsia	2.1-4.0
Chronic hypertension	1.8-3.0
Preterm ruptured membranes	2.4-3.0
Cigarette smoking	1.4-1.9
Thrombophilias	NA
Cocaine use	NA
Prior abruption	10-25
Uterine leiomyoma	NA

NA = not available.

Adapted from Cunningham and Hollier (1997); risk data from Ananth and colleagues (1999a, 1999b) and Kramer and associates (1997).

TABLE 25-4. Signs and Symptoms Determined Prospectively in 59 Women with Abruption Placentae

Sign or Symptom	Frequency (%)
Vaginal bleeding	78
Uterine tenderness or back pain	66
Fetal distress	60
High frequency contractions	17
Hypertonus	17
Idiopathic preterm labor ^a	22
Dead fetus	15

^a All treated with tocolytic agents.

TABLE 25-6. Predisposing Factors and Causes of Immediate Postpartum Hemorrhage

Bleeding from Placental Implantation Site

Hypotonic myometrium—uterine atony
Some general anesthetics—halogenated hydrocarbons
Poorly perfused myometrium—hypotension
Hemorrhage
Conduction analgesia
Overdistended uterus—large fetus, twins, hydramnios
Following prolonged labor
Following very rapid labor
Following oxytocin-induced or augmented labor
High parity
Uterine atony in previous pregnancy
Chorioamnionitis
Retained placental tissue
Avulsed cotyledon, succenturiate lobe
Abnormally adherent—accreta, increta, percreta

Trauma to the Genital Tract

Large episiotomy, including extensions
Lacerations of perineum, vagina, or cervix
Ruptured uterus

Coagulation Defects

Intensify all of the above

TABLE 25-7. Classification of Causes of Uterine Rupture

Uterine Injury or Anomaly Sustained Before Current Pregnancy	Uterine Injury or Abnormality During Current Pregnancy
1. Surgery involving the myometrium Cesarean delivery or hysterotomy Previously repaired uterine rupture Myomectomy incision through or to the endometrium Deep cornual resection of interstitial oviduct Metroplasty	1. Before delivery Persistent, intense, spontaneous contractions Labor stimulation-oxytocin or prostaglandins Intra-amnionic instillation-saline or prostaglandins Perforation by internal uterine pressure catheter External trauma-sharp or blunt External version Uterine overdistention-hydramnios, multiple pregnancy
2. Coincidental uterine trauma Abortion with instrumentation-curette, sounds Sharp or blunt trauma-accidents, bullets, knives Silent rupture in previous pregnancy	2. During delivery Internal version Difficult forceps delivery Breech extraction Fetal anomaly distending lower segment Vigorous uterine pressure during delivery Difficult manual removal of placenta
3. Congenital anomaly Pregnancy in undeveloped uterine horn	3. Acquired Placenta increta or percreta Gestational trophoblastic neoplasia Adenomyosis Sacculation of entrapped retroverted uterus

TABLE 25-8. Blood Components Commonly Transfused in Obstetrics

Product	Indication	Contents	Effect
Whole blood (450 mL)	Symptomatic anemia with large volume deficits	All components	Increases hematocrit 3-4 vol% per unit
Packed red cells (250 mL)	Symptomatic anemia	Erythrocytes	Increases hematocrit 3-4 vol% per unit
Fresh-frozen plasma (250 mL)	Deficit of labile and stable coagulation factors	All clotting factors	Supplies fibrinogen 150 mg per unit and other factors
Cryoprecipitate (50 mL)	Hypofibrinogenemia	Factors VIII, vWF, XIII, fibronectin, fibrinogen	Supplies select clotting factors
Platelets (50 mL/U)	Bleeding from thrombocytopenia	Platelets	Increases platelet count 5000-8000/ μ L per unit

Modified from the American Association of Blood Banks (1994).

TABLE 25-9. Clinical Findings in 84 Women with Amnionic Fluid Embolism

Clinical Findings	Clark et al (1995) (n = 46)	Weiwen (2000) (n = 38)
Hypotension	43	38
Fetal distress	30/30	NS
Pulmonary edema or ARDS	28/30	11
Cardiopulmonary arrest	40	38
Cyanosis	38	38
Coagulopathy	38	12/16
Dyspnea	22/45	38
Seizure	22	6

ARDS = acute respiratory distress syndrome; NS = not stated.

FIGURE 25-1. Hemorrhage from premature placental separation. Upper left: Extensive placental abruption but with the periphery of the placenta and the membranes still adherent, resulting in completely concealed hemorrhage. Lower: Placental abruption with the placenta detached peripherally and with the membranes between the placenta and cervical canal stripped from underlying decidua, allowing external hemorrhage. Right: Partial placenta previa with placental separation and external hemorrhage.

26. Puerperal Infection

Puerperal infection is a general term used to describe any bacterial infection of the genital tract after delivery. Pelvic infections are the most common serious complications of the puerperium, and along with preeclampsia and obstetrical hemorrhage, for many decades of this century formed the lethal triad of causes of maternal deaths. Fortunately, maternal deaths from infection have become uncommon. [Koonin and associates \(1997\)](#) reported results from the National Pregnancy Mortality Surveillance System representing almost 1500 maternal deaths in the United States from 1987 through 1990. Infection comprised 13 percent of pregnancy-related deaths and was the fourth leading cause. In an earlier review of 2644 maternal deaths in the United States from 1979 to 1986, infection was associated with 8 percent of the total ([Atrash and colleagues, 1990](#)). [Jacob and co-workers \(1998\)](#) reported a similar rate of 10 percent for pregnancy-related deaths in Utah from 1982 through 1994.

PUERPERAL FEVER

Because most temperature elevations in the puerperium are caused by pelvic infection, the incidence of fever after childbirth is a reasonably reliable index of their incidence. The Joint Committee on Maternal Welfare was convened in 1919 ([Mussey and colleagues, 1935](#)). Several years later it modified European standards and defined puerperal morbidity as follows: *Temperature 38.0°C (100.4°F) or higher, the temperature to occur on any 2 of the first 10 days postpartum, exclusive of the first 24 hours, and to be taken by mouth by a standard technique at least four times daily.* This is still a commonly employed definition in the United States, and although it suggests that all puerperal fevers are the consequence of pelvic infection, temperature elevations may be the result of other causes.

DIFFERENTIAL DIAGNOSIS OF FEVER. When temperature persists at 38°C or more postpartum, the woman should be evaluated for extrapelvic causes of fever as well as for puerperal infection. **Most persistent fevers after childbirth are caused by genital tract infection.** [Filker and Monif \(1979\)](#) reported that only about 20 percent of febrile women (first 24 hours) delivered vaginally were subsequently diagnosed with pelvic infection, in contrast to 70 percent of those delivered by cesarean section. It must be emphasized that a high-spiking fever—39°C or higher—developing within the first 24 hours after birth may be associated with very virulent pelvic infection caused by either group A or group B streptococcus. The extragenital causes of puerperal fever described next need to be emphasized because they are more common.

BREAST ENGORGEMENT. This condition commonly causes a brief temperature elevation. About 15 percent of all postpartum women develop fever from breast engorgement, which rarely exceeds 39°C in the first few postpartum days. The fever characteristically lasts no longer than 24 hours ([Chap. 17, p. 413](#)). By contrast, the fever of **bacterial mastitis** develops later and usually is sustained. It is associated with other signs and symptoms of breast infection that become overt within 24 hours.

RESPIRATORY COMPLICATIONS. These problems are most often seen within the first 24 hours following delivery, and almost invariably are in women delivered by cesarean section. They are much less common if conduction analgesia is used. Complications include **atelectasis, aspiration pneumonia**, or occasionally, **bacterial pneumonia**. Atelectasis is best prevented with the use of routine coughing and deep breathing on a fixed schedule, usually every 4 hours for at least 24 hours following operative delivery. Hypoventilation causes alveolar collapse. Airway obstruction from thick secretions and diminished cough reflex increase this possibility. Fever associated with atelectasis is thought to be due to infection with normal flora that proliferate distal to the obstruction. [Engoren \(1995\)](#) found no association with fever and radiographic findings of atelectasis. With worsening symptoms, and because of severe sequelae, the possibility of aspiration must be suspected. These latter women most often will develop a high-spiking fever, varying degrees of respiratory wheezing, and in most instances, obvious signs of hypoxemia.

PYELONEPHRITIS. Acute renal infection may be difficult to distinguish from pelvic infection. In the typical case, bacteriuria, pyuria, costovertebral angle tenderness, and spiking temperature clearly indicate renal infection; however, the clinical picture varies. For example, in the puerperal woman the first sign of renal infection may be a temperature elevation, with costovertebral angle tenderness, nausea, and vomiting developing later. Actually, these infections are not as common as might be expected from their antenatal prevalence ([Chap. 47, p. 1255](#)). This likely is due to the brisk diuresis that normally begins early in the puerperium.

THROMBOPHLEBITIS. Superficial or deep venous thrombosis of the legs may cause minor temperature elevations in the puerperal woman. The diagnosis is made by the observation of a painful, swollen leg, usually accompanied by calf tenderness, or occasionally femoral triangle area tenderness. Diagnosis and treatment are discussed in [Chapter 46 \(p. 1235\)](#).

UTERINE INFECTION

Postpartum uterine infection has been called variously *endometritis, endomyometritis, and endoparametritis*. Because infection actually involves not only the decidua but also the myometrium and parametrial tissues, we prefer the term **metritis with pelvic cellulitis**. Uterine infections are relatively uncommon following uncomplicated vaginal delivery, but they continue to be a major problem in women delivered by cesarean section. **The route of delivery is the single most significant risk factor for the development of postpartum uterine infection.**

PREDISPOSING FACTORS

VAGINAL DELIVERY. Compared with cesarean section, metritis following vaginal delivery is relatively uncommon. [Sweet and Ledger \(1973\)](#) reported that the incidence of postpartum uterine infections after vaginal delivery was 2.6 percent. A 6-month survey during 1987 of nearly 5000 women delivered vaginally at Parkland Hospital showed that only 1.3 percent were given treatment for metritis. However, when women at high risk—defined by prolonged membrane rupture and labor, multiple cervical examinations, and internal fetal monitoring—were analyzed separately, the incidence of metritis after vaginal delivery was nearly 6 percent. If there is intrapartum chorioamnionitis, the risk of infection increases to 13 percent ([Maberry and colleagues, 1991](#)). [Libombo and colleagues \(1994\)](#) reported that metritis following vaginal delivery developed more frequently in women who had pregnancies associated with adverse fetal outcomes, including stillbirth, low birthweight, preterm delivery, and serious neonatal morbidity. Interestingly, women readmitted to the hospital with postpartum metritis are more likely to have been delivered vaginally ([Atterbury and colleagues, 1998](#)).

CESAREAN DELIVERY. The incidence of metritis following surgical delivery varies with socioeconomic factors, and over the years this has been altered substantively by the almost universal use of perioperative antimicrobials ([Chap. 23, p. 559](#)). Prior to use of antimicrobial prophylaxis, [Sweet and Ledger \(1973\)](#) reported an overall incidence of uterine infection of 13 percent among affluent women undergoing cesarean section at the University of Michigan Hospital; however, they reported the incidence to be 27 percent in indigent women delivered at Wayne County Hospital. [Cunningham and associates \(1978\)](#) found an overall incidence of about 50 percent in women delivered by cesarean section at Parkland Hospital. Important risk factors for infection included duration of labor and membrane rupture, multiple cervical examinations, and internal fetal monitoring. Women with all of these factors delivered for cephalopelvic disproportion, who were not given perioperative prophylaxis, had an incidence of serious pelvic infection that was nearly 90 percent ([DePalma and colleagues, 1982](#); [Gilstrap and Cunningham, 1979](#)).

OTHER RISK FACTORS. It is generally accepted—albeit unknown why—that pelvic infection is more common in women of lower socioeconomic status compared with middle- or upper-class patients. [Goldenberg and associates \(1996\)](#) have shown significant racial differences in vaginal colonization during pregnancy with potential pathogens. Precise reasons for these differences are unclear, but they could not be attributed to differences in health behavior.

The evidence that **anemia** increases the likelihood of infection is not conclusive ([Cook and Lynch, 1986](#)). The results obtained from both animal and in vitro experiments are consistent with the view that iron-deficiency anemia does not predispose to infection, and some believe it may actually prevent infection. For example, transferrin, which is increased in iron-deficiency anemia, appears to have significant antibacterial action. Moreover, growth of a variety of pathogenic bacteria in vitro is inhibited by lack of iron. Finally, there is no impairment of wound healing in animals previously made iron deficient.

The role of **nutrition** in the genesis of infection is also unclear, although cell-mediated immunity is impaired in malnourished laboratory animals. An increased incidence of puerperal infection resulting from recent **sexual intercourse** has not been clearly demonstrated.

Bacterial colonization of the lower genital tract with certain microorganisms—for example, group B streptococcus, *Chlamydia trachomatis*, *Mycoplasma hominis*, and *Gardnerella vaginalis*—has been associated with an increased risk of postpartum infection ([Berenson and colleagues, 1990](#); [Berman and associates, 1987](#)). In a study of almost 8000 women, [Krohn and colleagues \(1999\)](#) reported an increased risk of intrapartum but not postpartum infection in women with heavy versus light group B streptococcal colonization. Of 345 cases of group B bacteremia identified by an active surveillance program, [Schrag and co-workers \(2000\)](#) reported one maternal death. While [Watts and associates \(1990\)](#) reported an increased risk of puerperal metritis with bacterial vaginosis, [Carey and collaborators \(2000\)](#) reported that its treatment antepartum did not affect the postpartum infection rate. [Andrews and colleagues \(1995\)](#) reported that colonization with *Ureaplasma urealyticum* of intact

membranes was a significant risk factor for infection following cesarean delivery.

Some other factors include cesarean delivery for **multifetal gestation** ([Suonio and Huttunen, 1994](#)). **Young maternal age and nulliparity** are associated with a higher incidence of metritis following cesarean delivery ([Magee and associates, 1994](#); [Suonio and Huttunen, 1994](#); [Tran and co-workers, 2000](#)). [Bahn and associates \(1998\)](#), as well as many others before, reported an increased risk of maternal infectious morbidity associated with **prolonged labor induction**. [Tran and colleagues \(2000\)](#) found a twofold increase in cesarean infections for every 5-unit increase in body mass index. Finally, [Rotmensch and associates \(1999\)](#) reported an increase in infection-related maternal morbidity with three or more courses of **betamethasone** given to women at risk for preterm delivery.

BACTERIOLOGY

Organisms that invade the placental implantation site, incisions, or lacerations as a consequence of delivery typically are those that normally colonize the cervix, vagina, and perineum. Most of these bacteria are of relatively low virulence and seldom initiate infection in healthy tissues. Although an occasional epidemic caused by group A β -hemolytic streptococcus has been reported, these are usually endemic ([Anteby and associates, 1999](#)).

Over the past decade, there have been reports of this organism causing toxic shock-like syndrome ([Dotters and Katz, 1991](#); [Nathan and Leveno, 1994](#); [Whitted and colleagues, 1990](#)). [Udagawa and associates \(1999\)](#) recently reviewed 30 cases of group A infections in women either peripartum or postpartum. Of 17 women in whom infection manifested before or during labor, or within 12 hours of delivery, maternal mortality was 88 percent and fetal mortality was 60 percent. In 13 women who deteriorated more than 12 hours postpartum, the maternal death rate was 55 percent and there were no fetal deaths. [Anteby and associates \(1999\)](#) reviewed their experiences with 47 women who had group A streptococcal infections intrapartum or in the puerperium. A prominent risk factor was prematurely ruptured membranes. Three women had septic shock.

COMMON PATHOGENS. In the great majority of instances, bacteria responsible for pelvic infection are those that normally reside in the bowel and also colonize the perineum, vagina, and cervix. Bacteria commonly responsible for female genital tract infections are listed in [Table 26-1](#). Usually, multiple species of bacteria are isolated, and although typically considered to be of relatively low virulence, they may become pathogenic as a result of hematomas and devitalized tissue.

Although the cervix and lower genital tract routinely harbor such bacteria, the uterine cavity is usually sterile before rupture of the amniotic sac. As the consequence of labor and delivery and associated manipulations, the amniotic fluid and perhaps the uterus commonly become contaminated with anaerobic and aerobic bacteria ([Fig. 26-1](#)). [Gilstrap and Cunningham \(1979\)](#), from cultures of amniotic fluid obtained at cesarean delivery in women in labor with membranes ruptured more than 6 hours, identified anaerobic and aerobic organisms in 63 percent, anaerobes alone in 30 percent, and aerobes alone in 7 percent. Predominant anaerobic organisms were gram-positive cocci (*Peptostreptococcus* and *Peptococcus* species), 45 percent; *Bacteroides* species, 9 percent; and *Clostridium* species, 3 percent. Gram-positive aerobic cocci also were common (*Enterococcus*, 14 percent, and group B streptococcus, 8 percent). *Escherichia coli* comprised 9 percent of isolates. An average of 2.5 organisms was identified from each specimen. [Walmer and colleagues \(1988\)](#) provided evidence for *Enterococcus* species in the pathogenesis of these infections. [Sherman and co-workers \(1999\)](#) showed that bacterial isolates from the lower uterine segment at cesarean delivery correlated with isolates taken at 3 days postpartum when metritis had developed.

Chlamydia trachomatis has been implicated as a cause of late-onset, indolent metritis that may develop in a third of women who had antepartum chlamydial cervical infection ([Ismail and co-workers, 1985](#)). [Berenson and colleagues \(1990\)](#) reported that *C. trachomatis* was isolated significantly more often from adolescents with postcesarean metritis compared with adults. Of interest, *Gardnerella vaginalis* also was isolated more often in the younger women. Whether these organisms are truly pathogenic or simply "markers" of risk factors for infection is unclear. [Gibbs and colleagues \(1987\)](#) reported that *Gardnerella* lacked a pathogenic role in puerperal infections. The role of genital mycoplasmas and ureaplasma is less clear, but some researchers have implicated these organisms in the etiology of puerperal metritis ([Andrews and co-workers, 1995](#); [Blanco and colleagues, 1983](#)).

BACTERIAL CULTURES. Precise identification of bacteria specifically responsible for any puerperal infection is quite difficult. For example, using double-lumen catheters, [Gibbs and associates \(1975\)](#) cultured one or more pathogens from the uterine cavity in 70 percent of clinically healthy puerperal women. For these reasons, routine pretreatment genital tract cultures are of little clinical utility, and they add significantly to hospitalization costs. Similarly, the utility of routine blood cultures obtained before antimicrobials are given is questionable. In two earlier studies, blood cultures were positive in 13 percent of women at Parkland Hospital and 24 percent at Los Angeles County Hospital who had postcesarean pelvic infections ([Cunningham and colleagues, 1978](#); [DiZerega and co-workers, 1979](#)).

PATHOGENESIS

Puerperal infection following vaginal delivery primarily involves the placental implantation site and the decidua and adjacent myometrium. In some cases, the discharge is foul, profuse, bloody, and sometimes frothy. In others, the discharge is scant. Uterine involution may be retarded. Microscopical sections may show a superficial layer of necrotic material containing bacteria and a thick zone of leukocytic infiltration.

As shown in [Figure 26-1](#), the pathogenesis of uterine infection following cesarean delivery is that of an infected surgical incision. Bacteria that colonized the cervix and vagina gain access to amniotic fluid during labor, and postpartum they invade devitalized uterine tissue at the hysterotomy site. Parametrial cellulitis next follows with infection of the pelvic retroperitoneal fibroareolar connective tissue ([Fig. 26-2](#)). It may be caused by the lymphatic spread of organisms from an infected cervical laceration or uterine incision or laceration. The process is usually limited to the paravaginal tissue and rarely extends deeply into the pelvis.

CLINICAL COURSE

Whenever fever develops postpartum, uterine infection should be suspected. Fever is probably proportional to the extent of infection, and when confined to the endometrium (decidua) and superficial myometrium, cases are mild and associated with minimal fever. More commonly, temperature exceeds 38 to 39°C. Chills may accompany fever and suggest bacteremia, which is documented in 10 to 20 percent of women with pelvic infection following cesarean delivery. The pulse rate typically follows the temperature curve.

The woman usually complains of abdominal pain, and parametrial tenderness is elicited upon abdominal and bimanual examination. Because of incisional pain, abdominal and uterine fundal tenderness may be more helpful in establishing the diagnosis of metritis in women following vaginal than cesarean delivery. Even in the early stages, an offensive odor may develop; however, in many women foul-smelling lochia without other evidence for infection is found. Some infections, and notably those due to group A β -hemolytic streptococci, are frequently associated with scanty, odorless lochia. Leukocytosis may range from 15,000 to 30,000 cells/uL. The average increase in the leukocyte count postpartum is 22 percent ([Hartmann and co-workers, 2000](#)). **Thus, fever after exclusion of other causes remains the most important criterion for the diagnosis of postpartum metritis.** If the process is localized to the uterus, the temperature may return to normal without antimicrobial treatment. Indeed, localized metritis may be misdiagnosed as a urinary infection, breast engorgement, or pulmonary atelectasis. Without treatment, uterine and pelvic cellulitis worsen; however, resolution usually is prompt with appropriate antimicrobial therapy.

TREATMENT

For mild cases of metritis following vaginal delivery diagnosed after discharge, an oral agent may suffice. For moderately to severely infected women, however, including those delivered by cesarean, parenteral therapy with a broad-spectrum antimicrobial regimen is indicated. Improvement will follow in 48 to 72 hours in nearly 90 percent of women treated with one of the regimens discussed next. Persistence of fever after this interval mandates a careful search for causes of refractory pelvic infection, although nonpelvic sources are occasionally found. Complications of metritis that cause persistent fever despite appropriate therapy include parametrial phlegmons or intense cellulitis, surgical incisional and pelvic abscesses, infected hematomas, and septic pelvic thrombophlebitis. Bacteria resistant to initial therapy occasionally may be a cause of persistent fever, but this is rare in our experiences. Drug fever also is very uncommon.

In the usual contemporaneous practice, the woman is discharged without further therapy after she has been afebrile for at least 24 hours. [Dinsmoor and colleagues \(1991\)](#) found no differences in infection-related complications when oral antimicrobials were compared with placebo for afebrile women discharged following intravenous therapy.

PRINCIPLES OF ANTIMICROBIAL TREATMENT. Few, if any, antimicrobial regimens are effective against all putative pathogens that cause pelvic infection and initial antibiotic therapy is empirical. Despite this, initial treatment following cesarean delivery is directed against at least most of the polymicrobial and mixed flora that typically cause puerperal infections ([Table 26-1](#)). Fortunately, selection of an agent(s) effective against the most common ones usually proves suitable. Such broad-spectrum coverage is often not necessary to treat infection following vaginal delivery, and up to 90 percent of such women will respond to regimens such as ampicillin plus gentamicin. In contrast, the importance of including anaerobic coverage for those with infections following cesarean delivery is exemplified in that only

60 to 70 percent have a satisfactory response to ampicillin plus gentamicin. A number of effective regimens is shown in [Table 26-2](#).

In 1979, DiZerega and colleagues compared the effectiveness of clindamycin plus gentamicin with penicillin G plus gentamicin given for treatment of pelvic infections following cesarean section. Women given the **clindamycin-gentamicin** regimen had a favorable response 95 percent of the time, and this regimen now is considered by most to be the standard by which others are measured. [Walmer and colleagues \(1988\)](#) later provided evidence that enterococcal infections may be associated with its clinical failure; thus, many add ampicillin to the clindamycin-gentamicin regimen, either initially or if there is no response by 48 to 72 hours. Most recently, vancomycin-resistant enterococcal infections have been problematic in nonobstetrical units ([Murray, 2000](#)).

[Brumfield and colleagues \(2000\)](#) at the University of Alabama at Birmingham reaffirmed the efficacy of this regimen given to 322 women with postcesarean metritis and pelvic cellulitis. Over half (54 percent) were cured with the original two-drug regimen and another 40 percent in whom ampicillin was added at 48 hours responded. Of the 19 women (6 percent) who did not respond to "triple therapy," 7 had a wound infection that required drainage.

Although many authorities recommend that serum gentamicin levels be periodically monitored, we do not feel it necessary to measure peak and trough serum concentrations in most women. [Liu and associates \(1999\)](#) compared multiple- versus single-daily dosing with gentamicin and found that both provided adequate serum levels which avoided the need for routine measurement. Because of the potential for nephrotoxicity and ototoxicity with gentamicin in the event of diminished glomerular filtration, some have recommended a combination of clindamycin and a second-generation cephalosporin to treat such women. Others have recommended a combination of clindamycin and aztreonam, a monobactam compound with activity against gram-negative aerobic pathogens similar to aminoglycosides ([American College of Obstetricians and Gynecologists, 1998](#)).

The spectra of **β -lactam antimicrobials** include activity against many anaerobic pathogens, and these antimicrobials have been used successfully for decades to treat such infections. Some examples include cephalosporins—cefotetan, cefotaxime, and others—as well as extended-spectrum penicillins such as piperacillin, ticarcillin, and mezlocillin. Beta-lactam antimicrobials are inherently safe, and except for allergic reactions, are free of major toxicity. Another advantage is the cost-effectiveness of administering only one drug. The **β -lactamase inhibitors**, clavulanic acid, sulbactam, and tazobactam, have been combined with ampicillin, amoxicillin, ticarcillin, and piperacillin to extend their spectra, and these also have been proven effective.

Metronidazole has superior in vitro activity against most anaerobes, and it is recommended by some to be given intravenously in combination with gentamicin. The use of metronidazole plus ampicillin and an aminoglycoside provides coverage against most organisms encountered in serious pelvic infections.

Imipenem is a carbapenem that has broad-spectrum coverage against the majority of organisms associated with metritis. It is used in combination with **cilastatin**, which inhibits renal metabolism of imipenem. Although this combination will most certainly be effective in most cases of metritis, it seems reasonable from both a medical and economic standpoint to reserve it for more serious infections.

COMPLICATIONS OF PELVIC INFECTIONS

In over 90 percent of women, metritis responds within 48 to 72 hours to treatment with one of the aforementioned regimens. In the others, any of a number of complications may arise.

WOUND INFECTIONS

The incidence of abdominal incisional infections following cesarean delivery ranges from 3 to 15 percent, with an average of about 6 percent ([Faro, 1990](#); [Owen and Andrews, 1994](#)). When prophylactic antibiotics are given, the incidence is probably 2 percent or less. According to [Soper and co-workers \(1992\)](#), wound infection is the most common cause of antimicrobial failure in women treated for metritis. Risk factors for wound infections include obesity, diabetes, corticosteroid therapy, immunosuppression, anemia, and poor hemostasis with hematoma formation.

Incisional abscesses that develop following cesarean section usually cause fever beginning on about the fourth postoperative day. In many cases, these are preceded by uterine infection, and there is persistent fever despite adequate antimicrobial therapy. Erythema and drainage may also be present. Wound cultures are almost always positive ([Owen and Andrews, 1994](#); [Roberts and colleagues, 1993](#)). Organisms causing these infections are usually the same as those isolated from amniotic fluid at cesarean delivery, but hospital-acquired pathogens must be suspected ([Emmons and colleagues, 1988](#); [Owen and Andrews, 1994](#)). Treatment is with antimicrobials and surgical drainage, with careful inspection to ensure that the fascia is intact; if not, secondary closure must be performed.

WOUND DEHISCENCE. Wound disruption, dehiscence, or "burst abdomen" refers to separation of the wound involving the fascial layer. [McNeely and colleagues \(1998\)](#) studied 8590 women undergoing cesarean delivery at Hutzel Hospital in Detroit. They reported that 27 of these women developed fascial dehiscence—about 1 in 300 operations. Most disruptions do not manifest until about the fifth postoperative day, at which time there is a serosanguinous discharge. Most instances of wound dehiscence develop following treatment for postcesarean metritis. Two thirds of the 27 fascial dehiscences identified by [McNeely and associates \(1998\)](#) were associated with infection and tissue necrosis.

Fascial dehiscence is a serious complication. Treatment includes secondary closure of the incision in the operating room with adequate anesthesia. Surgical debridement is carried out first, followed by fascial or myofascial closure.

NECROTIZING FASCIITIS. Fortunately, this most serious of wound infections is rare, but it is associated with very high mortality. It may involve abdominal incisions following cesarean delivery or it may complicate episiotomy or perineal lacerations (see p. 682). As the name implies, these infections are associated with significant tissue necrosis. Of the risk factors for fasciitis summarized by [Owen and Andrews \(1994\)](#), three of these—diabetes, obesity, and hypertension—are relatively common in pregnant women. Infections are either monobacterial, as with group A β -hemolytic streptococcus, but more commonly they are polymicrobial. Bacterial isolates are those shown in [Table 26-1](#). Occasionally, these infections are caused by rarely encountered pathogens ([Barber and Swygert, 2000](#)).

At the University of Alabama, [Goepfert and colleagues \(1997\)](#) reviewed their experiences with incisional necrotizing fasciitis following cesarean delivery. From 1987 through 1994, there were nine cases in 5048 cesarean deliveries—1.8 per 1000 cesareans. In two women, including one with metastatic breast cancer, the infection was fatal.

Adequate antimicrobial therapy is continued as discussed previously. [Zimbleman and co-workers \(1999\)](#) reported preliminary observations that clindamycin given along with a β -lactam agent may be the most effective regimen. Additional treatment includes prompt and aggressive wide debridement in the operating room. With extensive resection, fascial closure may require synthetic mesh to eventually effect closure ([McNeely and associates, 1998](#)).

PERITONITIS

This complication is rarely seen with prompt therapy, but may be encountered with infections following cesarean delivery when there is uterine incisional necrosis and dehiscence. It also is occasionally seen in women who have undergone vaginal delivery following prior cesarean section. Also rare, late in the course of pelvic cellulitis, a parametrial or adnexal abscess may rupture and produce catastrophic generalized peritonitis.

Clinically, puerperal peritonitis resembles surgical peritonitis, except that abdominal rigidity usually is less prominent because of the abdominal stretching associated with pregnancy. Pain may be severe. Marked bowel distention is a consequence of paralytic ileus. It is important to identify the cause of the generalized peritonitis. If the infection began in the uterus and extended into the peritoneum, the treatment is usually medical. Conversely, peritonitis as the consequence of a bowel lesion or uterine incisional necrosis is usually best treated surgically. Antimicrobial therapy is continued, but septicemic shock may supervene ([Chap. 43, p. 1167](#)).

ADNEXAL INFECTIONS

Most often with puerperal infections the fallopian tubes are involved only with perisalpingitis without subsequent tubal occlusion and sterility. An *ovarian abscess* rarely develops as a complication of puerperal infection, presumably from bacterial invasion through a rent in the ovarian capsule ([Wetchler and Dunn, 1985](#)). The abscess is usually unilateral and women typically present 1 to 2 weeks after delivery. In many cases, rupture causes peritonitis, which prompts surgical exploration.

PARAMETRIAL PHLEGMON

In some women in whom metritis develops following cesarean delivery, parametrial cellulitis is intensive and forms an area of induration, termed a *phlegmon*, within

the leaves of the broad ligament ([Fig. 26-3](#)). These infections should be considered when fever persists after 72 hours despite adequate treatment of pelvic infections that complicate cesarean delivery ([DePalma and colleagues, 1982](#)). In some cases, infection may not manifest before discharge. [Kindig and colleagues \(1998\)](#) described a woman with uterine dehiscence at 6 weeks postpartum.

Areas of parametrial cellulitis are more often unilateral, and although they frequently may remain limited to the base of the broad ligament, if the inflammatory reaction is more intense, cellulitis extends along natural lines of cleavage. The most common form of extension is directly laterally, along the base of the broad ligament, with a tendency to extend to the lateral pelvic wall. Posterior extension may involve the rectovaginal septum, producing a firm mass posterior to the cervix.

Intensive cellulitis of the uterine incision may cause necrosis and separation with extrusion of purulent material into the peritoneal cavity. Clinical findings then are as described earlier for peritonitis. Frequently, the first symptoms of peritonitis are those of *adynamic ileus*, which usually is absent or mild following uncomplicated cesarean delivery. Because puerperal metritis with cellulitis is typically a retroperitoneal infection, evidence for peritonitis suggests the possibility of uterine incisional necrosis, or less commonly a bowel injury or other lesion.

In the majority of women with a phlegmon, clinical response follows continued treatment with one of the intravenous antimicrobial regimens previously discussed. These women usually remain febrile for 5 to 7 days, and in some cases even longer. Absorption of the induration follows, but it may take several days to weeks to dissipate completely. Surgery is reserved for women in whom uterine incisional necrosis is suspected. Hysterectomy and surgical debridement are usually difficult, and there is often appreciable blood loss. Frequently, the cervix and lower uterine segment are involved with an intensive inflammatory process that extends to the pelvic sidewall to encompass one or both ureters, and supracervical hysterectomy should be considered. The adnexae are seldom involved, and depending on their appearance, one or both ovaries may be conserved.

IMAGING STUDIES. Evaluation of persistent pelvic infections using sonography has been less than satisfactory because these areas of cellulitis usually have ultrasonic characteristics suggesting an abscess. As discussed, surgical drainage of a phlegmon is inadvisable. [Brown and colleagues \(1991\)](#) described the use of computed tomography in 74 women to assess refractory pelvic infections, and there was at least one abnormal radiological finding in three fourths of these women. [Lev-Toaff and colleagues \(1991\)](#) reported similar findings in 31 women using ultrasound along with computed tomography or magnetic resonance imaging. Only two of these women had negative findings. Utilizing magnetic resonance imaging, [Maldjian and associates \(1999\)](#) studied 50 women with persistent low-grade fever following cesarean delivery. Bladder flap hematomas were found in two thirds, three had parametrial edema, and two had pelvic hematomas.

Sometimes evidence for uterine incisional dehiscence can be detected using computed tomographic scanning ([Figs. 26-4](#) and [26-5](#)). It is important that these x-ray findings be interpreted along with the clinical course, because apparent uterine incisional defects can be visualized after cesarean section with no other evidence for infection or other complications ([Twickler and colleagues, 1991](#)).

PELVIC ABSCESS

Rarely, despite prompt and appropriate antimicrobial treatment for metritis, a parametrial phlegmon will suppurate, forming a fluctuant broad ligament mass that may point above the Poupart ligament. Should the abscess rupture into the peritoneal cavity, life-threatening peritonitis may develop as previously described. More likely, these abscesses will dissect anteriorly, and may be amenable to needle drainage directed by computed tomography ([Fig. 26-5](#)). Occasionally they dissect posteriorly to the rectovaginal septum, where surgical drainage is easily effected by colpotomy incision. [Segal and colleagues \(1996\)](#) have described two cases of **psaos abscess** following normal delivery.

Sometimes following cesarean section, collections of blood develop under the bladder flap ([Maldjian and associates, 1999](#)). Hematomas may also form in the broad ligament near the uterine incision. These may become infected and require drainage. They usually can be aspirated using computed tomography guidance.

SEPTIC PELVIC THROMBOPHLEBITIS

The first reports of surgical excision for pelvic thrombophlebitis appeared at the turn of the last century in the German literature. In [1909, Williams](#) reported a 50 percent mortality rate among 56 women undergoing excision of thrombosed pelvic veins complicating "puerperal pyemia." In [1919, Halban and Kohler](#) performed autopsies in 163 women who died from puerperal infection and reported that half of these had pelvic thrombophlebitis. In [1951, Collins and colleagues](#) described the pathogenesis of suppurative pelvic thrombophlebitis in 70 women cared for from 1937 through 1946 at Charity Hospital at New Orleans. Septic embolization was common in these women and caused a third of maternal deaths during those times. With the advent of antimicrobial therapy, the mortality from these infections diminished as did the need for surgical therapy.

PATHOGENESIS. Bacterial infection begins as usual in the placental implantation site, or more commonly, the uterine incision. These infections are associated with myometrial venous thromboses. As shown in [Figures 26-2](#) and [26-6](#), puerperal infection may extend along venous routes. There often is coexisting lymphangitis. As shown in [Figure 26-7](#), the ovarian veins may then become involved because they drain the upper uterus, which most often includes veins draining the placental site. The experiences of [Witlin and Sibai \(1995\)](#) and [Brown and colleagues \(1999\)](#) suggest that puerperal septic thrombophlebitis is likely to involve one or both ovarian venous plexuses. In a fourth of women with pelvic thrombosis, clot extends into the inferior vena cava ([Fig. 26-8](#)). Septic phlebitis of the left ovarian vein may extend to the renal vein ([Bahnsen and colleagues, 1985](#)).

INCIDENCE. During a 5-year survey of 45,000 women delivered at Parkland Hospital, [Brown and associates \(1999\)](#) found an incidence of septic thrombophlebitis of 1:9000 for vaginal and 1:800 for cesarean delivery. The overall incidence of 1:3000 deliveries was very similar to 1:2000 reported by [Dunnihoo and colleagues \(1991\)](#), who used modern imaging techniques to study women with prolonged fever in a population of over 60,000 deliveries.

CLINICAL FINDINGS. Women with septic thrombophlebitis usually experience most aspects of clinical improvement of pelvic infection following antimicrobial treatment; however, they continue to have hectic fever spikes. They usually do not appear clinically ill, and may be asymptomatic except for chills. This clinical picture was aptly termed *enigmatic fever* by [Dunn and Van Voorhis \(1967\)](#). In some women, the cardinal symptom of ovarian vein thrombophlebitis is pain typically manifest on the second or third postpartum day ([Munsick and Gillanders, 1981](#)). In some cases, a tender mass is palpable just beyond the uterine cornu on either side. In many cases, pelvic findings are inconclusive by clinical examination. Thus, diagnosis is by either pelvic computed tomography or magnetic resonance imaging. Using these, [Brown and co-workers \(1999\)](#) found that 20 percent of 69 women who had fever despite 5 days of appropriate antimicrobial therapy for metritis had confirmed septic phlebitis.

Because variable degrees of pelvic thrombophlebitis accompany most cases of metritis and parametrial cellulitis, initial treatment is directed at both. Before imaging methods were available to confirm clinical suspicions of venous involvement, the *heparin challenge test* was advocated. Supposedly, after intravenous heparin was given, there was lysis of fever; this was taken as diagnostic of pelvic phlebitis and heparin treatment continued ([Duff and Gibbs, 1983](#); [Josey and Staggers, 1974](#)). This was subsequently disproven by [Brown and colleagues \(1986\)](#) who showed that despite withholding heparin from 6 of 11 women with computed tomography-proven pelvic thrombophlebitis, continued antimicrobial therapy resulted in clinical resolution. Conversely, in five women given heparin along with antimicrobial drugs, the prolonged febrile course was not appreciably abbreviated. [Witlin and Sibai \(1995\)](#) reported similar observations in 11 women with ovarian vein thrombophlebitis. In a follow-up randomized study of 14 women by [Brown and associates \(1999\)](#), the addition of heparin to antimicrobial therapy for septic thrombophlebitis did not improve outcome nor did it hasten the time to defervescence or hospital discharge.

INFECTIONS OF THE PERINEUM, VAGINA, AND CERVIX

Surprisingly, infections of perineal wounds, including episiotomy incisions and repaired lacerations, are relatively uncommon considering the degree of bacterial contamination that accompanies normal delivery. [Sweet and Ledger \(1973\)](#) reported only 21 infected episiotomies (0.35 percent) among nearly 6000 women delivered vaginally at the University of Michigan and Wayne County Hospitals. [Owen and Hauth \(1990\)](#) described only 10 (0.05 percent) episiotomy infections with over 20,000 deliveries at the University of Alabama at Birmingham. [Ramin and colleagues \(1992\)](#) reported a 0.5 percent incidence of episiotomy breakdown at Parkland Hospital, and 80 percent of these were due to infection. Perhaps not surprisingly, serious infection is more likely in women who sustain a fourth-degree laceration. [Goldaber and colleagues \(1993\)](#) described the clinical courses of 390 such women of whom 5.4 percent had morbidity: dehiscence developed in 1.8 percent, infection and dehiscence in 2.8 percent, and infection only in 0.8 percent. Although rare, life-threatening septic shock may still occur as a result of an infected episiotomy wound ([Soltesz and colleagues, 1999](#)).

PATHOGENESIS AND CLINICAL COURSE

The apposing wound edges become red, brawny, and swollen. The sutures then often tear through the edematous tissues, allowing the necrotic wound edges to

gape, with the result that serous, serosanguineous, or frankly purulent material exudes. Episiotomy breakdown or dehiscence is most commonly associated with infection. Other reported predisposing factors include coagulation disorders, cigarette smoking, and human papillomavirus ([Ramin and Gilstrap, 1994](#)). Local pain and dysuria, with or without urinary retention, are common symptoms. [Ramin and colleagues \(1992\)](#), in a series of 34 women with episiotomy dehiscence, reported that the most common signs and symptoms were pain (65 percent), purulent discharge (65 percent), and fever (44 percent). In extreme cases, the entire vulva may become edematous, ulcerated, and covered with exudate. Fortunately, provided drainage is good, superficial infections are seldom severe.

Vaginal lacerations may become infected directly or by extension from the perineum. The mucosa becomes edematous and hyperemic and may then become necrotic and slough. Parametrial extension may result in lymphangitis.

Cervical infection is probably more common than appreciated because lacerations are common and the cervix normally harbors potentially pathogenic organisms. Moreover, because deep cervical lacerations often extend directly into the tissue at the base of the broad ligament, infections may cause lymphangitis, parametritis, and bacteremia.

TREATMENT

Infected perineal wounds, like other infected surgical wounds, should be treated by establishing drainage. In most cases, sutures are removed and the infected wound opened. In some women with obvious cellulitis but no purulence, broad-spectrum antimicrobial therapy with close observation is appropriate. In others, drainage is necessary. Classically, it has been recommended with episiotomy dehiscence—especially if associated with infection—that a repair not be attempted for at least 3 to 4 months. It was postulated that such a delay would allow for adequate vascularization of the involved tissue and resolution of infection and cellulitis. This approach was challenged by [Hauth and colleagues \(1986\)](#), who advocated early repair after evidence of infection subsided. Subsequently, two large studies have attested to the efficacy of such practices. [Hankins and co-workers \(1990\)](#) described their experiences with early repair of episiotomy breakdown in 31 women. The average duration from breakdown to episiotomy repair was 6 days. All but two women had a successful repair; both developed a pinpoint rectovaginal fistula soon after repair and both were treated successfully with a small rectal flap. [Ramin and colleagues \(1992\)](#) reported successful early repair of episiotomy breakdown associated with infection in 32 of 34 women (94 percent).

TECHNIQUE FOR EARLY REPAIR. A preoperative protocol for early repair is summarized in [Table 26-3](#). **Prior to attempting early repair of episiotomy dehiscence, the surgical wound must be properly cleaned and free of infection.** As shown in [Figure 26-9](#), once the surface of the episiotomy wound is free of infection and exudate and covered by pink granulation tissue, secondary repair can be accomplished in the operating suite. Good tissue mobility must be accomplished, including identification and mobilization of the sphincter ani muscle. Secondary closure of the episiotomy is accomplished in layers as described for primary episiotomy closure in [Chapter 13 \(p. 326\)](#). Postoperative care includes local care, low-residue diet, stool softeners that avoid diarrhea, and nothing per vagina or rectum until healed.

NECROTIZING FASCIITIS

A rare but frequently fatal complication of perineal and vaginal wound infections is deep soft tissue infection involving muscle and fascia. These may also complicate vulvar infections in diabetic and immunocompromised women, and they rarely develop in otherwise healthy women. The microbiology of these serious perineal infections appears to be similar to those that cause other pelvic infections, as well as necrotizing fasciitis of the abdominal incision described previously. Although uncommon today, [Shy and Eschenbach \(1979\)](#) reported that necrotizing fasciitis was responsible for 20 percent of 15 maternal deaths in King County, Washington in the 1970s.

Necrotizing fasciitis of the episiotomy site may involve any of the several superficial or deep perineal fascial layers, and thus it may extend to the thighs, buttocks, and abdominal wall ([Fig. 26-10](#)). Although some infections may develop within a day of delivery, they more commonly do not cause symptoms until 3 to 5 days afterward. Clinical symptoms vary, and it is frequently difficult to differentiate superficial perineal infections from deep fascial ones. A high index of suspicion, with surgical exploration if the diagnosis is uncertain, may be lifesaving. [Stamenkovic and Lew \(1984\)](#) recommend biopsy of the fascial edges with frozen section microscopical examination when the diagnosis is uncertain. We have not found this advantageous, but aggressively pursue early exploration. Certainly, if myofasciitis progresses, the woman becomes very ill from septicemia, there is profound hemoconcentration from capillary leakage with circulatory failure, and death soon follows. Early diagnosis, surgical debridement, antibiotics, and intensive care are of paramount importance in the successful treatment of necrotizing soft tissue infections ([Urschel, 1999](#)).

Aggressive surgical treatment is indicated and includes wide debridement of all infected tissue. As shown in [Figure 26-10](#), this may include extensive vulvar debridement with unroofing and excision of abdominal, thigh, or buttock fascia. Split-thickness skin grafts later are used to repair the defects. **Mortality is virtually universal without surgical treatment, and it approaches 50 percent even if aggressive excision is performed.**

TOXIC SHOCK SYNDROME

Although not typically a puerperal infection, toxic shock syndrome is considered here because it has been reported in the puerperium. This is an acute febrile illness with severe multisystem derangement and a case-fatality rate of 10 to 15 percent. The illness is usually characterized by fever, headache, mental confusion, diffuse macular erythematous rash, subcutaneous edema, nausea, vomiting, watery diarrhea, and marked hemoconcentration. Renal failure followed by hepatic failure, disseminated intravascular coagulation, and circulatory collapse may follow in rapid sequence. During recovery, the rash-covered areas undergo desquamation. *Staphylococcus aureus* has been recovered from almost all of afflicted persons, and a staphylococcal exotoxin, termed *toxic shock syndrome toxin-1*, and formerly called both *enterotoxin F* and *pyrogenic exotoxin C*, causes the syndrome by provoking profound endothelial injury.

In many cases, infection is not documented and colonization alone is found. [McGregor and colleagues \(1988\)](#) have described almost identical findings in women with infection complicated by *Clostridium sordelli* colonization.

When first described, toxic shock syndrome was associated with young menstruating women who used tampons. Because of educational efforts, as well as changes in tampon manufacture, it is much less prevalent. It has, however, been reported in a variety of other clinical situations. Nearly 10 percent of pregnant women have vaginal colonization with *S. aureus*; thus it is not surprising that the disease develops in postpartum women ([Guerinot and co-workers, 1982](#)). It has also been described in a mother-and-newborn pair ([Green and LaPeter, 1982](#)).

There have been several reports of a **toxic shock-like syndrome** associated with group A β -hemolytic streptococcal infection. [Whitted and colleagues \(1990\)](#) described this in a woman 2 weeks postpartum. [Dotters and Katz \(1991\)](#) reported a similar case in a 40-year-old woman following spontaneous abortion. As previously discussed, we have experienced similar cases of severe group A streptococcal infection in postpartum women ([Nathan and colleagues, 1994](#)). The toxin is quite potent, and the mortality rate correspondingly high.

Principal therapy for toxic shock is supportive, while allowing reversal of capillary endothelial injury. Treatment is similar to that for septic shock, discussed in [Chapter 43 \(p. 1169\)](#). In severe cases, it requires massive fluid replacement, mechanical ventilation with positive end-expiratory pressure, and renal dialysis. Antimicrobial therapy with specific antistaphylococcal drugs is given, although their value is questioned in cases without infection. With evidence for infection, for example wound cellulitis, antimicrobial therapy must include agents used for all puerperal infections.

HISTORY OF PUERPERAL INFECTION

The earliest reference to puerperal infection is found in the 5th century BC works of Hippocrates. In his discussion of women, *De Muliebrum Morbis*, he described the condition and attributed it to retention of bowel contents. By AD 200, Celsus and Galen had written in support of the theories of Hippocrates, and they recommended purgation. It was not until the late 1500s that lochial putrefaction or uterine inflammation were suspected as the cause of childbed fever, which had been linked to difficult labor. William Harvey (1651) aptly described the placental implantation site as a "vast internal ulcer" that may lead to gangrene. In 1659, Willis wrote on the subject of *febris puerperarum*, although the English term *puerperal fever* was probably first employed by [Strother in 1716](#).

The theory of *milk metastasis* of [Puzos \(1686\)](#) followed next and predominated for 100 years, but in the 1700s, uterine inflammation was again thought to cause febrile morbidity. John [Leake \(1772\)](#) first suggested the contagious nature of puerperal infection, and Alexander [Hamilton embraced this in 1781](#). Alexander Gordon of Aberdeen, in a treatise on epidemic puerperal fever in 1795, discussed its infectious and contagious nature, antedating [Holmes \(1855\)](#) and [Sammelweis \(1861\)](#) by half a century. Charles [White \(1773\)](#) of Manchester postulated that puerperal fever was dependent on lochial stagnation, and advised complete isolation of infected women.

It was not until the mid-1800s that such views were becoming acceptable. In 1843, Oliver Wendell Holmes presented *Contagiousness of Puerperal Fever* before the Boston Society for Medical Improvement. He showed clearly that at least the epidemic forms of the infection could always be traced to the lack of proper precautions on the part of the physician or nurse. Four years later, Semmelweis, then an assistant at the Vienna Lying-In Hospital, began a careful inquiry into the causes of the frightful mortality rate following delivery in that institution, as compared with the relatively small number of women who died as a result of infection following home delivery. He concluded that the morbid process was essentially a wound infection caused by the introduction of septic material by the examining finger. He issued stringent orders that physicians, students, and midwives disinfect their hands with chlorine water, the forerunner of Dakin solution, before examining parturient women. Despite immediate and surprising results in which the mortality rate fell from over 10 percent to 1 percent, both his work and that of Holmes were ridiculed by many prominent physicians of the time. His discovery remained unappreciated until Lister's teachings in 1867 regarding antiseptics, and the development of bacteriology by Pasteur.

The history of puerperal infection is discussed in greater detail in prior editions of *Williams Obstetrics*. The reader is also referred to the monographs of [Eisenmann \(1837\)](#), [Burtenshaw \(1904\)](#), and [Peckham \(1935\)](#). [Willson \(1988\)](#) provided a review of cesarean section infections, and [Raju \(1999\)](#) presented the theories of Semmelweis regarding neonatal infections transmitted at delivery in the woman with puerperal fever.

Pelvic cellulitis (parametritis) associated with puerperal infection. Bacteria may enter the parametrial tissue between the leaves of the broad ligament by direct extension or by lymphatic transmission from cervical lacerations or foci of trauma within the uterus, including the placental implantation site or cesarean incision. Bacterial spread may also develop across the wall of an infected vein. Lacerations of the perineum or vagina usually cause only localized cellulitis, but may extend to pelvic lymphatics.

27. Preterm Birth

Low birthweight is the term used to define infants who are born too small, and *preterm* or *premature birth* are the terms used to define infants who are born too soon. Prior to the last century, when the expression premature birth was first used, infants delivered before term were usually referred to as "weaklings" or "congenitally debilitated babies" (Cone, 1985). Indeed, prior to 1872, infants were not even weighed at birth whether full term or premature. In 1900, Ransom wrote that in the United States "of the thousands of premature infants born ... most are quietly laid away with ... little if any effort being made for their rescue." In his first edition of this textbook, Williams (1903) wrote: "Generally speaking, premature children weighing less than 1500 g (3 lbs 3 oz) have practically no chance of life, though exceptional cases have been reported." As the 20th century progressed, there was an increasing awareness that preterm infants required special care, as evidenced by the development of incubators and intensive care nurseries. Prematurity became nationally visible as the most frequent cause of death in infancy when country-wide statistics became available with the 1949 revision of the birth certificate, which specified gestational age and birthweights.

More recently, infant mortality has become a benchmark for international comparisons of health-care systems. In this regard, the United States has ranked poorly. For example, in 1995 the United States ranked 25th in the world, well behind Japan, Singapore, Germany, and most of the Scandinavian countries (National Center for Health Statistics, 1999). Those countries with higher rates of preterm delivery have higher rates of infant mortality. Moreover, within the United States, African-Americans are disproportionately affected by preterm delivery and infant mortality. As shown in Table 27-1, more than 28,000 infants died during infancy in 1998 in the United States, and 66 percent of these were within 4 weeks of birth. Moreover, preterm birth is implicated in at least two thirds of these early infant deaths.

Sachs and associates (1995) have legitimately challenged international comparisons of infant mortality, because they found enormous regional and international differences in the way preterm births are classified.

DEFINITIONS

In 1935, the American Academy of Pediatrics defined prematurity as a live-born infant weighing 2500 g or less (Cone, 1985). These criteria were used widely until it became apparent that there were discrepancies between gestational age and birthweight because of restricted fetal growth. The World Health Organization in 1961 added gestational age as a criterion for premature infants, defined as those born at 37 weeks or less. A distinction was made between low birthweight (2500 g or less) and prematurity (37 weeks or less). Others have suggested that preterm birth be defined as those infants delivered prior to the completion of 37 weeks (American College of Obstetricians and Gynecologists, 1995).

With continued improved care of the preterm infant, other definitions have been developed. For example, the Collaborative Group on Antenatal Steroid Therapy (1981) reported that the great preponderance of mortality and serious morbidity from preterm birth is prior to 34 weeks. Moreover, low birthweight, defined as less than 2500 g, has been modified now to describe very-low birthweight, infants weighing 1500 g or less; and extremely-low birthweight, those who weigh 1000 g or less. As shown in Table 27-2, almost 90 percent of live births in the United States occur at 37 weeks or later in gestation, and progressively fewer births are recorded with decreasing gestational weeks at delivery. The disproportionate contribution of multiple gestations to preterm births is discussed in Chapter 30 (p. 780).

In many industrialized countries including the United States (Fig. 27-1), the proportion of infants born before term has increased in the past 20 years (Joseph and associates, 1998). In Canada, for instance, births at 36 weeks' gestation or less increased from 6.3 percent in 1981 to 6.8 percent in 1992. This increase in preterm births has been attributed to changes in the frequency of multiple births, increases in obstetrical intervention, improved ascertainment of early preterm births, and increased use of ultrasound for estimating gestational age (Joseph and associates, 1998). Similar factors are undoubtedly operative in the rise in preterm births that has occurred in the United States.

The importance of low birthweight, which is approximately equivalent to birth before 37 weeks, as a predictor of infant death within 28 days of birth (neonatal death), is shown in Figure 27-2. Neonatal mortality rates by state are directly proportional to the delivery of low-birthweight infants. Those states with large urban populations, or where poverty is common, have the highest incidence. In response, the United States greatly expanded the Medicaid program in 1986 with the aim of increasing prenatal and other health services for pregnant women (Dubay and colleagues, 1995). Similarly, the federal government also initiated the Healthy Start Program in 1991 for the 15 urban areas with the worst infant mortality rates.

With respect to gestational age, a fetus or infant may be preterm, term, or postterm. With respect to size, the fetus or infant may be normally grown or appropriate for gestational age, small in size or small for gestational age, or overgrown and consequently large for gestational age. In recent years, the term *small for gestational age* has been widely used to categorize an infant whose birthweight is usually below the 10th percentile for its gestational age. Other often-used terms have included *fetal growth retardation* or *intrauterine growth retardation*. Within the past 5 years the term *restriction* has largely replaced *retardation*, because the latter may erroneously convey mental delay rather than only the intended suboptimal fetal growth (Chap. 29, p. 745). The infant whose birthweight is above the 90th percentile has been categorized as *large for gestational age*, and the infant whose weight is between the 10th and 90th percentiles is designated *appropriate for gestational age*. Thus, an infant born before term can be small or large for gestational age and still be preterm according to chronological gestational age. Moreover, some preterm infants have also suffered growth restriction in utero. It is important to recognize that preterm birth also frequently includes infants who have suffered subnormal in utero growth. Fetal growth restriction is discussed in Chapter 29, and this chapter will focus on preterm births where the only perceived problem is delivery before full maturation. Shown in Table 29-1 are birthweight percentiles for each gestational week between 20 and 44 weeks, which may be helpful in estimating when a preterm infant's birthweight is subnormal or excessive.

IMPACT OF PRETERM BIRTH

Obstetrical approaches to preterm labor and delivery are guided in large part by expectations that the obstetrician has for survival of the premature neonate as well as the therapeutic alternatives available for management of preterm labor (Bottoms and colleagues, 1997). That some very small infants do survive when provided with prolonged, very expensive intensive care has created serious problems in decision making. The obstetrician faces the challenge of effecting delivery in such a way as to optimize the status of the fetus-infant at birth, in the event that intensive care will be applied. The neonatologist in turn must make a judgment as how best to dispense the finite resources for medical care provided by the insurance carrier, the family, governmental agencies, the hospital, and the health-care team.

Aside from survival, another important issue is the quality of life achieved by quite immature, extremely-low-birthweight infants. It is apparent that appreciable compromise, both physical and intellectual, afflicts many such children. Given these concerns, at what time in gestation should obstetrical interventions be practiced? Although it is impossible to precisely set the earliest limit for neonatal survival, certain factors inevitably have an impact on the clinical decision-making process.

Obstetrical perception of viability probably influences survival of extremely-low-birthweight infants. Amon and co-workers (1992) and Bottoms and co-workers (1997) surveyed American obstetricians to determine their clinical opinions regarding intrapartum management of the severely preterm fetus requiring delivery. Intrapartum fetal heart rate monitoring was initiated at 23, 24, and 25 weeks by 10, 45, and 65 percent of respondents, respectively. Cesarean delivery was not performed at less than 24 weeks or less than 500 g fetal weight. Almost 90 percent of respondents were willing to perform cesarean delivery for fetal distress or breech presentation at 26 weeks or 750 g fetal weight. Delivery management prior to 26 weeks, or for fetuses smaller than 750 g, was variable and individualized. Haywood and associates (1994) found that physicians significantly underestimated survival and handicap-free survival rates, particularly in those infants delivered between 23 and 29 weeks. Doron and co-workers (1998) analyzed delivery room decisions by neonatologists to provide or withhold resuscitation for 41 infants born between 23 and 26 weeks' gestation. They concluded that the delivery room is not the best place to decide on withholding life support and that this decision is best made later in the neonatal course.

It is important to emphasize that the obstetrical decision not to perform cesarean delivery or use intrapartum monitoring does not necessarily imply that the fetus is "nonviable" or "written off." For example, Kitchen and co-workers (1992) analyzed the outcomes of live-born infants weighing 500 to 999 g and found that although 50 percent of the infants survived and only 7 percent were severely disabled, these outcomes were unrelated to the use of cesarean delivery or electronic monitoring.

Perceptions of the potential for survival are inevitably confused by difficulties incurred by imprecisely known gestational age. Most survival data are based upon birthweight, which may vary appreciably between 24 and 26 weeks. For example, infants born between 24 and 26 weeks can vary in weight from 435 g to 1640 g (Alexander and associates, 1996). Perinatal mortality and morbidity decreases markedly from 24 to 26 weeks' gestation. Indeed, survival increases from approximately 20 percent at 24 weeks' gestation up to 50 percent at 25 weeks, or an increase of almost 4 percent each day. Similarly, serious perinatal morbidity also markedly decreases each day from 24 to 26 weeks' gestation. Clinically, this daily marked association with improved outcomes is of immense importance when determining obstetrical management at the lowest end of gestational ages.

The birthweight-linked survival rates for live births during 1999 at Parkland Hospital are shown in [Table 27-3](#). Survival data for infants 500 to 1500 g are remarkably similar to rates reported by [Fonaroff and colleagues \(1995\)](#) for the National Institutes of Health (NIH)-sponsored Neonatal Research Network. Chances for survival increase appreciably at or above 1000-g birthweight. These data indicate that survival is possible for infants weighing 500 to 750 g. Many of these extremely-low-birthweight infants, however, were growth restricted and therefore of more advanced maturity. For example, survival of a 380-g infant has been reported, but the gestational age was confirmed to be 25^{3/7} weeks ([Ginsberg and associates, 1990](#)). Clearly, expectations for neonatal survival are primarily influenced by gestational age and maturity rather than simply by birthweight.

LOWER LIMIT OF SURVIVAL. The frontier for infant survival has been progressively pushed earlier into gestation primarily as a result of continued innovations in neonatal intensive care. [Copper and associates \(1993\)](#) compiled gestational age-specific neonatal mortality rates for 3386 live-born infants prospectively enrolled between 1982 and 1986 in the March of Dimes Multicenter Preterm Birth Prevention Project. As shown in [Figure 27-3](#), neonatal mortality decreased from 100 percent at 23 weeks to about 10 percent at 29 weeks, with little additional improvement through 34 weeks. Virtually identical mortality rates for 2678 live-born infants delivered in England between 1990 and 1993 were reported by [Rutter \(1995\)](#). The period of gestation from 23 to 25 weeks poses the greatest dilemma for both the obstetrician and pediatrician. As shown in [Figure 27-3](#), the probability of neonatal death before 26 weeks exceeds 75 percent. [Stevenson and colleagues \(1998\)](#) reported very similar low-birthweight outcomes from an inborn cohort of the [NICHD¹](#) Neonatal Research Network in 1993 and 1994. Based on the "best obstetrical assignment of gestational age," death, severe infant morbidities, or both were great before 26 weeks' gestation and almost universal before 24 weeks' gestation. [Bottoms and co-workers \(1999\)](#), for the NICHD Maternal-Fetal Medicine Units Network, concluded that in newborns weighing less than 1000 g, ultrasound assessment of either fetal femur length or gestational age were most predictive of neonatal mortality.

LONG-TERM OUTCOMES. Whereas few infants with birthweights below 750 g were actively treated during the 1970s, beginning in the 1980s, treatment was often practiced for infants with birthweights of at least 500 g and those born at 24 weeks or more ([Hack and colleagues, 1994](#)). The high rate of significant neonatal morbidity in these tiny infants, and the likelihood of a normal life, must be weighed against the apparent triumph of survival. As shown in [Figure 27-4](#), among 501- to 1500-g newborns in the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network Centers, mortality and major morbidity among survivors decreased from 1988 to 1994, but both occurred in half of newborns at 501- to 750-g birthweight. [Allen and co-workers \(1993\)](#) described outcomes to 6 months of life for infants delivered at 22 to 25 weeks, and who were aggressively supported with intensive care. No infants survived at 22 weeks, and virtually all survivors at 23 and 24 weeks had significant brain abnormalities ([Table 27-4](#)). They concluded that whether the occasional child who is born at 23 or 24 weeks and does well justifies the considerable mortality and morbidity of the majority is a question that should be discussed by parents, health-care providers, and society. More recently, [Wood and colleagues \(2000\)](#) confirmed these data in a similar study from the United Kingdom.

Several groups of investigators have attempted to measure long-term outcomes in infants delivered at the very frontier of survival during the 1980s. [Whyte and co-workers \(1993\)](#) prospectively followed for a minimum of 2 years 321 infants born at their hospital between 23 and 26 weeks. There were no survivors among infants delivered at 23 weeks, and only 6 percent of the survivors at 24 weeks did not sustain major long-term morbidity. Approximately half of infants delivered at 25 and 26 weeks were intact at a minimum of 2 years of age. [Doyle and colleagues \(1994\)](#) followed infants born at 24 to 26 weeks for 5 years or longer. Even fewer infants (approximately 20 percent) were totally free of impairment with longer intervals of survival. [Hack and colleagues \(1994\)](#) studied the health and developmental outcomes at early school age of 68 children with birthweights below 750 g who were born from 1982 through 1986. They concluded from their unique study that children with birthweights below 750 g who survived are at "serious disadvantage in every skill required for adequate performance." Specifically, 45 percent of the survivors needed special education facilities, 21 percent had subnormal intelligence quotient (IQ) (less than 70), and many had subnormal growth and visual ability. [Rutter \(1995\)](#) concluded in his review of outcomes in extremely preterm infants that full resuscitation and intensive care should definitely be given at 26 weeks, probably be given at 25 weeks, possibly be given at 24 weeks, but not at 23 weeks or earlier.

[Vohr and co-workers \(2000\)](#) assessed neurodevelopmental and functional outcomes at 18 to 22 months corrected age of 1151 (401 to 1000 g) survivors cared for in the 12 participating centers of the [NICHD¹](#) Neonatal Research Network and who were born in 1993 and 1994. Only half of the 1151 survivors had a normal neurodevelopmental and sensory assessment, and those at the lower birthweights had markedly worse outcomes as predicted by chronic lung disease, grades 3 and 4 intraventricular hemorrhage, and periventricular leukomalacia.

[Wood and associates \(2000\)](#) reported results from the EPI Cure Study Group of the United Kingdom. They performed careful mental and psychomotor evaluations at a median of 30 months in 283 surviving infants born at 25 completed weeks or less. Infant neurological survival without disability was reported in 1 of 138 infants born during the 22nd week; 11 of 241 (5 percent) during the 23rd week; 45 of 382 (12 percent) during the 24th week; and 98 of 424 (23 percent) born during the 25th week.

UPPER LIMIT OF SIGNIFICANT PREMATURITY. Not only has the frontier for neonatal survival been pushed earlier into pregnancy, but survival of larger preterm infants has become as good as that for term infants. Is there a birthweight or gestational age threshold after which attempts to delay delivery are unwarranted? In an effort to address this question, [Robertson and colleagues \(1992\)](#) analyzed neonatal outcomes between 1983 and 1986 from five tertiary care centers in the United States. A total of 20,680 carefully dated pregnancies without complications such as diabetes or hypertension were identified. Most thresholds—defined as the gestational week at which the incidence of complications attributable to preterm delivery became indistinguishable from term infants—were between 32 and 34 weeks. Respiratory distress syndrome, although decreasing precipitously between 33 and 34 weeks (31 to 13 percent), still developed in about 6 percent of births between 35 and 38 weeks. [DePalma and co-workers \(1992\)](#) found that the birthweight threshold for neonatal mortality at Parkland Hospital was 1600 g, and the threshold for neonatal morbidity due to complications of preterm delivery was approximately 1900 g. They concluded that aggressive obstetrical attempts to prevent preterm births for infants whose weights exceed 1900 g offer few apparent benefits.

ECONOMIC IMPACT OF PRETERM BIRTH. The dollar cost of the resources used to care for low-birthweight infants is one measure of the national burden of preterm birth. These dollar costs are shown in [Table 27-5](#). A proportionately small number of births in the United States (approximately 7 percent) consume more than a third of health-care expenditures during the first year of life. On an individual basis, it is not uncommon for the smallest surviving infants to incur special care nursery costs exceeding several hundred thousand dollars ([Walker and associates, 1984](#)). Costs exceeding \$1 million are possible in those hospitalized for up to a year or longer. Moreover, because of the long-term outcomes already described, additional expenditures for developmental handicaps are necessary during the remainder of childhood for many infants.

Recently, [St. John and associates \(2000\)](#) used a cost-analysis model to determine that 12 percent of initial neonatal care dollars in the United States were spent on infants born between 24 and 26 weeks' gestation for 1989 through 1992, and that 43 percent was spent on those born at 37 weeks' gestation or later.

CAUSES OF PRETERM BIRTH

A wide spectrum of causes and demographic factors have been implicated in the birth of preterm infants ([Table 27-6](#)).

MEDICAL AND OBSTETRICAL COMPLICATIONS

[Meis and colleagues \(1995b, 1998\)](#) analyzed the causes of delivery before 37 weeks in a population-based study of singleton pregnancies performed in the [NICHD¹](#) Maternal-Fetal Medicine Units Network. Approximately 28 percent of preterm births were indicated due to preeclampsia (43 percent), fetal distress (27 percent), fetal growth restriction (10 percent), abruptio placentae (7 percent), and fetal death (7 percent). The remaining 72 percent were due to spontaneous preterm labor with or without ruptured membranes. Women with placenta previa and multiple gestations, both common associations of preterm birth, were excluded from this analysis.

LIFESTYLE FACTORS

Behaviors such as cigarette smoking, poor nutrition and poor weight gain during pregnancy, and use of drugs such as cocaine or alcohol have been reported to play important roles in the incidence and outcome of low-birthweight infants. Some of this effect is undoubtedly due to restricted fetal growth ([Chap. 29, p. 745](#)) as well as preterm birth. [Hickey and colleagues \(1995\)](#), however, have shown that low maternal prenatal weight gain is associated specifically with an increased risk for preterm birth.

Alcohol abuse has been linked not only to preterm birth but also to substantially increased risk of brain injury in premature infants ([Holzman and co-workers, 1995](#)). [DiFronza and Lew \(1995\)](#) reviewed smoking during pregnancy and reported that tobacco use was responsible for 32,000 to 61,000 low-birthweight infants each year in the United States.

Other maternal factors implicated include young maternal age ([Satin and co-workers, 1994](#)), poverty ([Meis and colleagues, 1995b](#)), short stature ([Kramer and colleagues, 1995](#)), and occupational factors ([Henriksen and co-workers, 1995](#); [Luke and associates, 1995](#)).

Another lifestyle factor that seems intuitively important, yet has seldom been formally studied, is psychological stress in the mother. [Hedegaard and associates \(1993\)](#) performed a prospective follow-up study of measures of psychological stress, using questionnaires in 5872 women with singleton pregnancies. A direct association was found between psychological stress in the 30th week of pregnancy and delivery before 37 weeks' gestation. [Peacock and co-workers \(1995\)](#) also found an association between psychological stress and preterm birth. [Copper and colleagues \(1996\)](#), from the NICHD¹ Maternal-Fetal Medicine Units Network Preterm Prediction Study, reported that maternal stress was associated with spontaneous preterm birth at less than 35 weeks' gestation and after adjustment for maternal demographic and behavioral characteristics.

GENETIC FACTORS

It has been observed for many years that preterm delivery is a condition that runs in families. This observation plus the recurrent nature of preterm birth and its differing prevalence between races has led to the suggestion of a genetic cause for preterm labor. [Hoffman and Ward \(1999\)](#) have reviewed the possible genetic factors implicated in preterm delivery.

AMNIONIC FLUID AND CHORIOAMNIONIC INFECTION

Chorioamnionic infection caused by a variety of microorganisms has emerged as a possible explanation for many heretofore unexplained cases of ruptured membranes and/or preterm labor. Although female reproductive tract infection was associated with prematurity more than 45 years ago ([Knox and Hoerner, 1995](#)), there was renewed interest when [Bobbitt and Ledger \(1977\)](#) implicated subclinical amniotic fluid infection as a cause of preterm labor. For example, pathogenic bacteria have typically been recovered at transabdominal amniocentesis from approximately 20 percent of women in preterm labor without evidence of overt clinical infection and with intact fetal membranes ([Cox and associates, 1996a](#); [Watts and co-workers, 1992](#)). [Hillier and colleagues \(1995\)](#) and [Hauth and co-workers \(1998\)](#) have reported that an appreciable number of women with spontaneous preterm birth have pathogenic organisms recovered from the chorioamnion. Indeed, the frequency of recovery of these organisms is increased in women with spontaneous onset of preterm labor with and without amnion rupture, but not increased in women delivered preterm for a medical or obstetrical complication such as maternal hypertension or hemorrhage ([Hauth and co-workers, 1998](#)). The recovery of upper genital tract pathogens is, therefore, increased in women with spontaneous labor and delivery and is inversely associated with gestational age ([Fig. 27-5](#)) and birthweight ([Fig. 27-6](#)).

PATHOGENESIS. [Schwarz and co-workers \(1976\)](#) suggested that term labor is initiated by activation of phospholipase A₂, which cleaves arachidonic acid from within fetal membranes, thereby making free arachidonic acid available for prostaglandin synthesis. Subsequently, [Bejar and colleagues \(1981\)](#) reported that many microorganisms produce phospholipase A₂, and thus potentially may initiate preterm labor. [Bennett and Elder \(1992\)](#) have shown that common genital tract bacteria do not themselves produce the prostaglandins. [Cox and associates \(1989\)](#) provided data that bacterial endotoxin (lipopolysaccharide) introduced into the amniotic fluid stimulates decidual cells to produce cytokines and prostaglandins that may initiate labor. [Romero and co-workers \(1987, 1988\)](#) and [Cox and associates \(1988a\)](#) reported that endotoxin was present in the amniotic fluid. [Andrews and colleagues \(1995\)](#) found a markedly higher mean amniotic fluid interleukin-6 concentration versus gestational age in women with the spontaneous onset of labor compared with women with indicated deliveries ([Fig. 27-7](#)).

It has now been established that endogenous host products secreted in response to infection are responsible for many of the effects of infection. In endotoxin shock, for example, bacterial endotoxins exert their deleterious effect through the release of endogenous cell mediators (cytokines) of the inflammatory response. Similarly, preterm parturition due to infection is thought to be initiated by secretory products resulting from monocyte (macrophage) activation ([Fig. 27-8](#)). Cytokines, including interleukin-1, tumor necrosis factor, and interleukin-6, are such secretory products implicated in preterm labor. [Narahara and Johnston \(1993\)](#) have suggested that platelet-activating factor, which is found in the amniotic fluid, is synergistically involved in activating the cytokine network ([Fig. 27-8](#)). Platelet-activating factor is thought to be produced in the fetal lungs and kidneys. Thus, the fetus appears to play a synergistic role in the initiation of preterm birth due to bacterial infection. Teleologically, this could be advantageous to the fetus interested in extricating itself from an infected environment.

[Gravett and colleagues \(1994\)](#), in a remarkable experiment with rhesus monkeys, have provided the first direct evidence that infection incites preterm labor. Group B streptococci were injected into the amniotic fluid in preterm rhesus monkeys, and concentrations of cytokines and prostaglandins shown in [Figure 27-8](#) were serially measured. Amniotic fluid cytokine concentrations increased about 9 hours after introduction of the bacteria, followed sequentially by production of the prostaglandins E₂ and F_{2a} and finally, uterine contractions. As observed in humans with preterm labor due to amniotic fluid infection, there was no clinical evidence of chorioamnionitis in these rhesus monkeys until after preterm labor ensued.

Although the pathway for bacteria to enter the amniotic fluid is obvious after membrane rupture, the route of access with intact membranes is unclear. [Gyr and colleagues \(1994\)](#) found that *Escherichia coli* can permeate living chorioamnionic membranes. Thus, intact fetal membranes at the cervix are not necessarily a barrier to ascending bacterial invasion of the amniotic fluid. Alternatively, the pathway for bacterial initiation of preterm labor described in [Figure 27-8](#) may not require colonization of the amniotic fluid. For example, [Cox and co-workers \(1993\)](#) found that the cytokine network of cell-mediated immunity can be activated locally in decidual tissue that lines the forebag fetal membranes.

DIAGNOSIS. The interest in a possible microbial pathogenesis of preterm labor has prompted many investigators to evaluate amniocentesis for management. [Garite and colleagues \(1979\)](#) successfully performed sonar-directed amniocentesis in 30 of 59 women with ruptured membranes between 28 and 35 weeks. As none had clinical infection, their purpose was to establish fetal lung maturity while evaluating Gram stain and culture of amniotic fluid. Surprisingly, the fluids from nine women (30 percent) contained bacteria; six of these women developed chorioamnionitis and two neonates developed infection. Despite these reports, it has not been shown that amniocentesis used to diagnose infection is associated with improved pregnancy outcome. [Feinstein and colleagues \(1986\)](#) compared 73 cases of preterm ruptured membranes managed with the aid of amniocentesis with 73 matched historical controls. There were no differences in fetal condition at delivery, incidence of neonatal infection, or perinatal mortality.

In centers using amniocentesis in the management of preterm labor, several laboratory methods have been reported helpful for the rapid detection of intraamniotic infection. [Romero and colleagues \(1993\)](#) evaluated the diagnostic value of amniotic fluid white blood cell count, low glucose and high interleukin-6 concentration, and Gram-stained positive bacteria in 120 women with preterm labor and intact fetal membranes. Those women with positive amniotic fluid cultures were considered infected. A negative Gram stain was the most reliable test to exclude amniotic fluid bacteria (specificity 99 percent), and a high interleukin-6 was the most sensitive test (sensitivity 82 percent) in detecting amniotic fluids containing bacteria. [Andrews and colleagues \(1995\)](#) also found good correlation between amniotic fluid interleukin-6 and chorioamnionic microbial colonization. [Yoon and associates \(1996\)](#) compared the accuracy of C-reactive protein levels or white blood cell counts in maternal blood with amniotic fluid white blood cell counts and found the latter to be superior in the confirmation of amniotic fluid infection.

[Gonik and colleagues \(1985\)](#) reported that oligohydramnios identified by ultrasound was linked to antepartum clinical chorioamnionitis. [Vintzileos and colleagues \(1986\)](#) found a similar association between oligohydramnios and bacterial colonization of amniotic fluid collected by amniocentesis. [Vintzileos and associates \(1985\)](#) observed that fetal infection could be predicted reliably using daily biophysical profiles; however, this was not confirmed by others ([Carroll and colleagues, 1995b](#); [DeVoe and colleagues, 1994](#); [Gauthier and co-workers, 1992](#); [Miller and associates, 1990](#)).

PRETERM RUPTURED MEMBRANES. An intense inflammatory reaction at the site of prematurely ruptured membranes was noted as early as 1950, and this suggested infection. [McGregor and colleagues \(1987\)](#) demonstrated that in vitro exposure to bacterial proteases reduced the bursting load of fetal membranes. Thus, microorganisms given access to fetal membranes may be capable of causing membrane rupture, preterm labor, or both.

BACTERIAL VAGINOSIS

Bacterial vaginosis is a condition in which the normal, hydrogen peroxide-producing lactobacillus-predominant vaginal flora is replaced with anaerobic bacteria, *Gardnerella vaginalis*, *Mobiluncus* species, and *Mycoplasma hominis* ([Hillier and colleagues, 1995](#); [Nugent and co-workers, 1991](#)). Clinical diagnostic features described by [Amsel and associates \(1983\)](#) include:

1. Vaginal pH greater than 4.5.
2. An amine odor when vaginal secretions are mixed with potassium hydroxide.
3. Vaginal epithelial cells heavily coated with bacilli—"clue cells."
4. A homogeneous vaginal discharge.

Bacterial vaginosis can also be diagnosed with Gram staining of vaginal secretions as reported by [Nugent and co-workers \(1991\)](#). Typically a Gram stain of vaginal secretion in women with bacterial vaginosis shows few white cells along with a mixed flora as compared with the normal predominance of lactobacilli.

Bacterial vaginosis has been associated with spontaneous preterm birth, preterm ruptured membranes, infection of the chorion and amnion, as well as amniotic fluid infection ([Hillier and colleagues, 1995](#); [Kurki and co-authors, 1992](#)). [Platz-Christensen and colleagues \(1993\)](#) have provided some evidence that bacterial vaginosis may precipitate preterm labor by a mechanism similar to the cytokine network pathway proposed for amniotic fluid bacteria ([Fig. 27-8](#)). In contrast, [Thorsen and associates \(1996\)](#), in a prospective study of 3600 Danish women, found that bacterial vaginosis diagnosed before 24 weeks was not related to ruptured membranes before 37 weeks or to low birthweight. The contrasting reports may relate to the diagnosis of the clinical syndrome of bacterial vaginosis. Because of its imprecise diagnosis, it is difficult to correlate each level of Gram stain score with adverse outcomes, and specifically with spontaneous preterm birth or membrane rupture. [Hauth and colleagues \(2000\)](#) presented data from the large prospective [NICHD¹ Maternal-Fetal Medicine Units Network](#) observational trial that confirmed a significant increase in spontaneous preterm birth when the vaginal pH is greater than 5.0 compared with 4.7 or less, and when the Gram stain score is 9 or 10 compared with 7 or 8 or less.

TRICHOMONAS AND CANDIDA VAGINITIS

[Cotch and associates \(1997\)](#), after adjusting for multiple confounding factors, including bacterial vaginosis, found that women with *Trichomonas vaginalis* were at 30 percent increased risk of having low-birthweight infants, 30 percent increased risk of preterm birth, and a nearly doubled risk of perinatal death. [Meis and co-workers \(1995a\)](#) examined 2929 women at 24 and 28 weeks using 10-percent potassium hydroxide wet mount preparations and found that detection of *Trichomonas* or *Candida* had no significant association with preterm birth. Most recently, [Carey and colleagues \(2000a\)](#) for the [NICHD¹ Maternal-Fetal Medicine Units Network](#) reported that of 617 women with asymptomatic vaginal trichomonas, 19 percent assigned to metronidazole treatment, compared with 11 percent assigned to placebo treatment, had a preterm birth ($P = .004$). These authors concluded that routine screening and treatment for this condition cannot be recommended.

CHLAMYDIAL INFECTION

Although *Chlamydia trachomatis* is the most common sexually transmitted bacterial pathogen in the United States ([Webster and colleagues, 1993](#)), the possible influence of cervical infection with this organism on preterm birth is unclear ([McGregor and French, 1991](#)). [Ryan and associates \(1990\)](#) used erythromycin to treat 1323 pregnant women with positive cervical cultures for *Chlamydia* at enrollment for prenatal care. Pregnancy outcomes in these women were compared with 1110 similar, but untreated women. Low birthweight and ruptured membranes more than 1 hour before labor were significantly decreased with erythromycin therapy. The effects on preterm birth, however, were not specified. [Andrews and colleagues \(2000\)](#) from the [NICHD¹ Maternal-Fetal Medicine Units Network Preterm Prediction Study](#) reported that genitourinary chlamydial infection at 24 weeks' gestation—but not at 28 weeks—detected via a ligase chain reaction assay was associated with a twofold increase in subsequent spontaneous preterm birth. The [Centers for Disease Control and Prevention guidelines for screening \(1993\)](#) and treatment ([1998](#)) of chlamydial infection during pregnancy are based on the prevalence of the infection in various populations, for example, teenagers, and on the likely benefit of third-trimester screening and treatment to reduce newborn ophthalmia neonatorum or pneumonitis, rather than reduce the incidence of preterm birth ([Chap. 57, p. 1493](#)).

IDENTIFICATION OF WOMEN AT RISK FOR PRETERM BIRTH

Obstetrical approaches to preterm birth have traditionally been focused primarily on treatment interventions rather than prevention of preterm labor. The first step in prevention is early identification of women at risk for preterm birth.

RISK-SCORING SYSTEMS

A risk-scoring system devised by Papiernik and modified by [Creasy and colleagues \(1980\)](#) has been tested in several regions of the United States. In this system, scores of 1 through 10 are given to a variety of pregnancy factors, including socioeconomic status, reproductive history, daily habits, and current pregnancy complications. Women with scores of 10 or more are considered to be at high risk for preterm delivery.

Although [Creasy and associates \(1980\)](#) and [Covington and co-workers \(1988\)](#) reported salutary results with this risk scoring coupled with an educational prevention program, the experiences of [Main and colleagues \(1989\)](#) in Philadelphia using this scoring system with indigent women was less satisfactory. Similar disappointing results in indigent women were obtained by [Mueller-Heubach and Guzick \(1989\)](#) and [Owen and associates \(1990b\)](#). The Creasy program also was not successful to reduce preterm birth in the multicenter randomized trial of 2395 pregnancies managed at five centers by the [Collaborative Group on Preterm Birth Prevention \(1993\)](#). [Hueston and colleagues \(1995\)](#) reviewed all published studies and found no benefits. Subsequently, the [NIH²-sponsored Maternal-Fetal Medicine Network Units](#) study showed that risk assessment failed to identify most women who have preterm delivery ([Mercer and colleagues, 1996](#)).

Although these scoring systems have been unsuccessful in identifying pregnancies at risk for preterm labor, certain features may be more useful than others in predicting the risk of preterm delivery. Complex combinations of risk scoring systems and other screening tests have been reported to increase the prediction of spontaneous preterm birth ([Crane and associates, 1999](#); [Goldenberg and co-workers, 1998](#)).

PRIOR PRETERM BIRTH

A history of prior preterm delivery strongly correlates with subsequent preterm labor. [Table 27-7](#) gives the incidence of recurrent spontaneous preterm birth in over 6000 Scottish women. The risk of recurrent preterm delivery for those whose first delivery was preterm increased threefold compared with women whose first infant reached term. Strikingly, almost a third of women whose first two infants were preterm subsequently delivered preterm infants during their third pregnancies. Almost identical results were obtained in an analysis of 13,967 pregnancies in Danish women ([Kristensen and co-workers, 1995](#)). [Iams and colleagues \(1998a\)](#) used the [NICHD¹ Maternal-Fetal Medicine Units Network Preterm Prediction Study](#) to detail the increased risk of spontaneous preterm birth before 36 weeks' gestation in women who had had a prior preterm birth. This increased risk was substantially further increased in association with a positive (≥ 50 ug/dL) midtrimester vaginal fetal fibronectin test or in relation to cervical shortening measured with ultrasound, especially in women with a cervix measurement at or below the 10th percentile (≥ 25 mm) at 24 weeks' gestation.

Not only are women who deliver preterm at risk themselves for recurrence, but recent evidence suggests that this risk is also transmitted to their children. [Wang and associates \(1995\)](#) and [Porter and colleagues \(1996\)](#) have found familial aggregation of preterm birth.

CERVICAL DILATATION

Asymptomatic cervical dilatation after midpregnancy has gained attention as a risk factor for preterm delivery. Some authorities have considered such dilatation to be a normal anatomical variant, particularly in parous women. Recent studies have suggested that parity alone is not sufficient to explain cervical dilatation discovered early in the third trimester. [Cook and Ellwood \(1996\)](#) longitudinally studied the cervix between 18 and 30 weeks using transvaginal ultrasound in both nulliparous and parous women. Cervical length and diameter were identical in both groups of women throughout these critical weeks.

[Table 27-8](#) gives the results of routine cervical examinations performed between 26 and 30 weeks in 185 women cared for at Parkland Hospital. Approximately a fourth of the women whose cervixes were dilated 2 or 3 cm delivered prior to 34 weeks. Many of these women had experienced the same complication in earlier pregnancies. Similarly, [Papiernik and colleagues \(1986\)](#), in a study of cervical status before 37 weeks in 4430 women, found that precocious cervical dilatation increased the risk of preterm birth. [Stubbs and colleagues \(1986\)](#) performed cervical examinations in 191 women between 28 and 34 weeks and found that those with dilatation of 1 cm or more, or effacement of more than 30 percent, were at increased risk for preterm delivery. [Copper and associates \(1995\)](#) examined 570 women at risk for preterm birth at about 28 weeks and found that cervical condition predicted delivery before 37 weeks.

ULTRASONIC MEASUREMENT OF CERVICAL LENGTH. [Iams and co-workers \(1996\)](#) used transvaginal sonography to measure the length of the cervix in 2915 women at approximately 24 weeks and again at 28 weeks. As shown in [Figure 27-9](#), the mean cervical length at 24 weeks was about 35 mm, and those women with progressively shorter cervixes experienced increased rates of preterm birth. These findings were supported by investigations of [Hartmann and colleagues \(1999\)](#). In another study performed in the [NICHD¹ Maternal-Fetal Medicine Units Network](#), [Owen and co-workers \(2000\)](#) correlated cervical length at 16 to 24 weeks' gestation with subsequent preterm birth before 35 weeks. [Guzman and colleagues \(2001\)](#) longitudinally evaluated 237 at-risk women with singletons between 15 and 24 weeks' gestation. At all testing periods the sensitivity and negative predictive value of cervical length to predict spontaneous preterm birth prior to 30 weeks' gestation were

excellent.

Transvaginal ultrasound cervical assessment requires special expertise. [Yost and colleagues \(1999\)](#) caution those who perform these examinations to be wary of falsely reassuring findings due to potential anatomical and technical pitfalls. In recent small randomized trials, cervical cerclage has not been found to be beneficial in preventing delivery before 35 weeks ([Althuisius and co-workers, 2000](#); [Rust and colleagues, 2000](#)). [Rust and colleagues \(2001\)](#) used ultrasonic cervical measurement criteria for cervical dilatation obtained between 16 and 24 weeks to identify and randomize 55 women to cerclage and 58 to a no cerclage intervention. The survival curve, generated with respect to gestational age at delivery, showed no significant difference between groups. However, [Althuisius and colleagues \(2001\)](#) randomized 35 women at high risk for cervical incompetence to either therapeutic cerclage or to bed rest. Women randomized to cerclage had significantly fewer births prior to 34 weeks and less neonatal morbidity.

Although it seems clear that pregnant women with cervical dilatation and effacement diagnosed early in the third trimester by direct cervical digital examination are at increased risk for preterm birth, it has not been established that detection appreciably improves pregnancy outcome. [Buekens and colleagues \(1994\)](#) randomized 2719 European women to routine cervical examinations at each prenatal visit compared with 2721 women in whom cervical examinations were not performed. Knowledge of antenatal cervical dilatation did not affect any pregnancy outcome related to preterm birth or the frequency of interventions practiced in the management of preterm labor. Importantly, cervical examinations were not related to preterm ruptured membranes. Thus, prenatal cervical examinations were neither beneficial nor harmful.

SIGNS AND SYMPTOMS

In addition to painful or painless uterine contractions, symptoms such as pelvic pressure, menstrual-like cramps, watery or bloody vaginal discharge, and pain in the low back have been empirically associated with impending preterm birth. Such symptoms are thought by some to be common in normal pregnancy, and are therefore often dismissed by patients, physicians, and nurses. The importance of these signs and symptoms has been emphasized by some investigators ([Iams and associates, 1990](#); [Kragt and Keirse, 1990](#)). Conversely, [Copper and colleagues \(1990\)](#) did not find these to be meaningful in the prediction of preterm birth. [Iams and colleagues \(1994\)](#), in a follow-up investigation to their 1990 study, found that the signs and symptoms signaling preterm labor, including uterine contractions, only appeared within 24 hours of preterm labor. Thus, these are a late warning sign of preterm birth.

FETAL FIBRONECTIN

Fibronectin is a glycoprotein produced in 20 different molecular forms by a variety of cell types, including hepatocytes, malignant cells, fibroblasts, endothelial cells, and fetal amnion. It is present in high concentrations in maternal blood and in amniotic fluid, and is thought to have a role in intercellular adhesion in relation to implantation as well as in the maintenance of adhesion of the placenta to the decidua ([Leeson and colleagues, 1996](#)). Fetal fibronectin can be detected in cervicovaginal secretions in normal pregnancies with intact membranes at term, and appears to reflect stromal remodeling of the cervix prior to labor. [Lockwood and co-workers \(1991\)](#) reported that detection of fetal fibronectin in cervicovaginal secretions prior to membrane rupture may be a marker for impending preterm labor. This report has stimulated considerable interest in the use of fibronectin assays for the prediction of preterm birth. Fetal fibronectin is measured using an enzyme-linked immunosorbent assay and values exceeding 50 ng/mL are considered a positive result. Contamination of the sample by amniotic fluid and maternal blood should be avoided.

[Leeson and associates \(1996\)](#) and [Peaceman and co-workers \(1996\)](#) have found that although fibronectin-positive tests are associated with preterm birth, negative results are more consistently meaningful in predicting that preterm labor will not ensue. [Cox and co-workers \(1996b\)](#) found cervical dilatation to be superior to detection of fibronectin to predict preterm birth. [Goldenberg and colleagues \(1996a\)](#) using the NICHD¹ Network Preterm Prediction Study reported that a positive cervical or vaginal fetal fibronectin at 24 weeks' gestation was a powerful predictor of subsequent spontaneous preterm birth. Most recently, [Goldenberg and co-authors \(2000\)](#) reported that detection of fetal fibronectin in cervical/vaginal secretions as early as 18 to 22 weeks' gestation was predictive of preterm delivery. In a meta-analysis of 27 studies, [Leitch and associates \(1999\)](#) also found it to be an effective predictor of preterm delivery.

Importantly, other factors such as cervical manipulation and peripartum infection can stimulate fetal fibronectin release ([Goldenberg and colleagues, 1996b](#); [Thorp and Lukes, 1996](#)). Similarly, [Jackson and colleagues \(1996\)](#) have shown that human amnion cells in vitro produce fetal fibronectin when stimulated by inflammatory products implicated in the initiation of preterm labor due to infection ([Fig. 27-8](#)).

AMBULATORY UTERINE CONTRACTION TESTING

The diagnosis of preterm labor, before it is irreversibly established, is a goal of management. To this end, uterine activity monitoring, using tocodynamometry, has received considerable interest. In 1957, [Smyth](#) described an external tocodynamometer with an innovative sensor that employed the so-called guard-ring principle. The abdominal wall is flattened by an outer ring, thus permitting the inner contraction-sensing transducer to be applied more directly to the underlying uterine wall. Several preterm birth-prevention programs incorporating such a device have been commercially available since 1985 for ambulatory uterine monitoring. The contraction sensor is belted around the abdomen and connected to a small electronic recorder worn at the waist. This recorder is used to transmit uterine activity via phone on a daily basis. Patients are educated concerning signs and symptoms of preterm labor, and their attending physicians are kept apprised of their progress. The program is expensive; for example, in Dallas in 1996 the list price was \$55 to \$154 per day, depending on the patient's risk status.

As shown in [Figure 27-10](#), [Katz and associates \(1986\)](#) found that women who subsequently had a preterm delivery experienced increased uterine activity beginning at about 30 weeks. Subsequent widespread clinical application of home uterine contraction monitoring for the purpose of preventing preterm birth has provoked considerable controversy in the United States. Currently, the [American College of Obstetricians and Gynecologists \(1995\)](#) continues to take the following position: "It is not clearly demonstrated that this expensive and burdensome system can be used to actually affect the rate of preterm delivery."

Recent studies continue to show that home uterine activity monitoring is ineffective in the prevention of preterm birth. In the [Collaborative Home Uterine Monitoring Study \(1995\)](#), sham transducers were used in 655 women and outcomes compared with 637 women with functioning monitors. Home monitoring was ineffective in the prevention of preterm birth. [Iams and colleagues \(1998b\)](#) longitudinally assessed uterine activity with daily home monitoring and reported on 34,908 hours of uterine contraction data from 306 women. Contraction frequency increased with advancing gestational age but did not efficiently predict preterm birth.

[Dyson and colleagues \(1998\)](#), in a multicenter trial conducted at Kaiser Permanente Hospital in California, also found no benefits for home uterine activity monitoring. They randomized 2422 women at risk for preterm birth (including 844 women with twins) to weekly contact with a nurse or to contraction monitoring at home. There were no differences in delivery before 35 weeks' gestation nor in birthweight less than 1500 g or less than 2500 g. Undesirable outcomes included a significant increase in unscheduled visits to obstetricians and significantly increased prophylactic tocolytic drug therapy in women with twins.

SALIVARY ESTRIOL

Several investigators have reported an association between increased maternal salivary estriol concentration and subsequent preterm birth ([Goodwin, 1996](#); [Heine, 1999](#); [McGregor, 1995](#); and their co-workers). [Goodwin \(1999\)](#) reviewed the potential value of maternal salivary estriol and concluded that this test requires further evaluation. We are also of the view that use of salivary estriol to predict preterm delivery is investigational.

MANAGEMENT OF PRETERM LABOR

There are a number of factors important in directing management of the woman with possible preterm labor. Foremost is its correct identification, along with whether there is accompanying membrane rupture.

DIAGNOSIS

Early differentiation between true and false labor is difficult before there is demonstrable cervical effacement and dilatation. Uterine contractions alone can be misleading because of *Braxton Hicks contractions* ([Chap. 14, p. 355](#)). These contractions, described as irregular, nonrhythmic, and either painful or painless, can cause considerable confusion in the diagnosis of preterm labor. Not infrequently, women who deliver before term have uterine activity that is attributed to Braxton Hicks contractions, prompting an incorrect diagnosis of false labor.

Because uterine contractions alone may be misleading, the [American Academy of Pediatrics and the American College of Obstetricians and Gynecologists \(1997\)](#) has proposed the following criteria to document preterm labor between 20 and 37 weeks' gestation:

1. Contractions occurring at a frequency of four in 20 minutes or eight in 60 minutes plus progressive change in the cervix.
2. Cervical dilatation greater than 1 cm.
3. Cervical effacement of 80 percent or greater.

ANTEPARTUM MANAGEMENT

It is not apparent that making prenatal care available to more women or making more visits available has reduced preterm births ([Buescher and associates, 1988](#); [Donaldson and colleagues, 1984](#); [Fink and co-workers, 1992](#); [Fiscella, 1995](#)). Despite this, women with pregnancies identified to be at risk for preterm birth, and also those who present with signs and symptoms of impending preterm delivery, have become candidates for a large number of interventions intended to improve infant outcomes. In the absence of maternal or fetal indications that warrant intentional delivery, most interventions are expected to forestall preterm birth or enhance the infants' ability to cope with the extrauterine environment. In many instances, the interventions described in the following section should be considered and not necessarily recommended for clinical practice.

PRETERM PREMATURELY RUPTURED MEMBRANES. Attempts to avoid delivery when there is preterm ruptured membranes are of two primary forms:

1. Nonintervention or expectant management, in which spontaneous labor is simply awaited.
2. Intervention that may include corticosteroids, given with or without tocolytic agents to arrest preterm labor in order that the corticosteroids have sufficient time to induce fetal maturation.

The [American College of Obstetricians and Gynecologists \(1998a\)](#) has recently reviewed preterm ruptured membranes.

Known risk factors for preterm rupture of the membranes include preceding preterm birth ([Guinn and co-workers, 1995](#)), occult amniotic fluid infection (see p. 696), multiple fetuses ([Chap. 30, p. 778](#)), and abruptio placentae ([Major and colleagues, 1995](#)).

NATURAL HISTORY OF PRETERM MEMBRANE RUPTURE. [Cox and associates \(1988b\)](#) described the pregnancy outcomes of 298 consecutive women delivered following spontaneously ruptured membranes between 24 and 34 weeks. Although this complication was identified in only 1.7 percent of pregnancies, it contributed to 20 percent of all perinatal deaths during that time period. Preterm membrane rupture was found to be associated with other obstetrical complications that affect perinatal outcome, including multifetal gestation, breech presentation, chorioamnionitis, and intrapartum fetal distress. As a consequence of these complications, cesarean delivery was done in nearly 40 percent of women. At admission, 75 percent of the women were already in labor, 5 percent were delivered for other complications, and another 10 percent were delivered following spontaneous labor within 48 hours. In only 7 percent was delivery delayed 48 hours or more after membrane rupture. This latter subgroup, however, appeared to benefit from delayed delivery, because no neonatal deaths occurred. This was in contrast to a neonatal death rate of 80 per 1000 in infants delivered within 48 hours of membrane rupture. [Nelson and colleagues \(1994\)](#) reported similar results. In women already in labor upon admission, about half were undelivered at 48 hours after membrane rupture but only 13 percent were undelivered at 7 days. Both of these studies attest to the inevitability of preterm labor and birth after preterm membrane rupture.

The time period from preterm ruptured membranes to delivery is inversely proportional to the gestational age when the membranes ruptured ([Carroll and associates, 1995a](#)). As shown in [Figure 27-11](#), very few days were gained when membranes ruptured during the third compared with the second trimester.

EXPECTANT MANAGEMENT. Despite an extensive literature concerning expectant management of preterm ruptured membranes, few randomized studies have been performed. An exception is the report by [Garite and colleagues \(1981\)](#), who studied 160 pregnancies with preterm ruptured membranes between 28 and 34 weeks. The women were divided into two groups that included expectant management only or corticosteroids plus tocolysis with either intravenous ethanol or magnesium sulfate. The authors concluded that active interventions did not improve perinatal outcomes and may have aggravated infection-related complications. Subsequent randomized studies by [Garite and associates \(1987\)](#) and [Nelson and colleagues \(1985\)](#) failed to show benefits for tocolysis, either with or without steroid therapy. [Morales and co-workers \(1989\)](#) studied 165 pregnancies with preterm ruptured membranes and lecithin:sphingomyelin ratios less than two. These were randomized to four treatment groups that included (1) expectant management only, (2) corticosteroids for fetal lung maturation, (3) ampicillin only, and (4) ampicillin plus corticosteroids. They concluded that ampicillin plus corticosteroids were beneficial because of less respiratory disease. Unfortunately, neonatal survival was not ultimately affected by any intervention, nor was the length of gestation.

[Alexander and colleagues \(2000\)](#), in a study performed in the [NICHD¹ Maternal-Fetal Medicine Units Network](#), found that one or two digital cervical examinations performed with expectant management of ruptured membranes between 24 and 32 weeks' gestation were associated with a significantly shorter rupture-to-delivery interval (3 days) compared with avoidance of such examinations (5 days). Importantly, however, this difference in latency from rupture-to-delivery interval did not worsen maternal or neonatal outcomes.

SECOND-TRIMESTER RUPTURED MEMBRANES. There are both maternal and infant risks to be considered when contemplating expectant management of ruptured membranes before 25 to 26 weeks. Maternal risks include the consequences of uterine infection and sepsis. Fetal risks include pulmonary hypoplasia and limb compression deformities, which have been associated with prolonged periods of oligohydramnios due to ruptured membranes ([Chap. 31, p. 822](#)). [Morales and Talley \(1993\)](#) expectantly managed 94 women with singleton pregnancies and ruptured membranes prior to 25 weeks and found that 41 percent ultimately survived to 1 year of age and 27 percent were neurologically normal. The average time gained during expectant management was 11 days. Similar results were reported by [Farooqi and colleagues \(1998\)](#) and [Winn and associates \(2000\)](#). In contrast, [Hibbard and colleagues \(1993\)](#) analyzed neonatal mortality, morbidity, and health-care costs in 44 pregnancies expectantly managed after membrane rupture at 25 weeks or less. They concluded that immediate delivery of the fetus less than 24 weeks may be the most cost-effective plan. In this report, 77 percent of the women expectantly managed developed chorioamnionitis.

The volume of amniotic fluid and fetal age at membrane rupture appears to have prognostic importance in pregnancies before 26 weeks. [Hadi and associates \(1994\)](#) analyzed 178 pregnancies with ruptured membranes between 20 and 25 weeks' gestation and 40 percent had oligohydramnios defined as no sonographic pockets of 2 cm or greater. Virtually all those with oligohydramnios delivered before 25 weeks, whereas 85 percent of those with adequate amniotic fluid volume delivered in the third trimester. [Carroll and colleagues \(1995a\)](#) observed no cases of pulmonary hypoplasia in fetuses born after membrane rupture at 24 weeks or beyond, suggesting 23 weeks or less is the threshold for lung hypoplasia.

HOSPITALIZATION. Most obstetricians hospitalize women with pregnancies complicated by preterm ruptured membranes. Concerns about the costs of lengthy hospitalizations are usually moot, because most women enter labor within a week or less of membrane rupture. [Carlan and co-workers \(1993\)](#) randomized 67 carefully selected pregnancies with ruptured membranes to home versus hospital management. All women were hospitalized until 72 hours after rupture; 20 women were ultimately sent home and 25 others randomized to hospitalization. No benefits were found for hospitalization and maternal hospital stay was reduced by 50 percent in those sent home (14 to 7 days). Three women sent home delivered at outside hospitals because their labor was too advanced to return to the research hospital. Importantly, these investigators emphasize that this study was too small to conclude that home management was safe.

Unfortunately, perinatal outcome in surviving infants in whom labor is delayed is not always satisfactory. In a previous study from Parkland Hospital, [Hankins and associates \(1984\)](#) reported that 30 percent of 176 such infants required ventilator therapy. Overall, 13 percent died in the neonatal period and another 3 percent died before age 1. Care of these infants born preterm required over 5100 newborn hospital days (almost 14 years) and cost \$2.3 million (in 1984 dollars) just for bed space. Importantly, follow-up to 4 years was carried out for 105 of these infants, and neurological abnormalities of varying degrees were found in 16 percent. Similarly, [Spinillo and colleagues \(1995\)](#) found that preterm infants delivered 48 hours or more after ruptured membranes were at high risk for subsequent moderate to severe neurodevelopmental impairment compared with infants born after spontaneous preterm labor with intact membranes.

INTENTIONAL DELIVERY. The prospect of deliberately delivering a pregnancy preterm seems imprudent, although intentional delivery was widely practiced prior to the 1970s due to fear of infection ([Reid and Christian, 1974](#)). Another more recent rationale for intentional delivery is to avoid the uncommon fetal death that occurs in pregnancies managed expectantly after preterm rupture. The typically very short interval from membrane rupture to onset of spontaneous labor also lends support to the rationale for intentional delivery, because so little time is gained from expectant management, especially later in the third trimester ([Fig. 27-11](#)).

There have been two randomized trials of intentional delivery of pregnancies complicated by preterm ruptured membranes. [Mercer and colleagues \(1993\)](#) randomized 93 pregnancies with ruptured membranes between 32 and 36 weeks to delivery compared with expectant management. All had documented fetal lung maturity.

Intentional delivery reduced the length of maternal hospitalization and also reduced infection rates in both mothers and neonates. [Cox and Leveno \(1995\)](#) similarly randomized 129 women with ruptured membranes between 30 and 34 weeks. There was one fetal death (due to sepsis) in those pregnancies managed expectantly and three neonatal deaths (two of which were due to sepsis and one due to pulmonary hypoplasia) among those intentionally delivered. Neither management approach was felt to be satisfactory.

OVERT CHORIOAMNIONITIS. Assuming that no untoward perinatal outcome occurs due to an entangled or prolapsed cord or from placental abruption, the greatest concern with prolonged membrane rupture is the risk of maternal or fetal infection. If chorioamnionitis is diagnosed, prompt efforts to effect delivery, preferably vaginally, are initiated. Unfortunately, fever is the only reliable indicator for making this diagnosis; a temperature of 38°C (100.4°F) or higher accompanying ruptured membranes implies infection. Maternal leukocytosis by itself has been found to be unreliable by most investigators, and this has also been our experience.

With chorioamnionitis, fetal and neonatal morbidity are substantively increased. In a prospective study of nearly 700 women between 26 and 34 weeks with preterm ruptured membranes, [Morales \(1987\)](#) reported that 13 percent developed chorioamnionitis diagnosed by oral temperatures of 38°C and no other cause for fever. Infants born to women with chorioamnionitis had a fourfold increased neonatal mortality and a threefold increase in the incidence of respiratory distress, neonatal sepsis, and intraventricular hemorrhage. [Alexander and colleagues \(1998\)](#) studied the effects of clinical chorioamnionitis in 1367 very-low-birthweight infants delivered at Parkland Hospital. Approximately 7 percent of the infants were exposed to chorioamnionitis and the outcomes of these infants were compared with those without overt infection. Neonatal sepsis, respiratory distress syndrome, seizures in the first 24 hours of life, intraventricular hemorrhage, and periventricular leukomalacia were all increased with chorioamnionitis. It was concluded that very-low-birthweight infants were vulnerable to neurological injury attributable to chorioamnionitis. Similarly, [Yoon and colleagues \(2000\)](#) found that intra-amniotic infection in preterm infants was related to cerebral palsy at 3 years of age.

ACCELERATED MATURATION OF PULMONARY FUNCTION. A variety of clinical events—some well defined and others not—have been proposed to accelerate surfactant production sufficient to protect against respiratory distress. [Gluck \(1979\)](#) emphasized that surfactant production is likely to be accelerated remote from term in pregnancies complicated by a number of maternal or fetal conditions or stresses. Examples included chronic renal or cardiovascular disease, long-standing hypertensive disorders due to pregnancy, heroin addiction, fetal growth restriction, placental infarction, chorioamnionitis, or preterm ruptured membranes. This view is widely held, although more recent data refute this association. For example, [Owen and associates \(1990a\)](#) concluded that a "stressed" pregnancy (primarily pregnancy-associated hypertension) conferred a negligible fetal survival advantage. Similarly, [Hallak and Bottoms \(1993\)](#) reviewed 1395 pregnancies delivered between 24 and 35 weeks and found that prematurely ruptured membranes was not associated with accelerated pulmonary maturation.

ANTIMICROBIAL THERAPY. The microbial pathogenesis for preterm ruptured membranes ([Fig. 27-8](#)) has prompted investigations of various antimicrobials to forestall delivery. [Mercer and Arheart \(1995\)](#) reviewed 13 randomized studies concerning the efficacy of antimicrobials compared with placebo treatment for ruptured membranes before 35 weeks. There was a combined total of 1594 pregnancies reported between 1974 and 1993. A total of 10 outcomes were subjected to meta-analysis and only three showed a possible beneficial effect of antimicrobials: fewer women developed chorioamnionitis, fewer infants developed sepsis, and pregnancy was more often prolonged 7 days in those given antimicrobials. Neonatal survival was unaffected, as was the incidence of necrotizing enterocolitis, respiratory distress, or intracranial hemorrhage.

To further address this issue, the [NICHD¹ Maternal-Fetal Medicine Units Network](#) conducted a prospective randomized trial of ampicillin or amoxicillin plus erythromycin in women with preterm rupture between 24 and 32 weeks' gestation ([Mercer and colleagues, 1997](#)). Tocolysis, corticosteroid treatment, or both were not given in this trial. There were significantly fewer newborns with respiratory distress syndrome, necrotizing enterocolitis, or a composite adverse outcome in pregnancies in which antimicrobials were given. Latency from membrane rupture to delivery was significantly longer at 7, 14, and 21 days in women given antibiotics compared with placebo. At 7 days, 50 percent of these women remained undelivered compared with only 25 percent of those assigned to placebo. These benefits were apparent whether or not the patient had a positive test for cervicovaginal group B streptococcus at the time of amnion rupture.

Prolonged antimicrobial therapy in such pregnancies may have unwanted consequences. [Kyle and Turner \(1996\)](#) reported superinfection with *Pseudomonas aeruginosa* as a result of prolonged antibiotic therapy for preterm ruptured membranes. [Carroll and colleagues \(1996\)](#) and [Mercer and associates \(1999\)](#) have also voiced concern that such therapy potentially increases the risk for selection of resistant pathogens.

DIAGNOSIS AND MANAGEMENT OF PRETERM MEMBRANE RUPTURE AT PARKLAND HOSPITAL. Pregnancy complicated by preterm rupture of the membranes is managed as follows:

1. In women with possible amnion rupture one sterile speculum examination is performed to identify fluid coming from the cervix or pooled in the vagina. Demonstration of visible fluid is indicative of ruptured membranes and is usually accompanied by ultrasound examination to confirm oligohydramnios, to identify the presenting part, and to estimate gestational age. Nitrazine paper testing of vaginal pH has an appreciable false-positive rate associated with blood contamination, semen, or bacterial vaginosis. The microscopic inspection of cervicovaginal dried secretions for NaCl crystallization (ferning) also has an appreciable false-positive rate. Infrequently, a compelling maternal history of amnion rupture is not supported by either gross visualization or vaginal pooling of amniotic fluid or ultrasound confirmation of decreased amniotic fluid. In these instances, instillation of indigo carmine dye (one ampule) into the amniotic fluid and assessing leakage of blue fluid into the vagina can be helpful in ascertaining the integrity of the membranes.

Attempts are made to visualize the extent of cervical effacement and dilatation, but a digital examination is not performed.

2. If the gestational age is less than 34 weeks and there are no other maternal or fetal indications for delivery, the woman is observed closely in Labor and Delivery. Continuous fetal heart rate monitoring is employed to look for evidence of cord compression, especially if labor supervenes.

3. If the fetal heart rate is reassuring, and if labor does not follow, the woman is transferred to the High Risk Pregnancy Unit for close observation for signs of labor, infection, or fetal jeopardy.

4. If the gestational age is greater than 34 completed weeks and if labor has not begun following adequate evaluation, labor is induced with intravenous oxytocin unless contraindicated. If induction fails, cesarean delivery is performed.

5. Dexamethasone, 5 mg intramuscularly every 12 hours for 4 doses, is given for enhancement of fetal maturation.

6. When labor is diagnosed, ampicillin, 2 g, is given intravenously every 6 hours prior to delivery for prevention of group B streptococcal infection in the neonate.

PRETERM LABOR WITH INTACT FETAL MEMBRANES. Antepartum management of women with signs and symptoms of preterm labor and intact membranes is much the same as already described for pregnancies with preterm ruptured membranes. That is, the cornerstone of treatment is to avoid delivery prior to 34 weeks' gestation if possible. Drugs intended to abate or suppress uterine contractions are commonly employed, and these will be discussed later. As in pregnancies with preterm ruptured membranes, antimicrobials, for the purpose of delaying delivery in women with preterm labor, have been studied specifically in women with intact membranes. Results with a variety of antimicrobial agents have been disappointing ([Cox, 1996a](#); [Gordon, 1995](#); [Klebanoff, 1995](#); [Romero, 1993](#), and their co-workers). Two smaller trials of metronidazole and ampicillin in women with suspected spontaneous preterm labor have shown a modest benefit ([Norman and associates, 1994](#); [Svare and colleagues, 1997](#)). It is likely that administration of antimicrobials after preterm labor has begun is too late to interfere with propagation of the biochemical cascade that modulates uterine activity ([Fig. 27-8](#)).

GLUCOCORTICOID THERAPY. On the basis of previous observations that corticosteroids administered to the ewe accelerated lung maturation in the preterm fetus, [Liggins and Howie \(1972\)](#) performed a randomized study to evaluate the effects of maternally administered betamethasone (12 mg intramuscularly in two doses, 24 hours apart) to prevent respiratory distress in the subsequently delivered preterm infant. Infants born before 34 weeks had a significantly lowered incidence of respiratory distress and neonatal mortality from hyaline membrane disease if birth was delayed for at least 24 hours after completion of 24 hours of betamethasone given to the mother and for up to 7 days after completion of steroid therapy. This study served to stimulate more than 20 years of research on fetal maturation, which culminated in 1995 with a position statement on usage of corticosteroids for fetal therapy by the National Institutes of Health ([NIH Consensus Development Panel, 1995](#)).

The mechanism by which betamethasone or other corticosteroids are currently thought to reduce the frequency of respiratory distress involves induction of proteins that regulate biochemical systems within type II cells in the fetal lung that produce surfactant ([Ballard and Ballard, 1995](#)). The reported physiological effects of glucocorticoids on the developing lungs include increased alveolar surfactant, compliance, and maximal lung volume.

COLLABORATIVE STUDY ON ANTENATAL STEROID THERAPY. The [NIH²-sponsored trial](#) by the [Collaborative Group on Antenatal Steroid Therapy \(1981\)](#) was

designed to study the effects of corticosteroid therapy on preterm fetuses. This double-blind collaborative trial was conducted at five centers, and of nearly 8000 women identified to be in preterm labor, 696 women at risk for preterm birth were enrolled. Women randomized to therapy were given intramuscular dexamethasone, 5 mg every 12 hours for a total of up to 4 doses. Including twins, a total of 720 infants was available for analysis. A significantly fewer number of infants whose mothers were given dexamethasone developed respiratory distress (13 versus 18 percent). Importantly, more than 80 percent in each study group did not develop respiratory distress. Neonatal mortality was not reduced by treatment. Similar results were obtained from a multicenter randomized trial of betamethasone performed in the United Kingdom between 1975 and 1978 ([Gamsu and colleagues, 1989](#)).

In 1985, a workshop reviewed the results of the Collaborative Study ([Avery and colleagues, 1986](#)). The group agreed that no differences in terms of cognitive, motor, or neurological function were found when 406 of the study infants were followed to 36 months of age, suggesting that steroid treatment did not adversely affect subsequent short-term neurological development ([Collaborative Group, 1984](#)). They further concluded that dexamethasone appeared beneficial only to a female fetus of older than 30 weeks and when the treatment-to-delivery interval exceeded 24 hours. Such therapy was not helpful in multiple gestations. These many caveats concerning the benefits (or lack thereof) of corticosteroids undoubtedly limited widespread use of this fetal therapy ([Jobe and colleagues, 1993](#)).

NATIONAL INSTITUTE OF HEALTH CONSENSUS DEVELOPMENT CONFERENCE ON CORTICOSTEROIDS FOR FETAL MATURATION. The proceedings of this conference were described in detail in the *American Journal of Obstetrics and Gynecology* ([NIH Consensus Development Conference Statement, 1995](#)). The resulting consensus on prescribing corticosteroids to accomplish fetal maturation was hailed by some as the most important development in perinatal care during 1995 ([Hayward and Diaz-Rossello, 1995](#)). [Grimes \(1995\)](#) took the position that because of the delay between 1972 and 1995 in adopting corticosteroids for fetal maturation, "tens of thousands of neonates died needlessly ... and our nation squandered millions of health care dollars treating preventable complications of prematurity."

The centerpiece used by the National Institutes of Health panel on corticosteroids to establish the efficacy of this therapy was a meta-analysis of randomized controlled trials ([Crowley, 1995](#)). Such analyses pool individual randomized controlled trials together to arrive at an overall estimate of the effect of an intervention, in this case, corticosteroids. This analytical approach assumes that the pooled studies are identical or nearly so in experimental design, definitions of disease end-points, patient populations, and treatment regimens. It is likely that most current meta-analyses have several sources of between-trial heterogeneity that could skew interpretation of pooled results ([Moher and Olkin, 1995](#)). For example, some trials included could use correctly concealed treatment allocation to randomize subjects whereas others may not be this rigorous in design. This is crucial, because trials with inadequate concealment generally produce results indicating that a particular treatment or intervention is beneficial ([Martyn, 1996](#)). An example of this type of heterogeneity can be found in the corticosteroid meta-analysis. [Morales and colleagues \(1986\)](#), in their randomized trial of corticosteroids for fetal maturation in 245 pregnancies with preterm ruptured membranes, used hospital medical record numbers in an unspecified design to randomize patients. This method of allocation to treatment or nontreatment with corticosteroids was thus not concealed from the clinicians. Despite this, the study by [Morales and colleagues \(1986\)](#) was pooled in the meta-analysis with other trials with more rigorous experimental design.

The next three figures include examples of meta-analysis on the fetal effects of corticosteroids using respiratory distress syndrome ([Fig. 27-12](#)), neonatal death ([Fig. 27-13](#)), and the summary of multiple effects on infant outcome ([Fig. 27-14](#)). A total of 15 randomized trials were chosen by [Crowley \(1995\)](#) to be included in the meta-analysis. Each horizontal line represents the results of one trial and the shorter the line, the more certain the result. If a horizontal line (study trial) touches the solid vertical line it means that that particular trial found no significant benefit. The total at the bottom of each figure is the result when all 15 trials are pooled together.

In the case of respiratory distress syndrome, nine trials found no benefit for corticosteroids and three others found only marginal benefits ([Fig. 27-12](#)). The total effect, however, when all the trials are pooled indicates that corticosteroids reduce respiratory distress by 50 percent. This beneficial effect is heavily dependent on the largest and original trial by [Liggins and Howie \(1972\)](#). An alternative interpretation could also be that no group of investigators has ever been able to reproduce that original trial. For neonatal deaths, 10 of the 15 trials analyzed showed no benefit ([Fig. 27-13](#)). Pooling of the data, however, indicates that corticosteroids reduced neonatal mortality by 50 percent. Meta-analysis for multiple infant outcomes related to corticosteroid therapy is shown in [Figure 27-14](#).

[Table 27-9](#) summarizes recommendations for use of corticosteroids for fetal maturation by the [NIH Consensus Development Panel \(1995\)](#). Data were deemed insufficient to assess effectiveness of corticosteroids in pregnancies complicated by hypertension, diabetes, multiple gestation, fetal growth restriction, and fetal hydrops. The Consensus Panel concluded, however, that in the absence of evidence of adverse effects, it is reasonable to use corticosteroids with these complications. It was also concluded, however, that there were insufficient data to comment on the benefits or risks of repeating maternal corticosteroid treatment weekly to enhance fetal maturation. The national response to dissemination of the [NIH² Consensus Panel](#) recommendations was dramatic, and the use of corticosteroids to enhance fetal maturation doubled within 12 months ([Leviton and colleagues, 1999](#)).

The [American College of Obstetricians and Gynecologists Committee on Obstetric Practice \(1994\)](#) supported the conclusions of the [NIH² Consensus Panel](#) with the exception of the recommendation for treatment of women with preterm ruptured membranes. They recommended further research. Indeed, [Chapman and colleagues \(1996\)](#) concluded that corticosteroid treatment for women with preterm ruptured membranes who were delivered of infants weighing less than 1000 g was not beneficial. More recently, the [American College of Obstetricians and Gynecologists Committee on Obstetric Practice \(1998\)](#) expressed concern about adverse fetal effects and possible effects on maternal immune status of repeated weekly courses of steroids. The College recommended that following the initial course of corticosteroids, repeated doses should be given only on an as-needed basis (i.e., a "rescue" dose given when the threat of preterm delivery recurred).

In the previous edition of this textbook, we predicted that "It is likely that some of the many benefits attributed to corticosteroid therapy by the Consensus Panel will be reassessed in the future." **Indeed, the Consensus Panel was reconvened on August 17-18, 2000 to reconsider the safety and efficacy of repeated courses of corticosteroids given for fetal maturation.** The conclusions of the panel are shown in [Table 27-10](#). To summarize, it is now recommended that repeated courses of antenatal corticosteroids be used only in clinical trials.

ADVERSE EFFECTS OF CORTICOSTEROIDS. Studies initiated in the 1970s, which followed the development of children treated antenatally with corticosteroids up to the age of 12 years, showed no adverse outcomes in the areas of long-term neurodevelopment. These were measured by learning, behavioral, and motor or sensory disturbances ([NIH Consensus Development Panel, 1995](#)). There are, however, short-term maternal effects to include pulmonary edema, infection, and more difficult glucose control in diabetic women. No long-term adverse maternal effects have been reported.

[Liggins and Howie \(1972\)](#) based their use of corticosteroids to promote fetal lung maturation on experiments in sheep that indicated that such therapy not only affected lung maturation but also stimulated labor. Corticosteroids were reported to induce labor in humans more than 20 years ago ([Jenssen and Wright, 1977](#); [Mati and colleagues, 1973](#)). [Elliott and Radin \(1995\)](#) confirmed that corticosteroids induce uterine contractions and preterm labor in humans.

Adverse fetal-newborn and long-term effects have been reported in regard to repeated versus single courses of maternal corticosteroid treatment to enhance pulmonary maturation. [Espino and colleagues \(2000\)](#) compared mental and psychomotor development of 429 low-birthweight infants exposed to two courses or more of antenatal corticosteroids with infants exposed to a single course or to no exposure. The authors found no benefits for repeated doses, and exposure to multiple courses of corticosteroids was independently and significantly associated with abnormal psychomotor development. [Vermillion and colleagues \(2000\)](#), in an analysis of 453 infants, determined that early-onset neonatal sepsis, chorioamnionitis, and neonatal death were significantly associated with multiple maternal dosing with betamethasone. [Thorp \(2000\)](#) and [Guinn \(2001\)](#) and their associates conducted large prospective trials and found no benefits of multiple steroid courses. Importantly, in a secondary analysis, [Thorp and co-workers \(2001\)](#) reported a significant reduction in head circumference in infants exposed to steroids. Likewise, [Mercer and associates \(2001\)](#) reported a dose-dependent decrease in birth weight and length in neonates exposed to antenatal steroid therapy. Some of these results were available and they played a prominent role in the conclusions reached by the reconvened Consensus Panel ([Table 27-10](#)).

USE OF CORTICOSTEROIDS AT PARKLAND HOSPITAL. As a result of the original Consensus Panel recommendations, dexamethasone, 5 mg intramuscularly every 12 hours for four doses every 7 days, was introduced at Parkland Hospital in May 1994 for selected women at risk for preterm birth between 24 and 34 weeks. Corticosteroids were not used for fetal maturation prior to this date. Outcomes of 370 singleton pregnancies ending between 24 and 34 weeks during 12 months before dexamethasone therapy was begun were compared with outcomes of 370 similar pregnancies in which dexamethasone therapy was subsequently given. We were unable to demonstrate much benefit, if any, in this before-after population based study. Publication of this experience has not been possible.

THYROTROPIN-RELEASING HORMONE FOR FETAL MATURATION. [Knight and colleagues \(1994\)](#) from New Zealand reported that administration of thyrotropin-releasing hormone (400 mg intravenously) in addition to betamethasone augmented fetal lung maturation compared with betamethasone used alone. This effect is based on experimental observations that tri-iodothyronine enhances surfactant synthesis. [Crowther and co-workers \(1995\)](#) and the Australian Collaborative Study Group randomized 1234 women to receive thyrotropin-releasing hormone in addition to corticosteroids or to corticosteroids alone and were unable to reproduce these beneficial results. Indeed, the incidence of respiratory disease was increased in the thyrotropin-treated group! In this ACTOBAT study, the investigators also observed that 7 percent of the mothers became overtly hypertensive as a result of thyrotropin therapy. They concluded that thyrotropin-releasing hormone given to augment fetal maturation "is associated with maternal and perinatal risks and cannot be recommended." [Ballard and associates \(1998\)](#) enrolled 996 women before 30

weeks' gestation in a multicenter randomized double-blind, placebo-controlled trial of maternal thyrotropin-releasing hormone treatment to decrease neonatal pulmonary morbidity. All women also received betamethasone treatment. The primary outcome was chronic lung disease or infant death before 28 days. Primary and secondary outcomes were almost identical in both groups. They concluded that antenatal administration of thyrotropin-releasing hormone was not beneficial.

ANTENATAL PHENOBARBITAL AND VITAMIN K THERAPY. As reviewed by [Thorp and colleagues \(1995\)](#), several studies have suggested that antenatal phenobarbital and vitamin K given to the mother may reduce the incidence of intracranial hemorrhage. They randomized 272 women at risk for preterm birth to placebo or treatment with phenobarbital and vitamin K and found that such therapy did not reduce the frequency or severity of neonatal intracranial hemorrhage.

CERCLAGE. Prophylactic cervical cerclage, which is typically recommended in the United States for women with a supporting history and recurrent midtrimester losses, has also been used in Europe to prevent preterm birth. Two randomized trials of cerclage included more than 700 women at risk for preterm delivery, and neither study showed a benefit ([Lazar and colleagues, 1984](#); [Rush and associates, 1984](#)). Prophylactic cerclage in twin pregnancies has also been shown to be of no benefit in a randomized trial ([Dor and associates, 1982](#)). The [Medical Research Council of the Royal College of Obstetricians and Gynaecologists \(1993\)](#) studied 1292 women from 12 countries with heterogeneous and often unclear indications for cerclage to assess if this procedure prolonged pregnancy. Approximately 75 percent of women enrolled in this randomized study had previously delivered preterm infants. In 647 women, cervical sutures were placed at about 16 weeks and their outcomes compared with 645 women randomized to no cerclage. A small—from 17 to 13 percent—but significant decrease in births before 33 weeks was observed in women undergoing cerclage. Importantly, there was no difference in neonatal death between the two groups. The use of cerclage, however, was linked to increased interventions such as tocolysis and hospital admission. The investigators concluded that cervical sutures should be offered to women with a history of three or more pregnancies ending before 37 weeks.

[Althuisius and co-workers \(2000\)](#) randomized 73 women who had had a prior preterm birth before 34 weeks' gestation either to cerclage or observation. These latter women were followed with transvaginal measurement of cervical length until 27 weeks, and cerclage was placed if the cervical length shortened to less than 25 mm. Delivery before 34 weeks and neonatal survival were similar in the two study groups. In a subgroup analysis, however, preterm birth was significantly reduced in women who received cerclage after developing ultrasound evidence of cervical shortening. [Rust and colleagues \(2000\)](#) randomized 61 women to cerclage or to expectant management based on ultrasound evidence of cervical funneling between 16 to 24 weeks' gestation. No benefits were apparent in the women randomized to cervical cerclage.

BACTERIAL VAGINOSIS. [Hillier and colleagues \(1995\)](#) detected bacterial vaginosis in 16 percent of 10,397 pregnant women without risk factors for preterm birth who were screened between 23 and 26 weeks. Bacterial vaginosis was linked to poverty and to significantly increased preterm birth at 32 weeks or less but not to premature membrane rupture. Microbes most strongly associated with bacterial vaginosis included *Gardnerella vaginalis*, *Bacteroides species*, and *Mycoplasma hominis*.

[Hauth and co-workers \(1995\)](#) studied 624 women at risk for preterm birth either because they had previously delivered preterm infants or because they weighed less than 50 kg before pregnancy. In this double-blind study, women were randomized to treatment with metronidazole, 250 mg three times a day for 7 days; erythromycin, 333 mg three times a day for 14 days; or placebo. About 40 percent of women in each arm had bacterial vaginosis at 22 to 24 weeks. Delivery before 37 weeks in women with bacterial vaginosis was significantly decreased from 40 to 25 percent when metronidazole or erythromycin was given. [Morales and co-workers \(1994\)](#) reported a similar benefit in 80 women at increased risk for preterm birth and with bacterial vaginosis and who were treated with metronidazole.

Carey and colleagues (2000), in a multicenter [NICHD¹](#) Maternal-Fetal Medicine Units Network trial, found that metronidazole treatment of asymptomatic pregnant women with bacterial vaginosis did not improve pregnancy outcomes despite that bacterial vaginosis resolved in 78 percent of women assigned to metronidazole treatment compared with 37 percent assigned to a placebo. Specifically, the incidence of preterm birth was similar in the 953 women treated with metronidazole compared with the 966 in the placebo group. Finally, treatment with metronidazole did not reduce clinical intra-amniotic or postpartum infections, neonatal sepsis, or admission to the neonatal intensive care unit.

Intravaginal topical treatment of bacterial vaginosis using clindamycin cream has not been shown to be effective to prevent preterm birth ([Joesoef and colleagues, 1995](#); [McGregor and associates, 1994](#)).

METHODS USED TO INHIBIT PRETERM LABOR

A great number of drugs and other interventions have been used to inhibit preterm labor, but unfortunately, none has been completely effective ([American College of Obstetricians and Gynecologists, 1995](#)). Potential maternal complications of tocolytic drugs are shown in [Table 27-11](#). Their importance cannot be underestimated. For example, tocolysis was the third most common cause of acute respiratory distress syndrome and death in pregnant women during a 14-year period in Jackson, Mississippi ([Perry and associates, 1996](#)). The [American College of Obstetricians and Gynecologists \(1998\)](#) has recommended that tocolysis be used in the presence of regular uterine contractions plus documented cervical change or appreciable cervical dilatation and effacement.

BED REST. The treatment regimen that has been used most often is bed rest either in the hospital or at home. [Goldenberg and colleagues \(1994\)](#) have reviewed bed rest used to treat a variety of pregnancy complications and found no conclusive evidence that bed rest was helpful in preventing preterm birth. [Kovacevich and associates \(2000\)](#) reported that enforced bed rest (except for bathroom privileges) for 3 days or more increased the risk of thromboembolic complications from 1 per 1000 women without bed rest to 16 per 1000 in those with bed rest for threatened preterm delivery.

HYDRATION AND SEDATION. [Helfgott and associates \(1994\)](#) performed the first randomized trial of hydration and sedation compared with bed rest alone in the treatment of 119 women in preterm labor. Women randomized to treatment received 500 mL of lactated Ringer solution intravenously over 30 minutes and 8 to 12 mg of intramuscular morphine sulfate. Such therapy was not found to be more beneficial than bed rest.

BETA-ADRENERGIC RECEPTOR AGONISTS. Earlier in this century, epinephrine in low doses was demonstrated to exert a depressant effect on pregnant myometrium. Its tocolytic effects, however, proved to be rather weak, quite transient, and likely to be accompanied by troublesome cardiovascular effects. Several compounds capable of reacting predominantly with β -adrenergic receptors have subsequently been investigated. Some of these now are used in obstetrics, but only ritodrine hydrochloride has been approved (1980) by the Food and Drug Administration to treat preterm labor.

The adrenergic receptors are located on the outer surface of the smooth muscle cell membrane, where specific agonists can couple with them. Adenyl cyclase in the cell membrane is activated by the receptor stimulation. Adenyl cyclase enhances the conversion of ATP to cyclic AMP, which in turn initiates a number of reactions that reduce the intracellular concentration of ionized calcium and thereby prevent activation of contractile proteins (also see [Chap. 11, p. 271](#)). [Flier and Underhill \(1996\)](#) have comprehensively reviewed adrenergic receptors.

There are two classes of β -adrenergic receptors: β_1 -receptors, dominant in the heart and intestines; and β_2 -receptors, dominant in the myometrium, blood vessels, and bronchioles. A number of compounds generally similar in structure to epinephrine have been evaluated in the search for one that ideally would provide optimal stimulation of myometrial β_2 -receptors and thus inhibit uterine contractions while simultaneously causing few adverse effects from stimulation of receptors elsewhere. Thus far, no compound has exhibited these utopian properties. In the United States, β -agonist compounds employed to arrest preterm labor include ritodrine and terbutaline.

RITODRINE. In a multicenter United States study, infants whose mothers were treated with ritodrine for presumed preterm labor had a lower mortality rate, developed respiratory distress less often, and achieved a gestational age of 36 weeks or a birthweight of 2500 g more often than did infants whose mothers were not so treated ([Merkatz and colleagues, 1980](#)). [Hesseldahl \(1979\)](#), however, in a multicenter controlled study in Denmark, did not find any of several ritodrine regimens tested to be more efficacious than treatment with bed rest, glucose infusion, and placebo tablets.

Because of contemporaneous concerns for the efficacy and safety of ritodrine, we evaluated the drug on the obstetrical service at Parkland Hospital ([Leveno and associates, 1986b](#)). Preterm labor was carefully defined to include cervical dilatation plus regular uterine contractions, and 106 women between 24 and 33 weeks were randomly allocated to receive either intravenous ritodrine or no tocolysis. Although ritodrine treatment significantly delayed delivery for 24 hours or less, it did not significantly modify ultimate perinatal outcomes. A significant delay in delivery at 48 hours was found in a randomized study involving 708 pregnancies reported by the [Canadian Preterm Labor Investigators Group \(1992\)](#). A likely explanation for the transient uterine tocolytic effects of ritodrine and ultimate failure of such therapy may be the phenomenon of β -adrenergic receptor desensitization ([Hausdorff and colleagues, 1990](#)).

The infusion of ritodrine, as well as the other β -adrenergic agonists, has resulted in frequent and at times serious side effects ([Table 27-11](#)). Maternal tachycardia, hypotension, apprehension, chest tightness or pain, electrocardiographic S-T segment depression, pulmonary edema, and death have all been observed. Maternal

metabolic effects include hyperglycemia, hyperinsulinemia (unless diabetic), hypokalemia, and lactic and ketoacidosis. Less serious but nonetheless troublesome side effects include emesis, headaches, tremulousness, fever, and hallucinations.

A single mechanism has not been identified to explain the development of pulmonary edema, but maternal infection appears to increase the risk ([Hatjis and Swain, 1988](#)). The cause of the pulmonary edema appears to be multifactorial. Beta-adrenergic agonists cause retention of sodium and water, and thus with time—usually 24 to 48 hours—may lead to volume overload ([Hankins and colleagues, 1988](#)). The drugs have also been implicated as a cause of increased capillary permeability, disturbances of cardiac rhythm, and myocardial ischemia. Simultaneous administration of glucocorticoids to try to hasten fetal maturation may also contribute, although pulmonary edema has developed in their absence.

Only parenteral ritodrine is now available in the United States since the manufacturer discontinued distribution of tablets in 1995. The efficacy of oral ritodrine had been challenged on pharmacokinetic grounds ([Schiff and colleagues, 1993](#)).

TERBUTALINE. This β -agonist is commonly used to forestall preterm labor although, like ritodrine, toxicity—especially maternal pulmonary edema and glucose intolerance—have been evident with its use ([Angel and associates, 1988](#)).

[Lam and colleagues \(1988\)](#) described long-term subcutaneous administration of low-dose terbutaline using a portable pump in nine pregnancies. It was claimed that the lower dose of terbutaline used likely prevented β -adrenergic desensitization, resulting in less "breakthrough tocolysis." The Tokos Corporation promptly marketed this approach, and between 1987 and 1993 had used these pumps in nearly 25,000 women with preterm labor ([Perry and colleagues, 1995](#)). The list price for terbutaline pump therapy in Dallas in 1996 was \$484 per day. The only other reports concerning terbutaline pumps include a sudden maternal death ([Hudgens and Conradi, 1993](#)) and a description of newborn myocardial necrosis after the mother used the pump for 12 weeks ([Fletcher and colleagues, 1991](#)).

Two prospective randomized trials have not found any benefit for terbutaline pump therapy. [Wenstrom and colleagues \(1997\)](#) randomized 42 women to therapy with a terbutaline pump, a saline pump, or to oral terbutaline. These three groups had similar gestational ages at entry and at delivery. [Guinn and associates \(1998\)](#) in a double-blind trial, randomized 52 women to terbutaline pump or to saline pump therapy. A sample size of 48 women was required to detect a 2-week intergroup difference in mean time to delivery. Terbutaline pump therapy did not significantly prolong pregnancy, prevent preterm delivery, or improve neonatal outcomes.

Oral terbutaline therapy has been reported ineffective by several groups ([How and associates, 1995](#); [Parilla and co-workers, 1993](#)). In a double-blind trial, [Lewis and colleagues \(1996\)](#) randomized 203 women with preterm labor following successful intravenous tocolysis at 24 to 34 weeks' gestation, to 5 mg oral terbutaline every 4 hours or placebo. Delivery at one week was similar in both groups as was median latency, mean gestational age at delivery, and the incidence of recurrent preterm labor. Post hoc analysis, however, of 96 women enrolled before 32 weeks' gestation suggested significant pregnancy prolongation with maintenance oral terbutaline.

OVERVIEW OF BETA-ADRENERGIC DRUGS TO INHIBIT PRETERM LABOR. Several meta-analyses of parenteral β -agonists given to prevent preterm birth have consistently confirmed that these agents delay delivery for no more than 48 hours ([Canadian Preterm Labor Group, 1992](#)). Moreover, this delay has not proven to be beneficial despite repeated attempts to revisit the data ([Lamont, 1993](#)). Finally, [Macones and colleagues \(1995\)](#) used meta-analysis to assess the available data on the efficacy of oral β -agonist therapy and found no benefits.

Thus, oral β -agonist therapy has convincingly been shown to be ineffective, and parenteral therapy can only delay delivery for a short time that has not been shown to be beneficial. [Keirse \(1995b\)](#) suggests that the brief delay in delivery afforded may be useful to facilitate maternal transport to tertiary care centers, and also delay delivery sufficiently to effect fetal maturation with glucocorticoids. Unfortunately, there are no data to support this viewpoint.

MAGNESIUM SULFATE. It has been recognized for some time that ionic magnesium in a sufficiently high concentration can alter myometrial contractility in vivo as well as in vitro. Its role is presumably that of a calcium antagonist.

[Steer and Petrie \(1977\)](#) concluded that intravenously administered magnesium sulfate, 4 g given as a loading dose followed by a continuous infusion of 2 g/hr, will usually arrest labor. [Elliott \(1983\)](#), in a retrospective study, found tocolysis with magnesium sulfate to be successful, inexpensive, and relatively nontoxic. He reported 87 percent success when the cervix was dilated 2 cm or less, but the period of inhibited labor was as short as 48 hours. [Spisso and co-workers \(1982\)](#) were also favorably impressed by the efficacy of magnesium sulfate when given intravenously in relatively large doses to women in the early latent phase of labor.

[Watt-Morse and associates \(1995\)](#) studied the inhibitory effects of magnesium concentrations up to 8.3 mEq/L in preterm sheep with oxytocin-induced contractions. They concluded that magnesium sulfate in tolerable, nontoxic doses has no direct effect on uterine contractility.

There have been only two randomized controlled studies of the tocolytic properties of magnesium sulfate in humans. [Cotton and associates \(1984\)](#) compared magnesium sulfate with ritodrine as well as with a placebo, and they identified little difference in outcomes. [Cox and associates \(1990\)](#) randomized 156 women in preterm labor with intact membranes to infusions of magnesium sulfate or normal saline. Magnesium sulfate (20 percent solution) was begun using a 4-g loading dose followed by 2 g/hr intravenously. If contractions persisted after 1 hour, the infusion was increased to 3 g/hr. Treated women had a mean plasma magnesium concentration of 5.5 mEq/L. No benefits for such therapy were found, and this method of tocolysis was abandoned at Parkland Hospital. Similar results were subsequently reported in an evaluation of nonrandomized women in preterm labor who were delivered of infants weighing less than 1000 g ([Kimberlin and associates, 1996a](#)).

[Hollander and colleagues \(1987\)](#) used an unprecedented infusion dose of magnesium sulfate that averaged 4.5 g/hr. They reported that such therapy was equivalent to ritodrine. Conversely, [Semchyshyn and associates \(1983\)](#) failed to stop labor in a woman who inadvertently was given 17.3 g of magnesium sulfate in 45 minutes! Women given high-dosage magnesium sulfate must be monitored very closely for evidence of hypermagnesemia that might prove toxic to them and their fetus-infants. The pharmacology and toxicology of parenterally administered magnesium are considered in more detail in [Chapter 24 \(p. 599\)](#).

PROSTAGLANDIN INHIBITORS. Compounds that inhibit prostaglandins have been the subject of considerable interest since it was appreciated that prostaglandins are intimately involved in myometrial contractions of normal labor ([Chap. 11, p. 274](#)). Antiprostaglandin agents may act by inhibiting the synthesis of prostaglandins or by blocking the action of prostaglandins on target organs. A group of enzymes collectively called prostaglandin synthase is responsible for the conversion of free arachidonic acid to prostaglandins. Several drugs are known to block this system, including aspirin and other salicylates, indomethacin, naproxen, and sulindac.

Unfortunately, prostaglandin synthase inhibitors may adversely affect the fetus, and this has prevented widespread use of these agents for tocolysis. Complications include closure of the ductus arteriosus, necrotizing enterocolitis, and intracranial hemorrhage ([Norton and co-workers, 1993](#)). [Parilla and colleagues \(2000\)](#) have challenged the association of indomethacin with necrotizing enterocolitis. [Van der Heijden and colleagues \(1994\)](#) linked long-term perinatal indomethacin to anemia, neonatal death, and cystic renal damage. The mother can be adversely affected by indomethacin therapy, and [Lunt and associates \(1994\)](#) reported that indomethacin tocolysis caused profound prolongation of maternal bleeding time.

Sulindac, closely related to indomethacin in structure, has been reported to have fewer side effects when used for tocolysis ([Rasanen and Jouppila, 1995](#)). Preliminary trials, however, indicate that oral sulindac therapy may not be very useful in the prevention of preterm birth ([Carlan and associates, 1995](#)). [Kramer and colleagues \(1996\)](#) measured the effects of sulindac on fetal urine production and amniotic fluid volume and compared them with terbutaline in a randomized, double-blind study. Sulindac administration decreased fetal urine flow and amniotic fluid volume. Two fetuses also developed severe ductal constriction. Thus, sulindac shares many of the fetal side effects associated with indomethacin.

[Panter and colleagues \(1996\)](#) reviewed all randomized trials that have compared indomethacin with β -agonists for tocolysis. Indomethacin was found to be more effective in delaying delivery by 48 hours, and there were fewer maternal side effects compared with ritodrine. Indomethacin was, however, associated with increased neonatal morbidity. These investigators concluded that indomethacin needs to be further evaluated before it is used routinely for tocolysis.

CALCIUM-CHANNEL-BLOCKING DRUGS. Smooth muscle activity, including myometrium, is directly related to free calcium within the cytoplasm, and a reduction in calcium concentration inhibits contraction. Calcium ions reach the cytoplasm through specific membrane portals or channels, and calcium-channel blockers act to inhibit, by a variety of different mechanisms, the entry of calcium through the cell membrane channels. Calcium-entry blockers, because of their smooth muscle arteriolar relaxation effects, are currently being used for the treatment of coronary artery disease and hypertension.

The possibility that calcium-channel-blocking drugs might have applications in the treatment of preterm labor has been the subject of research in both animals and humans since the late 1970s. [Saade and colleagues \(1994\)](#), using in vitro human myometrial strips, showed that nifedipine caused relaxation similar to ritodrine and more effectively than magnesium. The first clinical trial in which nifedipine was given for preterm labor was from Denmark by [Ulmsten and colleagues \(1980\)](#).

Nifedipine treatment postponed delivery at least 3 days in 10 women with preterm labor at 33 weeks or less. No serious maternal or fetal side effects were noted. There have been several subsequent studies of nifedipine tocolysis, and these have been reviewed comprehensively by [Childress and Katz \(1994\)](#). In all the studies, nifedipine was as successful or better than ritodrine in stopping preterm contractions without adverse fetal effects. Maternal side effects were much worse with ritodrine.

As promising as calcium-channel blockers may appear for treatment of preterm labor, some investigators caution that more research is needed to clarify their potential maternal or fetal dangers. This is because smooth muscle relaxation by nifedipine is not limited to uterine muscle, but also includes the systemic and uterine vasculature. Nifedipine-induced decreased vascular resistance can lead to maternal hypotension and thus decreased uteroplacental perfusion. [Parisi and colleagues \(1986\)](#) reported that hypercapnia, acidosis, and possibly hypoxemia developed in fetuses of hypertensive ewes given nifedipine. Similarly, [Lurette and colleagues \(1987\)](#) observed a fall in uteroplacental blood flow in pregnant rabbits. Other investigators, however, have not found these adverse fetal effects ([Childress and Katz, 1994](#)).

The efficacy of calcium-channel blockers, such as nifedipine, in suppressing preterm contractions or labor has not been adequately studied. Small trials have arrived at inconclusive results ([Kupferminc and colleagues, 1993](#); [Papatsonis and co-workers, 1997](#); [Read and associates, 1986](#); [Smith and Woodland, 1993](#)). In a review from the Cochrane Database comparing nifedipine and β -sympathomimetics, [Keirse \(1995a\)](#) concluded that nifedipine treatment reduced births less than 2500 g, but more infants were admitted to neonatal intensive care. Results such as these mandate further study of their safety and efficacy.

The combination of nifedipine and magnesium for tocolysis is potentially dangerous. [Ben-Ami and colleagues \(1994\)](#) and [Kurtzman and associates \(1993\)](#) have reported that nifedipine enhances the toxicity of magnesium to produce neuromuscular blockade that can interfere with both pulmonary and cardiac function. [Carr and colleagues \(1999\)](#) found that maintenance therapy with oral nifedipine did not significantly prolong pregnancy in women initially treated with intravenous magnesium sulfate for preterm labor.

ATOSIBAN. A nonapeptide oxytocin analog, atosiban has been shown to be a competitive oxytocin-vasopressin antagonist capable of inhibiting oxytocin-induced uterine contractions. [Goodwin and colleagues \(1995\)](#) reviewed atosiban and described its pharmacokinetics in pregnant women. Results of a multicenter, double-blind, placebo-controlled trial in 501 women assigned to intravenous atosiban or placebo were recently published ([Romero and colleagues, 2000](#)). Atosiban therapy did not significantly improve any clinically relevant infant outcome. Safety considerations were of great concern with more fetal-infant deaths in the atosiban group. Food and Drug Administration approval for the use of atosiban to arrest preterm labor has been denied due to concerns regarding efficacy and fetal-newborn safety (FDA, personal communication).

NITRIC OXIDE DONOR DRUGS. Nitric oxide is a potent endogenous smooth-muscle relaxant in the vasculature, the gut, and the uterus. Nitroglycerin is an example of a nitric oxide donor drug. [Clavin and colleagues \(1996\)](#) randomized 34 women in preterm labor to tocolysis with intravenous nitroglycerin or magnesium sulfate. There was no difference in the tocolytic efficacy of these two drugs, but 3 of 15 women given nitroglycerin had severe hypotension. [Lees and colleagues \(1999\)](#) randomized 245 women in preterm labor to transdermal glyceryl trinitrate or intravenous ritodrine. There was no overall superiority of glyceryl trinitrate in the inhibition of preterm labor.

COMBINED THERAPY. The use of multiple drugs to inhibit preterm labor suggests that no single drug is completely satisfactory. Unfortunately, there are no studies in which tocolytic combinations were compared with placebo. [Kosasa and colleagues \(1994\)](#) used long-term tocolysis with combined intravenous terbutaline and magnesium sulfate in 1000 pregnancies. The mean duration of intravenous therapy was 61 days in women with intact membranes, and one woman received this therapy for 123 days. This approach was claimed to be effective and safe because only 2 to 4 percent of the women developed pulmonary edema.

INTRAPARTUM MANAGEMENT

In general, the more immature the fetus, the greater the risks from labor and delivery.

LABOR. Whether labor is induced or spontaneous, abnormalities of fetal heart rate and uterine contractions should be sought, preferably by continuous electronic monitoring. Fetal tachycardia, especially in the presence of ruptured membranes, is suggestive of sepsis. There is some emerging evidence that intrapartum acidemia may intensify some of the neonatal complications usually attributed solely to prematurity. For example, [Low and colleagues \(1995\)](#) observed that intrapartum acidosis—umbilical artery blood pH less than 7.0—had an important role in neonatal complications. Similarly, [Kimberlin and colleagues \(1996b\)](#) found that increasing umbilical artery blood acidemia was related to more severe respiratory disease in preterm neonates, although no effects were found in short-term neurological outcomes that included intracranial hemorrhages.

Importantly, just as the markedly preterm infant is to be afforded special care in the neonatal intensive care unit, the mother and fetus should be observed very closely in the labor and delivery unit. Especially skilled physicians should monitor the labor and delivery of the markedly preterm fetus.

PREVENTION OF NEONATAL GROUP B STREPTOCOCCAL INFECTIONS. As discussed in [Chapter 56 \(p. 1471\)](#), group B streptococcal infections are common and dangerous in the preterm neonate. Since 1996 the Centers for Disease Control and Prevention, along with the American College of Obstetricians and Gynecologists, recommend either penicillin G or ampicillin intravenously every 6 hours until delivery for women in labor prior to 37 weeks and whose culture status is unknown or positive for group B streptococcus.

DELIVERY. In the absence of a relaxed vaginal outlet, an episiotomy for delivery may be advantageous once the fetal head reaches the perineum. Argument persists as to the merits of spontaneous delivery versus forceps delivery to protect the fragile preterm fetal head ([Chap. 21, p. 490](#)). It is doubtful whether use of forceps in most instances produces less trauma. Indeed, to compress and pull on the head of a grossly preterm infant might be more traumatic than natural expulsion. The use of outlet forceps of appropriate size may be of assistance when conduction analgesia is used and voluntary expulsion efforts are obtunded.

A physician and staff proficient in resuscitative techniques and fully oriented to the specific problems of the case should be present at delivery. Principles of resuscitation described in [Chapter 16](#) are applicable, including prompt tracheal intubation and ventilation. The importance of the availability of specialized personnel and facilities in the case of preterm infants is underscored by the improved survival of these infants when they are delivered in tertiary care centers ([Powell and colleagues, 1995](#)).

PREVENTION OF NEONATAL INTRACRANIAL HEMORRHAGE. Preterm infants frequently have germinal matrix bleeding that can extend to more serious intraventricular hemorrhage ([Bejar and colleagues, 1980](#)). It was hypothesized that cesarean delivery to obviate trauma from labor and vaginal delivery might prevent these complications. These initial observations have not been validated by most subsequent studies. In the largest study, [Malloy and colleagues \(1991\)](#) analyzed 1765 infants with birthweights less than 1500 g and found that cesarean delivery did not lower the risk of mortality or intracranial hemorrhage. [Anderson and colleagues \(1988\)](#), however, made an interesting observation regarding the role of cesarean delivery in the prevention of neonatal intracranial hemorrhages. These hemorrhages were related to whether or not the fetus had been subjected to the active phase of labor, defined as the interval before 5 cm cervical dilatation. As emphasized by [Anderson and colleagues \(1988\)](#), avoidance of active-phase labor is impossible in most preterm births because the route of delivery cannot be decided until labor is firmly established.

[Nelson and Grether \(1995\)](#) reported that magnesium sulfate given to women delivered preterm for either tocolysis or preeclampsia was associated with a significantly reduced incidence of cerebral palsy when surviving infants with birthweights less than 1500 g were followed to 3 years of age. It was suggested that magnesium given to the fetus via the mother perhaps played a role in regulation of the vasculature supplying the germinal matrix of the preterm fetal brain that is especially vulnerable to hemorrhage. [Murphy and colleagues \(1995\)](#), however, found that severe preeclampsia and delivery without labor were protective against cerebral palsy. They concluded that magnesium could not be the protective agent because this drug is not used for preeclampsia in England.

TABLE 27-10. Conclusions of the 2000 NIH Consensus Panel on Repetitive Courses of Corticosteroids Given for Fetal Maturation

1. The collective international data continue to support strongly the use and efficacy of a single course of antenatal corticosteroids using the dosage and interval of administration specified in the 1994 Consensus Development Conference report.
2. The current benefit and risk data are insufficient to support routine use of repeat or rescue courses of antenatal corticosteroids in clinical practice.
3. Clinical trials are in progress to assess potential benefits and risks of various regimens of repeat courses. Until data establish a favorable benefit-to-risk ratio, repeat courses of antenatal corticosteroids, including rescue therapy, should be reserved for patients enrolled in clinical trials.

28. Postterm Pregnancy

For almost three quarters of the 20th century, prolonged pregnancy was considered a nonproblem except that such pregnancies were sometimes associated with macrosomia and difficult delivery. Labor induction was recommended only when the intention was to circumvent continued fetal growth to prevent dystocia. In the 1950s, the possibility of increased perinatal mortality in pregnancies at or beyond 42 weeks was considered insufficient to warrant intervention. Induction, especially with an unfavorable cervix, was considered a greater hazard. By the 1970s, however, it was accepted that perinatal mortality increased appreciably in these pregnancies, and this led to interventions such as delivery or scrutiny of fetal health.

DEFINITIONS

The terms *postterm*, *prolonged*, *postdates*, and *postmature* are often loosely used interchangeably to signify pregnancies that have exceeded a duration considered to be the upper limit of normal. Imprecision in their use, along with varying definitions of the upper limit of normal pregnancy, make a search of the literature on postterm pregnancy bewildering.

Postmature should be used to describe the infant with recognizable clinical features indicating a pathologically prolonged pregnancy. **Postdates** probably should be abandoned, because the real issue in many postterm pregnancies is "post- *what* dates?" Therefore, **postterm** or **prolonged pregnancy** are the preferred expressions for extended pregnancies, and "postmature" is reserved for a specific clinical syndrome. Importantly, few infants from prolonged pregnancies are postmature, and indiscriminate use of this term can falsely imply a pathologically prolonged pregnancy.

The standard internationally recommended definition of prolonged pregnancy, endorsed by the [American College of Obstetricians and Gynecologists \(1997\)](#), is 42 completed weeks (294 days) or more from the first day of the last menstrual period.

It is important to emphasize the phrase "42 completed weeks." Pregnancies between 41 weeks 1 day and 41 weeks 6 days, although in the 42nd week, do not complete 42 weeks until the seventh day has elapsed. Thus, technically speaking, prolonged pregnancy could begin either on day 294 or on day 295 following the onset of the last menses. Which is it? Day 294 or 295? We cannot solve this question, and emphasize this dilemma only to ensure that litigators and others understand that some imprecision is inevitable when attempting to define prolonged pregnancy. [Amersi and Grimes \(1998\)](#) have cautioned against use of ordinal numbers such as "42nd week" because of their imprecision. For example, "42nd week" refers to 41 weeks and 1 through 6 days whereas the cardinal number "42 weeks" refers precisely 42 completed weeks.

MENSTRUAL DATES. The definition of postterm pregnancy as one that persists for 42 weeks or more from the onset of a menstrual period assumes that the last menses was followed by ovulation 2 weeks later. Although this may include perhaps 10 percent of pregnancies, some may not be actually postterm but rather the result of an error in estimation of gestational age. It is likely that there are two categories of pregnancies that reach 42 completed weeks:

1. Those truly 42 weeks past conception.
2. Those with less advanced gestations due to variations in timing of ovulation.

[Munster and associates \(1992\)](#) described a high incidence of large variations in menstrual cycles in normal women. [Boyce and associates \(1976\)](#) studied 317 French women with conceptional basal body temperature profiles and found that 70 percent who completed 42 postmenstrual weeks had less advanced gestations based on their ovulation dates. [Reuss and co-workers \(1995\)](#) found similar results when early pregnancy ultrasound dating was prospectively studied in 764 women. Postterm pregnancies decreased from 10 percent using menstrual history to 3 percent when ultrasound criteria were used. Finally, a small number of women ovulate sooner than expected, giving rise to the possibility that 40 completed postconceptional weeks could be achieved by 41 weeks of amenorrhea.

Thus, most pregnancies reliably 42 completed weeks beyond the last menses probably are not biologically prolonged, and a few not yet 42 weeks might be postterm. These variations in menstrual cycle likely explain, at least partially, why approximately 10 percent of human pregnancies reach 42 completed weeks, yet a relatively small proportion of fetuses have evidence of *postmaturity*. Because there is no method to identify pregnancies that are truly prolonged, all pregnancies judged to be 42 completed weeks should be managed as if abnormally prolonged.

INCIDENCE

Postterm pregnancy varies greatly depending on the criteria used for diagnosis, and reported frequencies range from 4 to 14 percent with an average of about 10 percent ([Bakketeig and Bergsjø, 1991](#)). As shown in [Figure 28-1](#) approximately 8 percent of 4 million infants born in the United States during 1997 were estimated to have been delivered at 42 weeks or more. In comparison, 11 percent of live births were preterm, defined as 36 weeks or less.

Contradictory results have been found concerning the significance of a variety of maternal demographic factors such as parity, prior postterm birth, socioeconomic class, and age. One interesting feature, the tendency for some mothers to repeat postterm births, suggests that some prolonged pregnancies are biologically determined. In an analysis of 27,677 births to Norwegian women, the incidence of a subsequent postterm birth increased from 10 to 27 percent if the first birth was postterm and to 39 percent if there had been two previous successive postterm deliveries ([Bakketeig and Bergsjø, 1991](#)). [Mogren and colleagues \(1999\)](#) reported that prolonged pregnancy also recurred across generations in Swedish women. When the mother had had a prolonged pregnancy in delivering her daughter, the risk for postterm pregnancy in the daughter's pregnancy was increased two- to threefold.

PERINATAL MORTALITY

The historical basis for the concept of an upper limit of human pregnancy duration was the observation that perinatal mortality increased after the expected due date was passed. This is best seen when perinatal mortality is analyzed from times before widespread use of interventions for pregnancies exceeding 42 weeks. As shown in [Figure 28-2](#), after reaching a nadir at 39 to 40 weeks, perinatal mortality increased in Sweden as pregnancy exceeded 41 weeks. The most recent data from Sweden ([Table 28-1](#)) indicate that this late-pregnancy trend has persisted for almost 50 years despite dramatic improvement in gestational age-specific mortality rates.

[Lucas and co-workers \(1965\)](#) compared perinatal outcomes in 6624 postterm pregnancies with almost 60,000 singleton pregnancies delivered between 38 and 41 weeks. The study was done before intentional delivery at 42 weeks was practiced. All components of perinatal mortality—ante-partum, intrapartum, and neonatal deaths—were increased at 42 weeks and beyond. The most significant increases occurred intrapartum. The major causes included pregnancy hypertension, prolonged labor with cephalopelvic disproportion, "unexplained anoxia," and malformations. Using data from the Collaborative Perinatal Project comprising 53,158 pregnancies delivered in the 1960s, [Naeye \(1978\)](#) also reported that malformations in postterm stillborns was common. As discussed in [Chapter 39](#) (p. 1074), most malformed fetuses are detected earlier in pregnancy, and thus the incidence of malformations is not currently increased compared with the general obstetrical population ([Clausson and co-workers, 1999](#)).

In 62,804 births at the National Maternity Hospital in Dublin between 1979 and 1986, excess perinatal mortality attributable to postterm pregnancy occurred only in the intrapartum and neonatal periods ([Crowley, 1991](#)). Intrapartum asphyxia and meconium aspiration were implicated in almost three fourths of these deaths. Moreover, early neonatal seizures, often used as an index of intrapartum events, occurred in 5.4 per 1000 postterm infants compared with 0.9 per 1000 infants born at term.

Thus, intrapartum perinatal risk is increased in prolonged pregnancies, particularly when meconium is present ([Chap. 14](#), p. 351). Meconium is found in more than a fourth of postterm pregnancies and, as shown in [Table 28-2](#), meconium aspiration syndrome is significantly increased. Labor induction, cesarean delivery, macrosomia, and shoulder dystocia are also significantly increased ([Eden and associates, 1987](#)).

The specific congenital malformations—*anencephaly* and *adrenal hypoplasia*—associated with prolonged pregnancy share a common feature of pituitary insufficiency and lack of the usually high estrogen levels that characterize normal pregnancy ([Chap. 6](#), p. 120). In these cases, the precursor hormone, dehydroisoandrosterone sulfate, is secreted in insufficient amounts for conversion to estradiol and indirectly to estriol in the placenta ([MacDonald and Siiteri, 1965](#)).

PATHOPHYSIOLOGY

[Clifford \(1954\)](#) described a recognizable clinical syndrome in some infants delivered after term that did much to dispel the prevailing obstetrical opinion that prolonged human pregnancy did not exist ([Calkins, 1948](#)). Infants, either live or stillborn, and demonstrating these clinical characteristics, are now diagnosed to be pathologically *postmature*. Actually, the postmature infant Clifford described had been reported more than 50 years earlier by [Ballantyne \(1902\)](#).

POSTMATURITY SYNDROME

[Clifford's 1954](#) description of the postmature infant was based on 37 births that typically occurred 300 or more days after the last menstruation. He divided postmaturity into three stages: in stage 1 the amniotic fluid was clear, in stage 2 the skin was stained green, and in stage 3 the skin discoloration was yellow-green.

The postmature infant presents a unique and characteristic appearance ([Fig. 28-3](#)). This includes wrinkled, patchy peeling skin, a long, thin body suggesting wasting, and advanced maturity because the infant is open-eyed, unusually alert, old, and worried-looking. Skin wrinkling can be particularly prominent on the palms and soles. The nails are typically quite long. Most such postmature infants are not growth restricted, because their birthweight seldom falls below the 10th percentile for gestational age. Severe growth restriction, however, which logically must have preceded completion of 42 weeks, can occur. Many of Clifford's postmature infants died, and many were seriously ill due to birth asphyxia and meconium aspiration. Several survivors were brain damaged.

The incidence of postmaturity syndrome in infants at 41, 42, or 43 weeks, respectively, has not been conclusively determined. [Shime and colleagues \(1984\)](#), in one of the rare contemporary reports to chronicle postmaturity, found that this syndrome occurred in about 10 percent of pregnancies between 41 and 43 weeks and increased to 33 percent at 44 weeks. Associated oligohydramnios substantially increases the likelihood of postmaturity. [Trimmer and colleagues \(1990\)](#) diagnosed oligohydramnios when the ultrasonic maximum vertical amniotic fluid pocket measured 1 cm or less at 42 weeks and 88 percent of the infants were postmature.

PLACENTAL DYSFUNCTION

[Clifford \(1954\)](#) proposed that the skin changes of postmaturity were due to loss of the protective effects of vernix caseosa. His second hypothesis that continues to influence contemporary concepts attributes postmaturity syndrome to placental senescence. Clifford could not, however, demonstrate placental degeneration histologically. Indeed, in the ensuing 40 years, no morphological or significant quantitative changes have been found ([Larsen and co-workers, 1995](#); [Rushton, 1991](#)). Of interest, [Smith and Barker \(1999\)](#) recently reported that placental apoptosis—programmed cell death—was significantly increased at 41 to 42 completed weeks compared with 36 to 39 weeks. The clinical significance of such apoptosis is unclear at this time.

[Jazayeri and co-workers \(1998\)](#) investigated umbilical cord plasma erythropoietin levels in 124 appropriately grown newborns delivered from 37 to 43 weeks. They sought to assess whether fetal oxygenation may be compromised, presumably due to placental aging, in pregnancies proceeding beyond their due date. Decreased partial oxygen pressure is the only known stimulator of erythropoietin. Each woman studied had an uncomplicated labor and delivery course without evidence of fetal stress or meconium passage. Cord plasma erythropoietin levels were significantly increased in pregnancies reaching 41 weeks or more ([Fig. 28-4](#)), and although Apgar scores and umbilical cord blood gases were not abnormal in these infants, the authors concluded that there was decreased fetal oxygenation in some postterm gestations.

The postterm fetus may continue to gain weight and thus be an unusually large infant at birth. That the fetus continues to grow serves to suggest that placental function is not compromised. Indeed, continued fetal growth, although at a slower rate, is characteristic between 38 and 42 weeks ([Fig. 28-5](#)). [Nahum and colleagues \(1995\)](#) more recently confirmed that fetal growth continues at least up until 42 weeks.

FETAL DISTRESS AND OLIGOHYDRAMNIOS

The principal reasons for increased risks to postterm fetuses were described by [Leveno and associates \(1984\)](#). They reported that both antepartum fetal jeopardy and intrapartum fetal distress were the consequence of cord compression associated with oligohydramnios. In their analysis of 727 postterm pregnancies, intrapartum fetal distress detected with electronic monitoring was not associated with late decelerations characteristic of uteroplacental insufficiency. Instead, one or more prolonged decelerations ([Fig. 28-6](#)) preceded three fourths of emergency cesarean deliveries for fetal jeopardy. In all but two cases, there were also variable decelerations ([Fig. 28-7](#)). Another common fetal heart rate pattern, although not ominous by itself, was the saltatory baseline shown in [Figure 28-8](#). These findings are consistent with cord occlusion as the proximate cause of fetal distress. Other correlates found were oligohydramnios and viscous meconium. These observations on the pathophysiology of postterm pregnancy were confirmed by [Phelan and co-workers \(1985\)](#) and [Bochner and associates \(1987\)](#). [Silver and colleagues \(1987\)](#) also reported that decreased umbilical cord diameter, measured ultrasonically, was predictive of intrapartum fetal distress, especially if associated with oligohydramnios.

Decreased amniotic fluid volume commonly develops as pregnancy advances beyond 42 weeks ([Fig. 28-9](#)). It is also likely that fetal release of meconium ([Chap. 14](#), p. 351) into an already reduced amniotic fluid volume is the reason for the thick, viscous meconium implicated in meconium aspiration syndrome.

[Trimmer and co-workers \(1990\)](#) measured hourly fetal urine production using sequential ultrasonic bladder volume measurements in 38 pregnancies of 42 weeks or more. Diminished urine production was found to be associated with oligohydramnios. It was hypothesized, however, that decreased fetal urine flow was likely the result of preexisting oligohydramnios that limited fetal swallowing of amniotic fluid. [Veille and co-workers \(1993\)](#), using pulsed Doppler waveforms, reported that fetal renal blood flow is reduced in postterm pregnancies with oligohydramnios.

FETAL GROWTH RESTRICTION

Until quite recently, the clinical significance of fetal growth restriction in the otherwise uncomplicated pregnancy has received little attention. [Divon and co-authors \(1998\)](#) and [Clausson and co-workers \(1999\)](#) have analyzed births of almost 700,000 women between 1987 and 1995 using the National Swedish Medical Birth registry. As shown in [Table 28-3](#), fetal growth restriction was implicated in stillbirths at 42 weeks or beyond as well as for term infants. Indeed, a third of the postterm stillbirths were growth restricted. At the time of these births in Sweden, induction of labor and antenatal fetal testing was usually commenced at 42 weeks. [Alexander and colleagues \(2000b\)](#) compared infant outcomes for 355 postterm infants (=42 weeks) with birthweights less than or equal to the third percentile for gestational age with the remaining 14,520 infants in higher percentiles delivered at Parkland Hospital. Morbidity and mortality were significantly increased in the growth-restricted infants. Indeed, a fourth of all stillbirths associated with prolonged pregnancy were in this comparatively small number of growth-restricted infants.

MANAGEMENT

It is generally accepted that antepartum interventions are indicated in management of prolonged pregnancies. The type(s) of interventions and when to employ them are somewhat controversial. One major issue is whether to intervene at 41 or 42 weeks. Another is whether labor induction is warranted compared with expectant management using antepartum fetal testing. [Roussis and colleagues \(1993\)](#) surveyed members of the Society for Maternal-Fetal Medicine in 1990 and found that approximately two thirds induced labor at 41 weeks if the cervix was favorable. Antepartum fetal testing was advocated at 41 weeks when the cervix was unfavorable. At 42 weeks, virtually all respondents induced labor when the cervix was favorable, and 58 percent would do this even when the cervix was unfavorable. Others (42 percent) recommended antepartum testing when the cervix was unfavorable at 42 weeks. Clearly, the inducibility of the cervix has considerable impact on management.

UNFAVORABLE CERVIX

It is difficult to precisely define the "unfavorable cervix" in prolonged pregnancies because investigators have used different criteria. For example, [Harris and colleagues \(1983\)](#) reported that 92 percent of women at 42 weeks had an unfavorable cervix defined by Bishop scores less than 7. [Hannah and colleagues \(1992\)](#), however, found that 40 percent of 3407 women with 41-week pregnancies had undilated cervixes. Importantly, women with dilatation of 3 cm or more were excluded from their study. Cervical dilatation is an important prognostic indicator for induction success. [Alexander and associates \(2000c\)](#) evaluated 800 women induced for postterm pregnancy at Parkland Hospital. They reported that women with no cervical dilatation had a twofold increased cesarean delivery rate for dystocia.

In the past 10 years, a number of investigations to evaluate management for prolonged pregnancies have included use of prostaglandin E₂ for cervical ripening. The Maternal-Fetal Medicine Units Network of the [National Institute of Child Health and Human Development \(1994\)](#) evaluated prostaglandin E₂ gel and found that it was not more effective than placebo. [Sawai and colleagues \(1994\)](#) used 2-mg prostaglandin E₂ vaginal suppositories daily for an average of 4 days in 42 women with a 41-week gestation and an unfavorable cervix (Bishop score less than 9). Although such treatment improved the Bishop score in an average of 4 days, it had no significant effect on any subsequent intrapartum outcomes. [Alexander and associates \(2000d\)](#) studied 393 women with postterm pregnancy who were given prostaglandin E₂ for cervical ripening. These women were treated even if the cervix was "favorable." They reported that almost half of the 84 women with cervical dilatation of 2 to 4 cm entered labor with prostaglandin E₂ alone. The [American College of Obstetricians and Gynecologists \(1997\)](#) has concluded that prostaglandin

gel can be used safely in postterm pregnancies. Use of prostaglandin for cervical ripening is discussed in [Chapter 20](#) (p. 471).

[Fassett and colleagues \(2000\)](#) presented preliminary data to indicate that mifepristone (RU486) did not stimulate sufficient uterine activity to effect cervical favorability in 97 women with postterm pregnancy.

Sweeping, or stripping of the membranes to induce labor and prevent postterm pregnancy has been studied in 15 randomized trials during the 1990s ([Chap. 20](#), p. 474). [Boulvain and co-authors \(1999\)](#) performed a meta-analysis of these and found that membrane stripping at 38 to 40 weeks decreased the frequency of postterm pregnancy. Membrane stripping, however, did not modify the risk of cesarean delivery nor were maternal or neonatal infections increased. The authors emphasized that membrane stripping could be painful and might provoke vaginal bleeding and irregular contractions.

INDUCTION VERSUS FETAL TESTING

A logical plan for reducing perinatal mortality and morbidity associated with prolonged pregnancy is to terminate pregnancy before such events occur. There have been doubts about the value of labor induction, mainly because it was feared that this would result in more operative intervention without preventing perinatal death. As a result, many clinicians prefer to employ fetal testing to avoid inductions. Major studies designed to resolve these questions have been done in both Canada and the United States.

[Hannah and colleagues \(1992\)](#) randomized 3407 Canadian women with pregnancies at 41 or more weeks to labor induction or fetal testing. Women assigned to fetal testing were asked to count the number of times they felt the fetus move over a 2-hour period each day, and they also underwent nonstress testing three times weekly. Amniotic fluid volume was assessed two to three times each week, and pockets less than 3 cm were considered abnormal. Labor induction resulted in a significantly lower cesarean rate (21 percent) compared with pregnancies managed with antepartum testing (24 percent). There were two stillbirths in the fetal testing group and none in the induction group. The lower cesarean rate in the induction group was due to fewer procedures for fetal distress. A cost-effectiveness analysis of the Canadian data was later reported by [Goeree and colleagues \(1995\)](#). The mean cost per patient managed with fetal testing was \$3132 compared with \$2939 in those who underwent labor induction. Thus, managing postterm pregnancy with labor induction resulted in more favorable outcomes than fetal testing and at a lower cost. A similar analysis, however, of the Maternal-Fetal Medicine Network study, showed no cost advantages for either scheme ([Gardner and associates, 1996](#)).

In the Maternal-Fetal Medicine Network randomized trial of induction versus fetal testing, nonstress tests and ultrasonic estimations of amniotic fluid volume were done twice weekly in 175 women whose pregnancies had reached 41 weeks or more. Their outcomes were compared with 265 women randomized to oxytocin induction with or without cervical ripening with prostaglandin E₂ gel. Oligohydramnios was diagnosed in the fetal testing group when the largest pocket of amniotic fluid was less than 2 cm. There were no perinatal deaths in any study subgroup, and the rate of cesarean delivery was not significantly different when labor induction was compared with expectant management. Thus, this study supported the validity of either management scheme.

[Crowley \(1997\)](#) used the Oxford Database of Perinatal Trials to perform a meta-analysis of 18 studies that assessed management of postterm pregnancy. Routine induction after 41 weeks resulted in reduced perinatal mortality without increased risk of cesarean or instrumental delivery. [Roberts and colleagues \(1999\)](#), in a study of 540,116 births, concluded that this meta-analysis prompted routine induction after 41 weeks to be widely adopted in New South Wales, Australia. Specifically, from 1990 to 1996 there was a significant decrease in births at 42 completed weeks or more—4.6 compared with 2.8 percent, respectively. This also was associated with an increased induction rate at 41 weeks. Importantly, the cesarean delivery rate also increased. Because infant outcomes were not described in this report, any beneficial neonatal effects are undetermined.

Because macrosomia is more prevalent, [O'Reilly-Green \(1996\)](#) tested the predictive value of sonographic estimates of fetal weight greater than 4500 g in 202 consecutive postterm pregnancies. They concluded that using 4500-g fetal weight estimates as an indication for cesarean delivery would be imprudent because two thirds of these were incorrect. Importantly, almost a fourth of these infants weighed more than 4000 g, thus attesting to the association of large infants with prolonged pregnancies.

INTERVENTION AT 41 VERSUS 42 WEEKS

Evidence to substantiate intervention—whether induction or fetal testing—commencing at 41 versus 42 weeks is limited. Most evidence used to justify intervention at 41 weeks is from the randomized Canadian and American investigations cited earlier. No randomized studies have specifically assessed intervention at 41 weeks versus an identical intervention employed at 42 weeks. Importantly, a national policy of intervention for prolonged pregnancy at 41 versus 42 weeks would mean that approximately 500,000 additional women would be subjected to interventions that are not conclusively proven necessary nor harmless.

Three randomized studies published between 1978 and 1986 compared induction at 40 weeks versus 42 weeks. The only benefit was reported by [Martin and associates \(1978\)](#), and this was limited to less frequent meconium-stained amniotic fluid. [Tylleskar and colleagues \(1979\)](#) found no benefits. In the study by [Husslein and co-workers \(1986\)](#), fetal testing was used between 40 and 42 weeks, but still no benefits were found. In subsequent observational studies, [Bochner and colleagues \(1988\)](#) and [Guidetti and associates \(1989\)](#) have advocated antepartum fetal testing beginning at 41 weeks. In none of these reports is there convincing evidence that starting fetal testing at 41 weeks significantly changed any outcome. Indeed, the reverse interpretation, that beginning fetal testing at 41 weeks offered no benefit, could have been easily made.

As previously seen in [Figure 28-2](#), perinatal mortality does not appreciably increase at 41 weeks, but does so at 42 weeks. [Usher and colleagues \(1988\)](#) analyzed several outcomes in 7663 pregnancies with gestational ages determined to be 40, 41, or 42 weeks confirmed by early ultrasound examinations. Perinatal death rates, corrected for malformations, were 1.5, 0.7, and 3.0 per 1000 for 40, 41, and 42 weeks, respectively. These results could be used to challenge the concept of routine intervention at 41 instead of 42 weeks. Interestingly, [Divon and colleagues \(1996\)](#) found that, although adverse fetal outcomes increased at 41 compared with 40 weeks, these were associated with growth restriction. They suggested that management strategies should be focused on fetal growth rather than simply gestational age in pregnancies reaching 41 weeks.

Based on results summarized in [Table 28-4](#), 41-week pregnancies without other complications such as hypertension are considered normal pregnancies at Parkland Hospital. No interventions are practiced solely on the basis of fetal age until 42 completed weeks. It is our view that large, randomized studies should be performed before 41-week gestations are routinely considered pathologically prolonged.

OLIGOHYDRAMNIOS

Several authors have suggested that the identification of diminished amniotic fluid determined by various ultrasonic methods may be helpful to identify a postterm fetus in jeopardy. There is no doubt that when amniotic fluid is decreased in a postterm pregnancy—or for that matter in any pregnancy—the fetus is at increased risk. Many different criteria for ultrasonic diagnosis of oligohydramnios have been proposed. [Fischer and colleagues \(1993\)](#) attempted to determine which criteria were most predictive of normal versus abnormal outcomes in postterm pregnancies. As shown in [Figure 28-10](#), the smaller the amniotic fluid pocket, the greater the likelihood that there was clinically significant oligohydramnios. Normal amniotic fluid volume, however, did not preclude abnormal outcomes. [Alfirevic and co-authors \(1997\)](#) randomized 500 women with postterm pregnancies—defined as 290 days or longer gestation—to assessment of amniotic fluid volume using either the amniotic fluid index or deepest vertical pocket. They concluded that the amniotic fluid index overestimated the number of abnormal outcomes in postterm pregnancies.

Regardless of criteria used to diagnose oligohydramnios in postterm pregnancies, most investigators have found an increased incidence of "fetal distress" during labor. Thus, oligohydramnios by most definitions is a clinically meaningful finding. Conversely, reassurance of continued fetal well-being in the presence of "normal" amniotic fluid volume is tenuous because it is unknown how quickly pathological oligohydramnios develops. [Clement and co-workers \(1987\)](#) reported six postterm pregnancies in which amniotic fluid volume diminished abruptly over 24 hours and one fetus died. [Wing and colleagues \(1996\)](#) recommended that amniotic fluid volume be assessed twice weekly in all pregnancies beginning at 41 weeks.

AMERICAN COLLEGE OF OBSTETRICIANS AND GYNECOLOGISTS RECOMMENDATIONS FOR 1997 AND 1999

Management recommendations for pregnancies at 42 weeks or more are summarized in [Table 28-5](#). The recommendations, although providing flexibility in the evaluation and management of pregnancies completing 42 weeks, indicate that either antenatal testing or labor induction should be commenced at 42 weeks. There was insufficient evidence to recommend a management strategy between 40 and 42 completed weeks.

Postterm pregnancy has been identified by the [American College of Obstetricians and Gynecologists \(1999\)](#) as a high-risk condition where twice weekly antepartum

fetal testing may be indicated. Doppler velocimetry was not recommended. Oligohydramnios detected using ultrasound, defined as no vertical pocket of amniotic fluid greater than 2 cm or an amniotic fluid index (AFI) 5 cm or less, is considered an indication for either delivery or close fetal surveillance.

MANAGEMENT OF POSTTERM PREGNANCY AT PARKLAND HOSPITAL

In women with a *certain* gestational age, labor is induced at the completion of 42 weeks ([Fig. 28-11](#)). Almost 90 percent of such women are induced successfully, or enter labor within 2 days of induction. For those who do not deliver with the first induction, a second induction is performed within 3 days. Almost all women will be delivered by this plan of management, but in the unusual few who are not delivered, management decisions are a third (or more) induction versus cesarean delivery.

Women classified as having *uncertain* postterm pregnancies are followed on a weekly basis and without intervention unless fetal jeopardy is suspected. The latter is based upon clinical or sonographic perception of decreased amniotic fluid volume. Equally worrisome is diminished fetal movement reported by the mother. If fetal jeopardy is suspected by either method, labor induction is carried out as described previously for the woman with certain postterm gestation. Other details of management are summarized in [Figure 28-11](#). This protocol has been used successfully for almost 20 years with very few adverse fetal or neonatal outcomes.

MEDICAL OR OBSTETRICAL COMPLICATIONS

In the event of a medical or another obstetrical complication, it is generally unwise to allow a pregnancy to continue past 42 weeks. Indeed, in many such instances *early* delivery is indicated. Timing of delivery will depend on the individual complication. Common examples include pregnancy-induced hypertension, prior cesarean delivery, and diabetes.

INTRAPARTUM MANAGEMENT

Labor is a particularly dangerous time for the postterm fetus. Therefore, it is important that women whose pregnancies are known or suspected to be postterm come to the hospital as soon as they suspect they are in labor. Upon arrival, while being observed for possible labor, we recommend that fetal heart rate and uterine contractions be monitored electronically for variations consistent with fetal distress ([American College of Obstetricians and Gynecologists, 1995](#)).

When to perform amniotomy is problematic. Further reduction in fluid volume following amniotomy can certainly enhance the possibility of cord compression. Conversely, amniotomy will aid diagnosis of thick meconium, which may be dangerous to the fetus if aspirated. Moreover, once the membranes are ruptured, a scalp electrode and intrauterine pressure catheter can be placed, which usually provide more precise data concerning fetal heart rate and uterine contractions.

Identification of *thick meconium* in the amniotic fluid is particularly worrisome. The viscosity probably signifies the lack of liquid and thus oligohydramnios. Aspiration of thick meconium may cause severe pulmonary dysfunction and neonatal death ([Chap. 39](#), p. 1044). This may be minimized but not eliminated by effective suctioning of the pharynx as soon as the head is delivered but before the thorax is delivered. If meconium is identified, the trachea should be aspirated as soon as possible after delivery. Immediately thereafter, the infant should be ventilated as needed. The likelihood of successful vaginal delivery is reduced appreciably for the nulliparous woman who is in early labor with thick, meconium-stained amniotic fluid. Therefore, when the woman is remote from delivery, strong consideration should be given to prompt cesarean section, especially when cephalopelvic disproportion is suspected or either hypotonic or hypertonic dysfunctional labor is evident. Some practitioners choose to avoid oxytocin use in these cases.

At times, the continued growth of the fetus postterm will result in a *large-for-gestational-age* infant, and shoulder dystocia may develop. Therefore, an obstetrician experienced in managing this complication should be available to effect delivery ([Chap. 19](#), p. 459).

TABLE 28-5. Recommendations by the American College of Obstetricians and Gynecologists (1997) for Evaluation and Management of Prolonged Pregnancies

1. Antenatal surveillance of postterm pregnancies should be initiated by 42 weeks despite a lack of evidence that monitoring improves outcomes.
2. There is insufficient evidence that initiating antenatal surveillance between 40 and 42 completed weeks improves outcomes.
3. No single antenatal surveillance protocol for monitoring fetal well-being in a postterm pregnancy appears superior to another.
4. It is unknown whether induction or expectant management (antenatal surveillance) is preferable in the postterm patient with a *favorable cervix*.
5. There is good evidence that either induction or expectant management will result in good outcomes in postterm patients with *unfavorable cervixes*.
6. Prostaglandin gel can be used safely in postterm pregnancies to promote cervical changes and induce labor.

29. Fetal Growth Disorders

Each year, about a fifth of the almost 4 million infants in the United States are born at the low and high extremes of fetal growth ([Fig. 29-1](#)). Low birthweight, defined as less than 2500 g, constitutes just less than half of these 700,000 births and includes preterm infants as well as those whose growth has been impaired in utero. Although the majority of these infants are preterm, the National Institutes of Health estimated that approximately 40,000 are at term, having suffered abnormal intrauterine growth ([Frigoletto, 1986](#)). Macrosomia, defined as birthweight of 4000 g or greater, occurred in 1 out of every 10 births in the United States in 1997. The incidence of macrosomic infants, however, has been declining since 1991 after peaking at about 11 percent in the 1980s ([Ventura and co-authors, 1999](#)).

NORMAL FETAL GROWTH

Human fetal growth is characterized by sequential patterns of tissue and organ growth, differentiation, and maturation that are determined by maternal provision of substrate, placental transfer of these substrates, and fetal growth potential governed by the genome. [Steer \(1998\)](#) has summarized the potential effects of evolutionary pressures on human fetal growth:

Over the last 3.5 million years the human species has become adapted to the upright posture, and the pelvis has maneuvered to facilitate walking. During the last 500,000 years human brain volume has increased from about 750 mL (*Homo erectus*) to about 1000 to 1800 mL (*Homo sapiens*); this compares with only 300–400 mL in chimpanzees. Because the head has to pass through the pelvis during parturition, there has developed an increasing conflict between the need to walk (requiring a narrow pelvis) and the need to think (requiring a large brain and therefore a large head), which leads to difficulty in labor (dystocia). This has to some extent been resolved by an evolutionary modification, known as neoteny, whereby humans are born increasingly early. If humans were born with the same level of functional maturity as the chimpanzee, human gestation would last 17 months. Another way the human fetus may be resolving this dilemma is by acquiring the ability to restrict its growth late in pregnancy. This characteristic "tail off" of fetal growth rates from 38 weeks onward as seen in human pregnancies is not evident in other mammals. Thus, the ability to "growth restrict" may be an adaptation which in the majority of cases is not patho-logical....

Fetal growth has been divided into three consecutive cell growth phases ([Lin and Santolaya-Forgas, 1998](#)). The initial phase of hyperplasia occurs during the first 16 weeks and is characterized by a rapid increase in cell number. The second phase, which extends up to 32 weeks, includes both cellular hyperplasia and hypertrophy. After 32 weeks, fetal growth occurs via cellular hypertrophy and it is during this phase that most fetal fat and glycogen deposition takes place. The corresponding fetal growth rates during these three cell growth phases are from 5 g/day at 15 weeks, 15 to 20 g/day at 24 weeks, and 30 to 35 g/day at 34 weeks ([Williams and co-authors, 1982](#)). [Owen and colleagues \(1996\)](#) measured the rate of human fetal growth using ultrasound in 274 normal pregnancies, and as shown in [Figure 29-2](#), there was considerable biological variation in the velocity of fetal growth in the last half of gestation.

Although many factors have been implicated in the process of fetal growth, the precise cellular and molecular mechanisms by which normal fetal growth occurs are not well understood. In early fetal life the major determinant of growth is the fetal genome, but later in pregnancy environmental, nutritional, and hormonal influences become increasingly important ([Holmes and colleagues, 1998](#)).

There is considerable evidence that insulin and insulin-like growth factors-I (IGF-I) and -II (IGF-II) have a role in the regulation of fetal growth and weight gain ([Verhaeghe and colleagues, 1993](#)). Insulin is secreted by fetal pancreatic β -cells primarily during the second half of gestation and is believed to stimulate somatic growth and adiposity. The insulin-like growth factors, structurally proinsulin-like polypeptides, are produced by virtually all fetal organs from early development onward and are potent stimulators of cell division and differentiation. [Verhaeghe and colleagues \(1993\)](#) have found that IGF-I¹ and IGF-II² and fetal insulin in the umbilical circulation are all related to fetal growth and weight gain, but that IGF-I correlates best with birthweight. Insulin is mainly related to fetal overgrowth (macrosomia), whereas IGF-binding protein may be a growth inhibitor. [Holmes and colleagues \(1998\)](#) found maternal levels of IGF-I to be low in women with growth-restricted fetuses and attributed this to compromised placental transfer.

Since the discovery of the "obesity gene" and its protein product, leptin, which is synthesized in adipose tissue, there has been interest in leptin levels in maternal and umbilical circulations. Fetal levels increase during the first two trimesters, and they correlate with birthweight ([Sivan and colleagues, 1998](#); [Tamura and colleagues, 1998](#)).

Fetal growth is also dependent on an adequate supply of nutrients. Indeed, [Williams \(1903\)](#) in the first edition of this text aptly commented, "the increase in size of the foetus affords conclusive evidence that materials in solution must, pass from the maternal to the foetal circulation...." Glucose transfer has been extensively studied during pregnancy as a result of interest in diabetes mellitus ([Chap. 51](#)). Both excessive and diminished maternal glucose availability to the fetus have been shown to affect fetal growth. In this scheme, excessive glycemia produces macrosomia whereas diminished glucose levels have been associated with fetal growth restriction. Indeed, the macrosomic infant of the mildly diabetic mother is the prototypical example of the effects of excessive maternal glucose supply. Characteristics of these infants include fetal hyperinsulinism and elevated umbilical cord levels of IGF-I¹ and IGF-II³ ([Roth and colleagues, 1996](#)).

There is relatively less information concerning the physiology of maternal-fetal transfer of other nutrients such as amino acids and lipids. [Ronconi and colleagues \(1999\)](#) studied maternal-fetal concentrations of amino acids in 26 normal pregnancies at the time of cesarean delivery. An increase in maternal amino acid levels lead to an increase in levels of most amino acids in the fetus. In growth-restricted fetuses, amino acid disturbance similar to the biochemical changes seen in postnatal protein-starvation states have been detected ([Economides and colleagues, 1989a](#)).

Although specific changes in lipid metabolism are associated with pregnancy—plasma triglycerides, low-density lipoprotein cholesterol, and total cholesterol all normally increase throughout gestation—studies of their fetal effects are limited. [Jones and colleagues \(1999\)](#) studied 38 growth-restricted infants and found impaired utilization of circulating triglycerides consistent with peripheral adipose depletion.

FETAL GROWTH RESTRICTION

In the past, low-birthweight infants who were small-for-gestational age were designated as suffering from *intrauterine growth retardation*. To avoid undue alarm in parents, to whom the term "retardation" implies abnormal mental function, the term *fetal growth restriction* is now preferred. It is estimated that from 3 to 10 percent of infants are growth restricted ([Divon and Hsu, 1992](#)).

It was not until about 30 years ago that physicians first recognized that *runting*—fetal growth restriction—was a human as well as an animal phenomenon. In 1961, [Warkany and co-workers](#) reported normal values for infant weights, lengths, and head circumferences which served to define fetal growth restriction. [Gruenwald \(1963\)](#) reported that approximately a third of low-birthweight infants were mature and that their small size could be explained by *chronic placental insufficiency*. These as well as observations by many others generated the concept that birthweight was governed not only by gestational length but also by fetal growth rate. It has been suggested that fetal size is largely determined in the first trimester or second half of pregnancy ([Dickey and Gasser, 1993](#); [Gluckman and Liggins, 1984](#)). [Smith and colleagues \(1998\)](#) examined the relation between the outcome of 4229 pregnancies and the difference between the measured and expected ultrasound crown-rump length in the first trimester. Suboptimal first-trimester growth was associated with fetal growth restriction as well as preterm delivery between 24 and 32 weeks. It may be that suboptimal environment in the first weeks of gestation limits fetal growth for the remainder of pregnancy and that such an environment may precipitate extremely preterm delivery.

DEFINITION

In 1963 [Lubchenco and co-workers](#) from Denver published detailed comparisons of gestational ages to birthweights in an effort to derive norms for expected fetal size, and therefore growth, at a given gestational week. [Battaglia and Lubchenco \(1967\)](#) then classified *small-for-gestational-age* (SGA) infants as those whose weights were below the 10th percentile for their gestational age. Such infants were shown to be at increased risk for neonatal death. For example, the neonatal mortality rate of a small-for-gestational-age infant born at 38 weeks was 1 percent compared with 0.2 percent in those with appropriate birthweights. [Seeds and Peng \(1998\)](#) concluded that the threshold for impaired growth, based upon the risk of fetal death, should be set even higher, at the 15th birthweight percentile.

Not all infants with birthweights less than the 10th percentile are pathologically growth restricted; some are small simply because of constitutional factors. Indeed, [Manning and Hohler \(1991\)](#) and [Gardosi and colleagues \(1992\)](#) concluded that 25 to 60 percent of infants conventionally diagnosed to be small-for-gestational age were in fact appropriately grown when determinants of birthweight such as maternal ethnic group, parity, weight, and height were considered.

A definition based upon birthweight below the fifth percentile has also been proposed ([Seeds, 1984](#)). In addition, [Usher and McLean \(1969\)](#) proposed that fetal growth

standards should be based on mean values with normal limits defined by ± 2 standard deviations because this definition would limit small-for-gestational-age infants to 3 percent of births instead of 10 percent with use of the 10th percentile. From a clinical standpoint, the definition proposed by [Usher and McLean \(1969\)](#) appears to be most meaningful. This is because, as shown in [Figure 29-3](#), most poor outcomes are in those infants with birthweights below the third percentile. In a study of 122,754 pregnancies delivered at Parkland Hospital, [McIntire and colleagues \(1999\)](#) found that mortality and morbidity were significantly increased among infants born at term only when their birthweights were at or below the third percentile for their gestational age.

NORMAL INFANT BIRTHWEIGHT. Normative data for fetal growth based upon birthweight have evolved considerably in the aftermath of the pioneering work done in Denver by [Lubchenko and co-workers \(1963\)](#). Their data were derived exclusively from births to white and Hispanic women who resided at high altitudes, and such infants are smaller than those born at sea level. For example, term infants average 3400 g at sea level, 3200 g at 5000 feet, and 2900 g at 10,000 feet altitude. Several fetal growth curves have been developed from various populations and geographic locations throughout the United States in the more than 30 years since Lubchenko and colleagues first described gestational age-specific birthweights. [Brenner and colleagues \(1976\)](#) used white and black infants delivered in Cleveland and aborted fetuses from North Carolina. [Williams \(1975\)](#) used live births in California to examine fetal growth curves in four ethnic groups. [Ott \(1993\)](#) used postnatal assessments of infants born in St. Louis. [Overpeck and colleagues \(1999\)](#) described birthweight standards specific to Mexican-American women. Because each of these curves was based on specific ethnic or regional groups, they were not considered to be necessarily representative of the entire population. For these reasons, fetal growth data have been derived on a nationwide basis in both the United States and Canada ([Alexander and colleagues, 1996](#); [Arbuckle and colleagues, 1993](#)).

Single live births to over 3.1 million mothers in the United States during 1991 were used to derive the growth curve shown in [Figure 29-4](#). Also shown in [Figure 29-4](#) is a comparison of the U.S. curve to those previously reported from different regions. In general, the previously published fetal growth curves underestimated the 1991 U.S. curve when used as a reference. This underestimation was most apparent between 33 and 38 weeks. [Table 29-1](#) shows the percentiles of birthweight for each week of gestation between 20 and 44 weeks.

BIRTHWEIGHT VERSUS GROWTH. Most of what is known about normal and abnormal human fetal growth is actually based on birthweight standards, which is the endpoint of fetal growth. These standards do not reveal the *rate* of fetal growth. Indeed, such birthweight curves only reveal compromised growth at the extreme of impaired growth. Importantly, these curves cannot currently be used to identify the fetus who fails to achieve an expected or potential size, but whose birthweight exceeds the 10th percentile. Thus, birthweight percentile is an incomplete measure of growth failure. Infants of apparently appropriate birthweight, but who "cross centiles," may be exhibiting signs of malnutrition because they have not achieved their full genetic potential ([Owen and colleagues, 1996](#)). Interest in the rate or velocity of human fetal growth is very recent and depends on serial ultrasonic fetal anthropometry. Early reports suggest that a diminished growth velocity is related to cesarean delivery for fetal distress and significant fetal growth restriction ([Owen and colleagues, 1997](#); [Owen and Khan, 1998](#)).

METABOLIC ABNORMALITIES. Fetal blood sampling from the umbilical vein done for karyotyping of severely growth-impaired fetuses has permitted remarkable insights into pathophysiology of fetal growth ([Chap. 37, p. 991](#)). [Soothill and colleagues \(1987\)](#) at Kings College Hospital in London measured umbilical venous PO_2 , PCO_2 , pH, lactate and glucose concentrations, nucleated red cell count, and hemoglobin concentrations in 38 growth-restricted fetuses. The severity of fetal hypoxia correlated significantly with fetal hypercapnia, acidosis, lactic acidemia, hypoglycemia, and erythroblastosis. Subsequently, [Economides and Nicolaidis \(1989b\)](#) found that the major cause of hypoglycemia in small-for-gestational-age fetuses was reduced supply rather than increased fetal consumption or decreased endogenous glucose production. [Economides and co-workers \(1989c\)](#) later found that these fetuses also had hypoinsulinemia, which they attributed to pancreatic dysfunction, as well as hypoglycemia. The degree of fetal growth restriction, however, did not correlate with plasma insulin, suggesting that it is not the primary determinant of poor fetal growth.

In children with *kwashiorkor*, the ratio of nonessential to essential amino acids is increased, presumably because of decreased intake of essential amino acids. [Economides and colleagues \(1989a\)](#) measured the glycine/valine ratio in umbilical vessel blood from growth-restricted fetuses and found ratios similar to those observed in children with protein deprivation and *kwashiorkor*. Moreover, protein deprivation correlated with fetal hypoxemia.

[Economides and associates \(1990\)](#) also measured plasma triglyceride concentrations in small but appropriate-for-gestational-age fetuses as well as growth-restricted fetuses. Growth-restricted fetuses demonstrated hypertriglyceridemia that was correlated with the degree of fetal hypoxemia. They hypothesized that hypoglycemic, growth-restricted fetuses mobilize adipose tissue, and that the hypertriglyceridemia is the result of lipolysis of fetal fat stores. Other findings include observations that growth-restricted fetuses may be thrombocytopenic, and that the degree of platelet abnormality is correlated with the degree of growth restriction, hypoxemia, and acidemia ([Van den Hof and Nicolaidis, 1990](#)).

In fetuses with growth restriction, plasma adenosine concentrations are elevated. [Yoneyama and associates \(1994\)](#) postulate that this represents an adaptive response to chronic asphyxia. Elevations in interleukin-10, placental atrial natriuretic peptide, and plasma endothelin-1 concentrations, as well as a defect in epidermal growth factor function, have also been described in growth-restricted fetuses ([Varner and colleagues, 1996](#)). These findings suggest a possible role for abnormal immune activation and abnormal placentation in the genesis of this condition ([Gabriel, 1994](#); [Heyborne, 1994](#); [Kingdom, 1994](#); [McQueen, 1993](#); [Neerhof, 1995](#), and all their associates). In animals, chronic reduction in nitric oxide, an endothelium-derived, locally acting vasorelaxant, has also been shown to result in diminished fetal growth ([Diket and associates, 1994](#)).

Fetal heart rate monitoring for 30 to 60 minutes was performed immediately before cordocentesis and results compared with fetal blood gases ([Visser and colleagues, 1990](#)). Repetitive fetal heart rate decelerations best identified hypoxemic growth-restricted fetuses. Several small infants with low normal PO_2 values still demonstrated heart rate acceleration. Such accelerations, however, indicated the absence of potentially damaging degrees of hypoxemia or acidosis.

MORTALITY AND MORBIDITY

As shown in [Figure 29-3](#), fetal growth restriction is associated with substantive perinatal morbidity and mortality. Fetal demise, birth asphyxia, meconium aspiration, and neonatal hypoglycemia and hypothermia are all increased, as is the prevalence of abnormal neurological development ([Paz and associates, 1995](#); [Piper and colleagues, 1996](#)). This is true for both term and preterm infants ([Minior and Divon, 1998](#)). [Kok and colleagues \(1998\)](#) analyzed the outcome up to 9 years of age of growth-restricted infants less than 32 weeks at birth. They found the mortality risk for growth-restricted infants was significantly increased compared with appropriately grown preterm infants. Growth-restricted preterm infants also more often required special education.

Postnatal growth and development of the growth-restricted fetus depends on the cause of restriction, nutrition in infancy, and the social environment ([Kliegman, 1997](#)). Infants with growth restriction due to congenital viral, chromosomal, or maternal constitutional factors remain small throughout life. Those infants with in utero growth restriction due to placental insufficiency will often have catch-up growth after birth and approach their inherited growth potential when provided with an optimal environment. Similarly, neurodevelopmental outcome of the growth-restricted fetus is influenced by postnatal environment. Such infants born to families of higher socioeconomic status demonstrate few developmental problems during follow-up, whereas those born to poorer families have significant developmental handicaps.

ACCELERATED MATURATION

There have been numerous reports describing accelerated fetal pulmonary maturation in complicated pregnancies associated with growth restriction ([Perelman and colleagues, 1985](#)). One explanation for this phenomenon is that the fetus responds to a stressed environment by increasing adrenal glucocorticoid production, which leads to earlier or accelerated fetal lung maturation ([Laatikainen and associates, 1988](#)). Although this concept pervades modern perinatal thinking, there is little clinical information to substantiate that pregnancy complications convey a fetal advantage.

[Owen and associates \(1990\)](#) analyzed perinatal outcomes in 178 pregnancies delivered primarily because of hypertension. They compared these with 159 pregnancies delivered because of spontaneous preterm labor or ruptured membranes. They concluded that a "stressed" pregnancy, which often resulted in small-for-gestational-age infants, did not confer an appreciable survival advantage. Similar findings were reported by [Friedman and colleagues \(1995\)](#) in women with fetal growth restriction due to severe preeclampsia. Two studies from Parkland Hospital substantiate that fetal growth restriction confers no apparent advantage to the preterm infant ([McIntire and colleagues, 1999](#); [Tyson and colleagues, 1995](#)). [Smulian and colleagues \(2000\)](#) analyzed U.S. national linked birth-infant death data for 1995 and 1996 to determine deaths during the first 12 months of life for infants with birthweights less than the 10th percentile. Compared with uncomplicated pregnancies, growth-restricted infants had higher death rates during infancy.

SYMMETRICAL VERSUS ASYMMETRICAL FETAL GROWTH RESTRICTION

[Campbell and Thoms \(1977\)](#) described the use of the sonographic *head-to-abdomen circumference ratio (HC/AC)* to differentiate fetuses into the subtypes "symmetrical," meaning proportionately small, and "asymmetrical," referring to those with disproportionately lagging abdominal growth. These authors constructed an HC/AC^4 ratio nomogram from approximately 500 normal fetuses and evaluated its use in 31 fetuses at risk for uteroplacental insufficiency. The 70 percent of fetuses

with an HC/AC ratio above the 95th percentile were termed asymmetrical. They found that although asymmetrical fetuses had relatively larger brains and were "preferentially protected from the full effects of the growth-retarding stimulus," they were at significantly greater risk for severe preeclampsia, fetal distress, operative intervention, and lower Apgar scores than their symmetrical counterparts.

It is compelling to relate the type of growth restriction to the onset or etiology of a particular insult. An early insult due to chemical exposure, viral infection, or inherent cellular development abnormality caused by aneuploidy could theoretically result in a relative decrease in cell number as well as cell size. The resultant proportionate reduction in both head and body size has been termed *symmetrical growth restriction*. Conversely, a late pregnancy insult such as placental insufficiency associated with hypertension would theoretically affect primarily cell size. Because placental insufficiency may result in diminished glucose transfer and hepatic storage, fetal abdominal circumference—which reflects liver size—would be reduced. This concept, however, has been challenged ([Roberts and co-authors, 1999](#)). Simultaneously, it is proposed that there is preferential shunting of oxygen and nutrients to the brain, which allows normal brain and head growth. This sequence of events can theoretically result in *asymmetrical growth restriction* with an abnormally increased relative brain size compared with the small liver. Because the fetal brain is normally relatively large and the liver relatively small, the ratio of brain weight to liver weight—usually about 3 to 1—over the last 12 weeks is increased to 5 to 1 or more in many severely growth-restricted infants ([Fig. 29-5](#)).

Although these generalizations about the potential pathophysiology of symmetrical versus asymmetrical growth restriction are interesting from a conceptual standpoint, there is considerable evidence that fetal growth patterns are more complex. For example, [Nicolaidis and co-authors \(1991\)](#) compared the ratios of fetal head-to-abdominal circumference in 376 growth-restricted fetuses with and without normal karyotypes. Those with aneuploidy typically had disproportionately large head sizes and were therefore *asymmetrically* growth restricted rather than the hypothetically expected symmetrical pattern. Similarly, most preterm infants with growth restriction due to preeclampsia and associated uteroplacental insufficiency demonstrate a *symmetrical* pattern of growth impairment rather than the hypothesized asymmetrical pattern ([Salafia and co-authors, 1995](#)).

Recognition of symmetrical and asymmetrical patterns of impaired fetal growth has prompted considerable interest in the antepartum diagnosis of these two forms because the pattern may potentially reveal the cause. This has been particularly true with ultrasonic evaluation of fetal growth restriction, where several fetal dimensions are now measured and can be related to each other. [Crane and Kopta \(1980\)](#) analyzed several anthropometric measurements in growth-restricted newborns and concluded that the concept of brain sparing was erroneous and could not be used to diagnose the cause of individual fetal growth restriction. [Dashe and colleagues \(2000\)](#) analyzed head-to-abdominal circumference ratios in 8722 consecutive liveborn singletons delivered at Parkland Hospital and who underwent ultrasound examinations within 4 weeks of delivery. Only 20 percent of growth-restricted fetuses demonstrated head-to-abdomen asymmetry, but importantly, these fetuses were at increased risk for intrapartum and neonatal complications. Symmetrically growth-restricted fetuses with birthweights less than the 10th percentile, when compared with those appropriately grown, were not at increased risk for adverse outcomes. It was concluded that asymmetrical fetal growth restriction represented significantly disordered fetal growth, whereas symmetrical growth restriction more likely represented normal, genetically determined small stature.

RISK FACTORS

CONSTITUTIONALLY SMALL MOTHERS. Small women typically have smaller babies. If a woman begins pregnancy weighing less than 100 pounds, the risk of delivering a small-for-gestational-age infant is increased at least twofold ([Simpson and colleagues, 1975](#)). Data from a longitudinal study of all births during one week in 1958 in England, Wales, and Scotland indicate that there are intergenerational effects on birthweight that are transmitted through the maternal line ([Emanuel and associates, 1992](#)). [Klebanoff and co-authors \(1997\)](#) also reported that reduced intrauterine growth of the mother is a risk factor for reduced intrauterine growth of her children. Whether or not the phenomenon of a small mother giving birth to a small infant is nature or nurture is unclear. [Brooks and co-authors \(1995\)](#) analyzed 62 births after ovum donation to examine the relative influence of the donor versus the recipient on birthweight. They concluded that the environment provided by the mother was more important than her genetic contribution to birthweight. Cryopreservation of embryos does not adversely affect fetal or postnatal growth ([Wennerholm and colleagues, 1998](#)).

POOR MATERNAL WEIGHT GAIN AND NUTRITION. In the woman of average or low weight, lack of weight gain throughout pregnancy may be associated with fetal growth restriction ([Simpson and colleagues, 1975](#)). Lack of weight gain in the second trimester is strongly correlated with decreased birthweight ([Abrams and Selvin, 1995](#)). If the mother is large and otherwise healthy, however, below-average maternal weight gain without maternal disease is unlikely to be associated with appreciable fetal growth restriction.

As discussed in [Chapter 10 \(p. 231\)](#), marked restriction of weight gain during the last half of pregnancy should not be encouraged. Even so, it appears that caloric restriction to less than 1500 kcal/day adversely affects fetal growth only minimally ([Lechtig and co-workers, 1975](#)). The best documented effect of famine on fetal growth was in the winter of 1944 in Holland, when the German Army restricted dietary intake to 600 kcal/day for all citizens, including pregnant women. The famine persisted for 28 weeks and there was an average birthweight decrease of 250 g ([Stein and colleagues, 1975](#)). Although there was only a small mean decrease in birthweight, fetal mortality rates increased significantly.

SOCIAL DEPRIVATION. The effect of social deprivation on birthweight is interconnected to the effects of associated lifestyle factors such as smoking, alcohol or other substance abuse, and poor nutrition. [Wilcox and associates \(1995\)](#), in a study of 7493 British women, found that the most socially deprived mothers had the smallest babies. Similarly, [Dejin-Karlsson and colleagues \(2000\)](#) prospectively studied a cohort of Swedish women and found that lack of psychosocial resources influenced the risk of growth-restricted infants. Almost 100 years ago, Williams, commenting in the first edition of this text (1903), wrote: "The social condition of the mother and the comforts by which she is surrounded also exert a marked influence upon the child's weight, heavier children being more common in the upper walks of life."

FETAL INFECTIONS. Viral, bacterial, protozoan, and spirochetal infections have been implicated in up to 5 percent of cases of fetal growth restriction ([Klein and Remington, 1995](#)). The best known of these are infections caused by rubella and cytomegalovirus ([Lin and Evans, 1984](#); [Stagno and associates, 1977](#)). Mechanisms affecting fetal growth appear to be different with these two viral infections. *Cytomegalovirus* is associated with direct cytolysis and loss of functional cells. *Rubella* infection causes vascular insufficiency by damaging the endothelium of small vessels. Cell division rate is also reduced in congenital rubella infections ([Pollack and Divon, 1992](#)). *Hepatitis A and B* are associated with preterm delivery but may also adversely affect fetal growth ([Waterson, 1979](#)). *Listeriosis, tuberculosis, and syphilis* have been reported to cause fetal growth restriction. Paradoxically, in cases of syphilis, the placenta is almost always increased in weight and size due to edema and perivascular inflammation ([Varner and Galask, 1984](#)). *Toxoplasmosis* is the protozoan infection most often associated with compromised fetal growth, but *congenital malaria* may produce the same result ([Varner and Galask, 1984](#)).

CONGENITAL MALFORMATIONS. In a study of over 13,000 infants with major structural anomalies, 22 percent had accompanying growth restriction ([Khoury and associates, 1988](#)). In general, the more severe the malformation, the more likely the fetus is to be small-for-gestational age. This is especially evident in fetuses with chromosomal abnormalities or those with serious cardiovascular malformations.

CHROMOSOMAL ABNORMALITIES. Placentas of fetuses with autosomal trisomies have a reduced number of small muscular arteries in the tertiary stem villi ([Rochelson and associates, 1990](#)). Thus, both placental insufficiency and primary abnormal cellular growth and differentiation may contribute to the significant degree of fetal growth restriction often associated with karyotype abnormalities. In a series of 458 fetuses with no sonographically visible structural anomalies, [Snijders and co-workers \(1993\)](#) found karyotype abnormalities in 20 percent. In the presence of growth restriction and fetal anomalies, the prevalence of chromosome abnormalities was even greater.

Although postnatal growth failure is prominent in children with *trisomy 21*, fetal growth restriction is generally mild ([Thelander and Pryor, 1966](#)). In fact, their mean birthweight was 2900 g. A significant first-trimester lag in crown-rump length among fetuses with trisomy 21 has been observed by some investigators, but not others ([Golbus 1978](#); [Stephens and Shepard, 1980](#)). After the first trimester, the length of all long bones in fetuses with trisomy 21 lags behind those of normal fetuses ([Fitzsimmons and colleagues, 1990](#)). Both shortened femur length and hypoplasia of the middle phalanx have been documented with increased frequency with trisomy 21.

In contrast to the mild and variable growth restriction that accompanies trisomy 21, fetuses with *trisomy 18* are virtually always significantly affected. In one series of trisomy 18 newborns, 10 of 11 weighed less than 2500 g at birth ([Moerman and associates, 1982](#)). Growth failure has been documented as early as the first trimester. By the second trimester, long bone measurements typically fall below the third percentile for age, and the upper extremity is more severely affected than the lower ([Droste and co-workers, 1990](#)). Visceral organ growth is also abnormal in this condition ([Droste, 1992](#)). Some degree of growth restriction is also commonly present in fetuses with trisomy 13, but it is generally not as severe as in trisomy 18.

Significant fetal growth restriction is not seen with *Turner syndrome* (45,X or gonadal dysgenesis) or *Klinefelter syndrome* (47,XXY) ([Droste, 1992](#)).

TRISOMY 16. Trisomy 16 is the most common trisomy in spontaneous abortions and is usually, if not always, lethal to the fetus in the nonmosaic state ([Lindor and associates, 1993](#)). As discussed in [Chapter 36 \(p. 949\)](#), patches of trisomy 16 in the placenta—called *confined placental mosaicism*—lead to placental insufficiency that may account for many cases of previously unexplained fetal growth restriction ([Kalousek and colleagues, 1993](#)). In these pregnancies, the chromosome abnormality is confined to the placenta. [Wolstenholme \(1995\)](#) has reviewed the significance of trisomy 16 placental mosaicism from gametogenesis to term and onwards.

PRIMARY DISORDERS OF CARTILAGE AND BONE. Numerous inherited syndromes such as *osteogenesis imperfecta* and various chondrodystrophies are associated with fetal growth restriction ([Chap. 39, p. 1068](#)).

CHEMICAL TERATOGENS. Any teratogen is capable of adversely affecting fetal growth. These are considered in detail in [Chapter 38](#). Some *anticonvulsants*, such as phenytoin and trimethadione, may produce specific and characteristic syndromes that include fetal growth restriction ([Hanson and co-workers, 1976](#)). *Cigarette smoking* causes growth restriction as well as preterm delivery in a direct relationship with the number of cigarettes smoked ([Cliver and associates, 1995](#); [Shah and Bracken, 2000](#)). *Narcotics* and related drugs act by decreasing maternal food intake and fetal cell number. *Alcohol* is a potent teratogen that acts in a linear dose-related fashion. *Cocaine* use is also associated with poor fetal weight gain ([LeBlanc and co-workers, 1987](#)). [Miller and associates \(1995\)](#) have suggested that this may be a result of frequent cigarette use and poor prenatal care, rather than a direct effect of cocaine.

VASCULAR DISEASE. Chronic vascular disease, especially when further complicated by superimposed preeclampsia, commonly causes growth restriction. Preeclampsia itself may cause fetal growth failure, especially when the onset is before 37 weeks ([Xiong and colleagues, 1999](#)). As discussed in [Chapter 24 \(p. 570\)](#), fetal growth restriction with preeclampsia is a marker of severity.

CHRONIC RENAL DISEASE. Renal disease may be accompanied by restricted fetal growth ([Cunningham and colleagues, 1990](#); [Stettler and Cunningham, 1992](#)).

CHRONIC HYPOXIA. When exposed to a chronically hypoxic environment, some fetuses have significant reduction in birthweight. As discussed earlier, fetuses of women who reside at high altitude usually weigh less than those born to women who live at a lower altitude. [Lichty and colleagues \(1957\)](#), reported a mean difference of 250 g among infants born to Peruvian women at altitudes above 10,000 feet compared with those at sea level. As discussed in [Chapter 44 \(p. 1193\)](#), fetuses of women with cyanotic heart disease are frequently severely growth-restricted ([Patton and co-worker, 1990](#)).

MATERNAL ANEMIA. In most cases, anemia does not cause growth restriction. Exceptions include sickle cell disease or other inherited anemias associated with serious maternal disease. Conversely, deficient total maternal blood volume early in pregnancy has been linked to fetal growth restriction ([Duvekot and colleagues, 1995](#)).

PLACENTAL AND CORD ABNORMALITIES. Chronic partial placental separation, extensive infarction, or chorioangioma are likely to cause restricted fetal growth. A circumvallate placenta or a placenta previa may impair growth, but usually the fetus is not markedly smaller than normal. Marginal insertion of the cord and especially velamentous insertions are more likely to be accompanied by a growth-restricted fetus ([Chap. 32, p. 833](#)).

Many cases of fetal growth restriction occur in pregnancies with apparently normal fetuses with grossly normal placentas. Growth failure in these cases is often presumed to be due to *uteroplacental insufficiency*. Women with otherwise unexplained fetal growth restriction demonstrated a fourfold reduction in uteroplacental blood flow compared with normally grown fetuses ([Lunell and Nylund, 1992](#)). Similar reductions were also seen in growth-restricted fetuses with congenital malformations, suggesting that maternal blood flow may in part be regulated by the fetus ([Howard, 1987](#); [Rankin and McLaughlin, 1979](#)). Uteroplacental blood flow is also reduced in women with preeclampsia compared with normotensive women. Interestingly, macrosomic infants do not have increased uteroplacental blood flow ([Lunell and Nylund, 1992](#)).

MULTIPLE FETUSES. As shown in [Figure 29-6](#), pregnancy with two or more fetuses is more likely to be complicated by diminished growth of one or both fetuses compared with normal singletons ([Chap. 30, p. 778](#)). Growth restriction has been reported in 10 to 50 percent of twins ([Hill and associates, 1994](#)).

ANTIIPHOSPHOLIPID ANTIBODY SYNDROME. Two classes of antiphospholipid antibodies have been associated with fetal growth restriction—*anticardiolipin antibodies* and *lupus anticoagulant* ([Lockwood and Rand, 1994](#)). These syndromes are considered in detail in [Chapters 33 \(p. 860\)](#) and [52 \(p. 1384\)](#). Pregnancy outcome in women with these antibodies is often poor, and may also involve early-onset preeclampsia and second or third trimester fetal demise ([Branch and associates, 1992](#)). Maternal morbidity due to vascular thrombotic events is not uncommon. Pathophysiological mechanisms in the fetus appear to be caused by maternal platelet aggregation and placental thrombosis. These antibodies may also be suspected in women demonstrating repetitive second-trimester fetal loss or early-onset fetal growth restriction, especially when accompanied by early, severe hypertensive disease.

EXTRAUTERINE PREGNANCY. The fetus gestated outside the uterus is usually growth-restricted ([Chap. 34, p. 887](#)). Also, some maternal uterine malformations have been linked to impaired fetal growth ([Chap. 35, p. 915](#)).

SCREENING AND IDENTIFICATION OF FETAL GROWTH RESTRICTION

Early establishment of gestational age, attention to maternal weight gain, and careful measurement of uterine fundal growth throughout pregnancy will serve to identify many cases of abnormal fetal growth in women without risk factors. Identification of risk factors, including a *previously growth-restricted fetus*, should raise the possibility of recurrence during the current pregnancy. In women with significant risk factors, consideration should be given to serial sonography. Although their frequency will vary depending upon clinical circumstances, an initial dating examination, followed by a second examination at 32 to 34 weeks, should serve to identify many cases of growth restriction. If clinical findings suggest inadequate fetal growth prior to this time, earlier sonography is done. *Definitive diagnosis*, however, usually cannot be made until delivery.

Identification of the inappropriately growing fetus remains a challenge. This is underscored by the fact that such identification is not always possible even in the nursery. Regardless, there are both simple clinical techniques and more complex technologies that may prove useful in helping to exclude and diagnose fetal growth restriction. Some of the widely used techniques, as well as those of potential use, are described next.

UTERINE FUNDAL HEIGHT. Carefully performed serial fundal height measurements throughout gestation are a simple, safe, inexpensive, and reasonably accurate *screening* method to detect many small-for-gestational-age fetuses ([Gardosi and Francis, 1999](#)). Its principal drawback is imprecision. [Jensen and Larsen \(1991\)](#) and [Walraven and colleagues \(1995\)](#) found that symphysis-to-fundus measurements helped to correctly identify only 40 percent of such infants. Thus, small-for-age infants were both overlooked and overdiagnosed. Despite this, these results do not diminish the importance of carefully performed fundal measurements as a simple screening method.

The method used in most clinics in the United States was reported by [Jimenez and colleagues \(1983\)](#). Briefly this consists of a tape calibrated in centimeters being applied over the abdominal curvature from the upper edge of the symphysis to the upper edge of the uterine fundus, which is identified by palpation or percussion. The tape is applied with the markings away from the examiner to avoid bias. Between 18 and 30 weeks, the uterine fundal height in centimeters coincides with weeks of gestation. If the measurement is more than 2 to 3 cm from the expected height, inappropriate fetal growth may be suspected.

ULTRASONIC MEASUREMENTS. Central to the debate over whether all pregnancies should routinely receive ultrasonic evaluations is the potential for diagnosis of fetal growth restriction ([Ewigman and colleagues, 1993](#)) ([Chap. 41, p. 1113](#)). Typically, such routine screening incorporates an ultrasound examination at 16 to 20 weeks to establish gestational age and rule out visible anomalies, and then follow-up imaging at 32 to 34 weeks to evaluate fetal growth.

The optimal ultrasonographic method of estimating fetal size, and therefore fetal growth restriction, was reviewed by [Manning \(1995\)](#). Combining head, abdomen, and femur dimensions should in theory enhance the accuracy of predictions of fetal size. Unfortunately, any potential improvement is apparently lost by the cumulative error inherent in measurement of each individual fetal dimension. As a result, abdominal circumference measurements have been accepted by most experts as the most reliable index of fetal size ([Manning, 1995](#); [Smith and colleagues, 1997](#); [Snijders and Nicolaidis, 1994](#)). In these studies, the estimated fetal weight calculated with abdominal circumference measurements was almost always within 10 percent of the actual birthweight ([Fig. 29-7](#)).

Interestingly, abdominal circumference measured directly in the newborn was also shown to be an important anatomical marker of growth restriction ([Deter and colleagues, 1995](#)). The elegant observations on the metabolic effects of fetal growth restriction, performed at Kings College Hospital and described earlier, were all obtained in fetuses diagnosed to have growth restriction because their ultrasonic abdominal circumference was less than the fifth percentile for age ([Snijders and Nicolaidis, 1994](#)). As shown in [Figure 29-8](#), such small abdominal circumferences are linked to decreased Po_2 and pH. These observations emphasize that

sonographic measurements of the abdominal circumference can meaningfully signify pathological fetal growth restriction.

Use of ultrasound for detection of fetal growth restriction does not preclude missed diagnoses. [Dashe and colleagues \(2001\)](#) studied 8400 live births at Parkland Hospital who had antepartum ultrasound within 4 weeks of delivery. They found that although 70 percent of growth-restricted fetuses were detected, 30 percent were missed.

[Larsen and colleagues \(1992\)](#) performed ultrasound beginning at 28 weeks and every 3 weeks thereafter in 1000 pregnancies at risk for fetal growth restriction. They randomly withheld the results from clinicians. Revealing the results of ultrasonic estimates of growth during the third trimester significantly increased diagnosis of small-for-gestational-age fetuses. In this same group, elective deliveries also increased, but without overall improvement in neonatal mortality or morbidity. Thus, while this method of screening improved the diagnosis, it did not improve fetal outcome. [Goldenberg and colleagues \(1989\)](#) found that as the percentage of pregnancies undergoing ultrasound increased, fetal growth restriction decreased. This was attributed to accurate gestational age information obtained using ultrasound.

An association between oligohydramnios and pathological fetal growth restriction has long been recognized ([Chap. 31, p. 821](#)). As shown in [Figure 29-9](#), the smaller the vertical dimension of a sonographically measured pocket of amniotic fluid, the greater the perinatal mortality. The likely explanation for oligohydramnios ([Nicolaidis and associates, 1990](#)) is diminished fetal urine production caused by hypoxia and diminished renal blood flow.

DOPPLER VELOCIMETRY. Abnormal umbilical artery Doppler velocimetry—characterized by absent or reversed end-diastolic flow signifying increased impedance—has been uniquely associated with fetal growth restriction (American College of Obstetricians and Gynecologists, 2000). An example of this is shown in [Figure 29-10](#). The use of Doppler velocimetry in the management of fetal growth restriction has been recommended as a possible adjunct to other fetal evaluation techniques such as nonstress tests or biophysical profiles ([American College of Obstetricians and Gynecologists, 2000a](#)). Doppler velocimetry is more extensively reviewed in [Chapter 41 \(p. 1132\)](#).

MANAGEMENT

Once a growth-restricted fetus is suspected, efforts should be made to confirm the diagnosis, and if so, to determine if the fetus has anomalies or is in poor physiological condition. Some practitioners have performed cordocentesis for rapid karyotyping because detection of lethal aneuploidy may obviate cesarean delivery. Conversely, the [American College of Obstetricians and Gynecologists \(2000a\)](#) has concluded that there are not enough data to warrant cordocentesis for management of fetal growth restriction. The timing of delivery is crucial and the clinician must often weigh the risks of fetal death against the hazards of preterm delivery.

GROWTH RESTRICTION NEAR TERM. Prompt delivery is likely to afford the best outcome for the fetus who is considered growth restricted at or near term. In the presence of significant oligohydramnios, most fetuses will be delivered if gestational age has reached 34 weeks or beyond. Assuming that the fetal heart rate pattern is reassuring, vaginal delivery may be attempted. Unfortunately, such fetuses often tolerate labor less well than their appropriately grown counterparts, and cesarean delivery is necessary for intrapartum fetal compromise. Importantly, uncertainty about the diagnosis of fetal growth restriction should preclude intervention until fetal lung maturity is assured. Expectant management can be guided using antepartum fetal surveillance techniques described in [Chapter 40](#).

GROWTH RESTRICTION REMOTE FROM TERM. When a growth-restricted fetus is diagnosed prior to 34 weeks, and amniotic fluid volume and antepartum fetal surveillance are normal, observation is recommended. A sonographic search is made for fetal anomalies. Sonography is repeated at intervals of 2 to 3 weeks. As long as there is continued growth and fetal evaluation remains normal, pregnancy is allowed to continue until fetal maturity is achieved; otherwise, delivery is effected. At times, amniocentesis for assessment of pulmonary maturity may be helpful in clinical decision making.

Oligohydramnios is highly suggestive of fetal growth failure although a normal amniotic fluid volume does not preclude fetal growth restriction. Screening for toxoplasmosis, rubella, cytomegalovirus, herpes, and other viral agents is recommended by some clinicians, but we have not generally found this to be productive in most cases.

With growth restriction remote from term, there is no specific treatment that will ameliorate the condition. There is no evidence that bed rest actually results in accelerated fetal growth or improved outcome in growth-restricted fetuses. Despite this, many clinicians advise a program of modified rest in the lateral recumbent position in which maternal cardiac output—and presumably placental perfusion—is maximized. Nutrient supplementation, plasma volume expansion, oxygen therapy, antihypertensive drugs, heparin, and aspirin have not been shown to be effective ([American College of Obstetricians and Gynecologists, 2000a](#)).

In most cases of growth restriction diagnosed prior to term, neither a precise etiology nor a specific therapy is apparent. Management decisions in such cases hinge upon an assessment of the relative risks of fetal death with continued antepartum evaluation versus risks from preterm delivery. Although reassuring tests of fetal well-being will in many cases allow safe observation and continued maturation of preterm significantly growth-restricted fetuses, there is concern for their long-term neurological outcome ([Blair and Stanley, 1992](#)). Indeed, although it is generally believed various tests of fetal well-being appear to be effective in reducing risks for fetal death, some challenge this belief. [Weiner and colleagues \(1996\)](#) performed nonstress tests, biophysical profiles, and umbilical artery velocimetry within 3 days of delivery in 135 fetuses who, at birth, were confirmed to have growth restriction. Other than metabolic acidosis at birth, which was predicted by absent or reversed end-diastolic umbilical artery velocimetry, morbidity and mortality in the growth-restricted fetuses were determined primarily by gestational age and birthweight and not by abnormal fetal testing. Moreover, there is no convincing evidence that any such testing scheme reduces the risk of survival with long-term neurological deficit ([American College of Obstetricians and Gynecologists, 2000a](#)). Thus, the optimal management of the preterm growth-restricted fetus remains problematic.

LABOR AND DELIVERY

Throughout labor, spontaneous or induced, those fetuses suspected of being growth restricted should be monitored for evidence of compromise, most commonly manifested by fetal heart rate abnormalities. Fetal growth restriction is commonly the result of insufficient placental function as a consequence of faulty maternal perfusion, ablation of functional placenta, or both. These conditions are likely aggravated by labor. Importantly, diminished amniotic fluid volume also predisposes to cord compression and its dangers. Cesarean delivery is also increased in fetal growth restriction because breech presentation occurs more commonly ([Sherer and colleagues, 1996](#)).

It can be anticipated that the infant may need expert assistance in making a successful transition to air breathing. The fetus is at risk of being born hypoxic and of having aspirated meconium. It is essential that care for the newborn be provided immediately by someone who can skillfully clear the airway below the vocal cords, especially of meconium, and ventilate the infant as needed. The severely growth-restricted newborn is particularly susceptible to hypothermia and may also develop other metabolic derangements such as hypoglycemia, polycythemia, and hyperviscosity.

RECURRENT FETAL GROWTH RESTRICTION

The risk of fetal growth restriction is increased in subsequent pregnancies ([Bakketeig and colleagues, 1986](#)). This is particularly true in women with both a history of growth restriction and a continuing medical complication ([Patterson and colleagues, 1986](#)).

BARKER HYPOTHESIS. Barker and colleagues at the United Kingdom Medical Research Unit have over the past 12 years been responsible for a series of remarkable publications in which causes of adult mortality and morbidity have been related to fetal and infant life ([Fraser and Cresswell, 1997](#)). Most interesting, in the context of fetal growth restriction, is the suggestion that there is a relationship between suboptimal fetal nutrition and an increased risk for hypertension and atherosclerosis later in life. Although fascinating, it is important to emphasize the investigational nature of this hypothesis.

MACROSOMIA

Macrosomia is a term used rather imprecisely to describe a very large fetus-neonate. There is general agreement among obstetricians that newborns weighing less than 4000 g are not excessively large; but a similar consensus has not been reached that permits a precise definition of macrosomia. Indeed, the term macrosomia does not appear in the *New Shorter Oxford English Dictionary* (1993) although *Stedman's Medical Dictionary* (1995) offers the definition of "abnormally large size of the body." The key word is "abnormal." What is the threshold for the upper limit of normal human fetal growth above which birthweight is abnormal? What criteria should be used to define "abnormal"? For example, should the threshold for abnormal high birthweight be simply mathematically derived or should it include features of adverse pregnancy outcome? Given that the major hazard of excessive fetal growth is birth injury due to shoulder dystocia, should the threshold for excessive growth be defined in terms of the risk of brachial plexus injury? But this approach cannot entirely suffice to diagnose excessive and abnormal fetal growth because

shoulder dystocia would not be expected in an overgrown but preterm and thus physically small infant.

Newborn weight rarely exceeds 11 pounds (5000 g) and excessively large infants are still a curiosity. The birth of a 16-pound (7300 g) infant in the United States in 1979 was widely publicized. Two of the largest newborn weights ever recorded were those of a nearly 24-pound (10,800 g) infant described by Beach in 1879 ([Barnes, 1957](#)), and a 25-pound stillborn cited in [Chapter 7 \(p. 134\)](#). Among almost 170,000 infants who were delivered at Parkland Hospital between 1988 and 1999, only one weighed 6000 g or more for an incidence less than 1 in 200,000 births. This infant weighed 6025 g (13 lbs 4 oz) and was delivered by repeat cesarean incision to a 329-lb diabetic woman. The incidence of excessively large infants seems to have increased during the 20th century. For example, the incidence of birthweight 5000 g or greater was approximately 1 to 2 per 10,000 births at the beginning of the 20th century ([Williams, 1903](#)) compared with 15 per 10,000 at Parkland Hospital in 1999.

DEFINITIONS

As discussed, there is no precise definition of macrosomia. Several definitions are in general clinical use. In one scheme, macrosomia is viewed as those weights that exceed certain percentiles for populations. Another common scheme includes use of empirical birthweights.

BIRTHWEIGHT DISTRIBUTION. Commonly used definitions of macrosomia are based upon mathematical distributions of birthweight such as shown in [Figure 29-11](#). Birthweights exceeding the 90th percentile for a given gestational week are usually used as the threshold for macrosomia. For example, the 90th percentile at 39 weeks is 4000 g whereas the corresponding birthweight at 42 weeks is 4400 g. If, on the other hand, birthweights two standard deviations above the mean were used to define excessive fetal growth, the percentile threshold would be between the 97th and 99th percentile, or substantially larger infants when compared with the 90th percentile. For example, the birthweight threshold at 39 weeks would be approximately 4500 g (97th percentile) rather than 4000 g (90th percentile).

EMPIRICAL BIRTHWEIGHT. Absolute birthweight exceeding a specific threshold is also commonly used to define macrosomia. Newborn weight exceeding 4000 g (8 lbs 13¹/₂ oz) is a frequently used threshold. Others use 4250 g or even 4500 g (almost 10 lb). As shown in [Table 29-2](#), birthweights of 4500 g or more are rare. Over a 12-year period at Parkland Hospital, during which time there were almost 170,000 singleton births, only about 1 percent weighed 4500 g or more. We are of the view that the upper limit of fetal growth, above which growth can be deemed abnormal, is likely two standard deviations above the mean, representing perhaps 3 percent of births. At 40 weeks such a threshold would correspond to approximately 4500 g. This definition of excessive growth is clearly more restrictive than using the upper 10 percent to define macrosomia. The [American College of Obstetricians and Gynecologists \(2000b\)](#) concluded that the term "macrosomia" was an appropriate designation for fetuses who, at birth, weigh 4500 g or more.

RISK FACTORS

Maternal diabetes is an important risk factor for development of fetal macrosomia ([Chap. 51, p. 1364](#)). As shown in [Table 29-2](#), the incidence of maternal diabetes increases as birthweight above 4000 g increases. It should be emphasized, however, that maternal diabetes is associated with but a small percentage of such large infants. For example, of the 13,805 infants shown in [Table 29-2](#) who weighed 4000 g or more, only 823 or 6 percent were born to diabetic mothers. Among macrosomic fetuses of diabetic women, there is a greater shoulder circumference and a greater shoulder circumference-to-head circumference ratio. Consequent to this is a greater risk of shoulder dystocia compared with similar bodyweight fetuses of nondiabetic women ([Modenlau and colleagues, 1982](#); [Neiger, 1992](#); [Sachs, 1993](#)).

Among macrosomic fetuses of similar bodyweight, the presence of a relatively greater proportion of body fat is associated independently with an increased risk of labor dystocia and cesarean delivery ([Bernstein and Catalano, 1994](#)). For these reasons, and in the absence of a commonly agreed-upon definition of macrosomia, a generally accepted obstetrical management plan optimal for this pregnancy complication has not evolved.

There are several other factors that also favor the likelihood of a large fetus:

1. Large size of the parents, especially obesity of the mother.
2. Multiparity.
3. Prolonged gestation.
4. Maternal age.
5. Male fetus.
6. Previous infant weighing more than 4000 g.
7. Race and ethnicity ([Benito and co-workers, 1996](#); [Chervenak, 1992](#); [Johnson and co-workers, 1992](#); [Perlow and associates, 1992](#); [Sachs, 1993](#)).

When the pregnant woman weighs more than 300 pounds, her fetus has a 30 percent risk of macrosomia. Among women who are simultaneously diabetic, obese, and postterm, the incidence of fetal macrosomia can range from 5 to 15 percent ([Arias, 1987](#); [Chervenak, 1992](#)). Known maternal risk factors, however, are identified in only 40 percent of women who deliver macrosomic infants ([Boyd and associates, 1983](#)).

DIAGNOSIS

Currently, an accurate estimate of excessive fetal size is not possible; consequently, the diagnosis of macrosomia most commonly is not made until after delivery. Inaccuracy in clinical estimates of fetal weight by physical examination is often attributable, at least in part, to maternal obesity.

Numerous attempts have been made to improve the accuracy of fetal weight estimations by analysis of various measurements obtained by ultrasonography. A number of formulas have been proposed to estimate fetal weight using ultrasonic measurements of head, femur, and abdomen. The estimates provided by these computations, although reasonably accurate for predicting the weight of small, preterm fetuses are less valid in predicting the weight of very large fetuses. For example, and as shown in [Figure 29-12](#), an infant predicted to weigh 4000 g can actually weigh considerably more or less than predicted. Similar results were described by [Jazayeri and colleagues \(1999\)](#). [Rouse and co-authors \(1996\)](#) reviewed 13 studies from 1985 to 1995 which reported sensitivity (true positive) and specificity (true negative) for ultrasonic prediction of macrosomic fetuses. The methods were found to have only fair sensitivity (60 percent) in the accurate diagnosis of macrosomia but higher specificity (90 percent) in excluding excessive fetal size.

Unfortunately, a formula that gives estimates of fetal macrosomia with sufficiently accurate predictive value to be useful in constructing clinical management decisions has not been derived ([American College of Obstetricians and Gynecologists, 2000b](#)). In a comprehensive review of estimates of fetal weight from ultrasonic measurements to identify macrosomia, [Sandmire \(1993\)](#) argued that the use of such data in clinical decision making may cause more harm than good. He suggested that a moratorium be placed on the reporting and clinical use of sonographic data in estimates of excess fetal weight. Indeed, [Adashek and colleagues \(1996\)](#) found that women who had ultrasonography in the last 4 weeks of pregnancy were at significantly increased risk for cesarean delivery if estimated fetal size exceeded 4000 g, regardless of actual newborn weight.

We conclude that the estimation of fetal weight from ultrasonic measurements is not proven to be reliable. Nonetheless, sonographic measurements to evaluate excess fetal weight to assist in clinical management decisions may be warranted in rare circumstances. Routine use of these estimates to identify macrosomia is not recommended; indeed, the findings of several studies are indicative that estimates of fetal weight by physician-conducted physical examination of the pregnant woman are as reliable as, or even superior to, those made from ultrasonic fetal measurements ([Sherman and colleagues, 1998](#)).

CONTROVERSIES

Precise knowledge of fetal weight might permit the avoidance of vaginal delivery for women with pregnancies in which labor most likely would be arrested because of true fetopelvic disproportion or delivery complicated by shoulder dystocia. Avoidance of such complications has given rise to the controversies now described.

"PROPHYLACTIC" LABOR INDUCTION. Some have proposed induction of labor upon diagnosis of macrosomia in nondiabetic women as a way to avoid further fetal

growth and thereby reduce potential delivery complications. Theoretically, induction should reduce the risk of cesarean delivery and shoulder dystocia by preempting further fetal growth. [Gonen and colleagues \(1997\)](#) randomized 273 nondiabetic women with ultrasonic fetal weight estimates 4000 to 4500 g to either induction or expectant management. Labor induction did not decrease the rate of cesarean delivery or shoulder dystocia. Similar results were reported by [Leaphart and colleagues \(1997\)](#) with the added finding that induction unnecessarily increased the rate of cesarean delivery. According to the [American College of Obstetricians and Gynecologists \(2000b\)](#), current evidence does not support a policy for early induction with suspected macrosomia.

ELECTIVE CESAREAN DELIVERY. [Rouse and colleagues \(1996, 1999\)](#) analyzed the potential effects of a policy of elective cesarean delivery for ultrasonically diagnosed fetal macrosomia compared with standard obstetrical management. They concluded that for women who are not diabetic, a policy of elective cesarean delivery was medically and economically unsound. They did, however, conclude that a policy of elective cesarean delivery in *diabetic* women with macrosomic fetuses was a tenable approach. [Conway and Langer \(1998\)](#) reported that introduction of a protocol of routine cesarean delivery for ultrasonic estimates of 4250 g or greater in diabetic women significantly reduced the rate of shoulder dystocia from 2.4 to 1.1 percent.

PREVENTION OF SHOULDER DYSTOCIA. A major concern for delivery of macrosomic infants is shoulder dystocia and attendant risks of permanent brachial plexus palsy. Shoulder dystocia occurs when the maternal pelvis is of sufficient size to permit delivery of the fetal head, but not large enough to allow delivery of the very large-diameter fetal shoulders. In this circumstance, the anterior shoulder becomes impacted against the maternal symphysis pubis ([Chap. 19, p. 459](#)). Even with expert obstetrical assistance at delivery, stretching and injury of the brachial plexus of the affected shoulder may be inevitable ([Chap. 39, p. 1080](#)). Fortunately, fewer than 10 percent of all shoulder dystocia cases result in a persistent brachial plexus injury ([American College of Obstetricians and Gynecologists, 1997a](#)). [Ecker and colleagues \(1997\)](#) analyzed 80 cases of brachial plexus injury in 77,616 consecutive deliveries at Brigham and Women's Hospital in Boston and concluded that an excessive number of otherwise unnecessary cesarean deliveries would be needed to prevent a single brachial plexus injury in infants born to women without diabetes. As previously cited, however, elective cesarean delivery in diabetic women may be helpful in preempting shoulder dystocia ([Conway and Langer, 1998](#)).

The American College of Obstetricians and Gynecologists ([1997b, 2000](#)) has concluded that most cases of shoulder dystocia cannot be predicted or prevented. Planned cesarean delivery on the basis of suspected macrosomia in the *general population* was deemed an unreasonable strategy because of the number and cost of additional cesarean deliveries. Again, it was concluded that planned cesarean delivery may be a reasonable strategy for diabetic women with estimated fetal weights exceeding 4250 to 4500 g.

TABLE 29-2. Birthweight Distribution of 169,886 Infants Born at Parkland Hospital Between 1988 and 1999^a

Birthweight (g)	Births		Percent Maternal Diabetes
	No.	Percent	
500-3999	156,079	91.9	2
4000-4249	8,254	4.9	4
4250-4499	3,470	2.0	7
4500-4649	1,329	0.8	9
4700-4999	500	0.3	12
5000-5249	164	0.1	18
5250-5499	59	—	29
5500-5449	19	—	32
5750-5999	11	—	18
6000-6249	1 ^b	—	100
Total	169,886	—	2.4

^a Also shown is the association of birthweight with maternal diabetes.

^b 6025-g infant (13 lb 4 oz) delivered by repeat cesarean at 38 weeks to a 329-lb diabetic woman.

30. Multifetal Pregnancy

The number and rate of twin and triplet and other higher order multiple births have increased in the United States at an unprecedented pace over the past two decades (Kogan and colleagues, 2000; Martin and Park, 1999). As shown in Figure 30-1, between 1980 and 1997, the number of twin deliveries rose 52 percent and the number of triplets and other higher order multiple births soared 404 percent. Singleton births, in contrast, rose only 6 percent. This extraordinary increase in multiple births is a public health concern because these infants are less likely to survive and more likely to suffer life-long disability due to preterm delivery. Jewell and Yip (1995) profiled women delivering plural births in the United States during the 1980s and observed that the increase in multiple births was due to use of fertility-stimulating therapy by older, typically white women with high-education status. Multiple gestation currently accounts for 3 percent of all pregnancies (American College of Obstetricians and Gynecologists, 1998).

Powers and Kiely (1994) used United States linked birth/infant death certificates for 7.4 million singleton births and 156,690 twin births in 1985 and 1986 to measure the impact of twins on national infant morbidity and mortality. Although twins were relatively infrequent in the United States—approximately 1 in 94 pregnancies—they accounted for a disproportionately large share of adverse pregnancy outcomes, primarily as a consequence of preterm delivery. Similarly, at Parkland Hospital, twin infants represent only 1 in 45 births and yet account for 1 in 11 perinatal deaths (Table 30-1). In addition to the perinatal mortality and morbidity attributable to preterm delivery, fetuses in multiple gestations are vulnerable to a variety of unique complications such as structural malformations and twin-to-twin transfusion syndrome, so that stillbirth rates are also appreciably increased. As Powers and Kiely (1994) emphasized, postponing preterm delivery in twin pregnancy should become a national health priority because of its disproportionate adverse pregnancy outcomes. As also shown in Table 30-1, maternal complications are increased with multiple gestations. Conde-Agudelo and co-workers (2000) studied over 15,000 twin pregnancies and found a twofold significant risk for preeclampsia, postpartum hemorrhage, and maternal death.

ETIOLOGY OF MULTIPLE FETUSES

Twin fetuses commonly result from fertilization of two separate ova, that is, double-ovum, dizygotic, or fraternal twins. About a third as often, twins arise from a single fertilized ovum that subsequently divides into two similar structures, each with the potential for developing into a separate individual, that is, single-ovum, monozygotic, or identical twins. Either or both processes may be involved in the formation of higher numbers of fetuses. Quadruplets, for example, may arise from one to four ova.

FRATERNAL VERSUS IDENTICAL TWINS. Dizygotic twins are not in a strict sense true twins because they result from the maturation and fertilization of two ova during a single ovulatory cycle (Fig. 30-2). Also, monozygotic or identical twins are usually not identical. As discussed subsequently, the process of division of one fertilized zygote into two does not necessarily result in equal sharing of protoplasmic materials. Furthermore, the process of monozygotic twinning is in a sense a teratogenic event, and monozygotic twins have an increased incidence of (often discordant) structural malformations. In fact, dizygotic or fraternal twins of the same sex may appear more nearly identical at birth than do monozygotic twins, while growth of monozygotic twin fetuses may be discordant and at times dramatically so.

GENESIS OF MONOZYGOTIC TWINS. The physiological basis of monozygotic twinning is slowly coming to light. Evidence now suggests that the division of the fertilized ovum may occur as the result of a delay in the timing of normal developmental events. In humans, evidence suggests that delayed transport through the tube increases the risk of twinning. Because progestational agents and combination contraceptives decrease tubal motility, delayed tubal transport and implantation are believed to increase the risk of twinning in pregnancies conceived in close proximity to contraceptive use (Bressers and colleagues, 1987). It is also possible that minor trauma to the blastocyst during assisted reproduction techniques is responsible for the increased incidence of monozygotic twinning observed in pregnancies conceived in this manner (Wenstrom and co-workers, 1993).

The outcome of the twinning process depends on when the division occurs:

- If division occurs before the inner cell mass (morula) is formed and the outer layer of blastocyst is not yet committed to become chorion, that is, within the first 72 hours after fertilization, two embryos, two amnions, and two chorions will develop (Fig. 30-3). There will evolve a diamniotic, dichorionic, and monozygotic twin pregnancy. There may be two distinct placentas or a single fused placenta (Fig. 30-4).
- If division occurs between the fourth and eighth day, after the inner cell mass is formed and cells destined to become chorion have already differentiated but those of the amnion have not, two embryos will develop, each in separate amniotic sacs (Fig. 30-3). The two amniotic sacs will eventually be covered by a common chorion, thus giving rise to diamniotic, monochorionic, monozygotic twin pregnancy (Fig. 30-4C).
- If, however, the amnion has already become established, which occurs about 8 days after fertilization, division will result in two embryos within a common amniotic sac, or a monoamniotic, monochorionic, monozygotic twin pregnancy.
- If division is initiated even later, that is after the embryonic disk is formed, cleavage is incomplete and conjoined twins are formed.

CHIMERISM. A chimera is an individual whose cells originated from more than one fertilized ovum. Chimerism is to be distinguished from mosaicism, in which two or more cell lines of different chromosomal composition arise from the same zygote as the consequence of nondisjunction during meiotic division (Chap. 36). One possible mechanism for chimerism is the transfer of genetic material from one nonidentical twin fetus to the other across chorionic vascular anastomoses. The transposed cells are not destroyed, because the transfer occurs before the maturation of the fetal immune system and the recipient fetus becomes tolerant to the dissimilar antigens on the donor tissues. Blood chimerism is most commonly discovered at the time of blood typing when cells with two different blood types are found in one individual (Benirschke, 1974).

SUPERFETATION AND SUPERFECUNDATION. In superfetation, an interval as long as or longer than an ovulatory cycle intervenes between fertilizations. Superfetation requires ovulation during the course of an established pregnancy, which would theoretically be possible until the uterine cavity is obliterated by the fusion of the decidua capsularis to the decidua vera. Although known to occur in mares, superfetation is as yet unproven in humans. Most authorities believe that the alleged cases of human superfetation result from marked inequality in growth and development of twin fetuses of the same gestational age.

Superfecundation refers to the fertilization of two ova within a short period of time but not at the same coitus, nor necessarily by sperm from the same male. It may be that twin ova are not fertilized by sperm from the same ejaculate, but that fact can be demonstrated only in exceptional circumstances.

An instance of superfecundation, documented by Harris (1982), is demonstrated in Figure 30-5. The mother was raped on the 10th day of her menstrual cycle and had intercourse 1 week later with her husband. She went into labor very near term and was delivered of a black infant whose blood type was A and a white infant whose blood type was O. The blood type of both the mother and her husband was O. HLA typing was not done. Terasaki and co-workers (1978) described the use of HLA typing to establish that dizygotic twins were sired by different fathers.

FREQUENCY OF TWINS. The frequency of monozygotic twin births is relatively constant worldwide, at approximately one set per 250 births, and is largely independent of race, heredity, age, and parity. The frequency was once thought to be independent of therapy for infertility; however, there is now evidence that the incidence of zygotic splitting is increased following assisted reproductive technologies. The incidence of dizygotic twinning is influenced remarkably by race, heredity, maternal age, parity, and especially, fertility drugs.

THE "VANISHING TWIN." Improved ultrasound technology has facilitated sonographic studies of early gestations which show that the first trimester incidence of twins is much greater than the incidence of twins at birth. Multiple gestations are now estimated to occur in 12 percent of all spontaneous conceptions, but only 14 percent of these survive to term (Boklage, 1990). Monochorionic twins have a significantly greater risk of abortion than dichorionic twins (Sebire and colleagues, 1997). In some cases the entire pregnancy is lost, but in many cases, only one fetus is lost and the pregnancy delivers as a singleton. Studies in which pregnancies were evaluated with ultrasound in the first trimester have shown that one twin is lost or "vanishes" before the second trimester in 21 to 63 percent of spontaneous conceptions (Kol and associates, 1993; Landy and colleagues, 1986; Parisi and co-workers, 1983). Undoubtedly, some threatened abortions have resulted in actual abortion of one embryo from an unrecognized twin gestation while the other embryo continued its growth and development (Jauniaux and co-workers, 1988).

This event can be upsetting to patients who worry about the fate of the remaining fetus. Usually, there is no evidence of the lost fetus at birth, and patients can be reassured that losing a fetus in this manner does not increase the risk of pregnancy complications. It is important to establish the diagnosis, however, because it may complicate maternal serum screening for Down syndrome or neural-tube defects, and can result in abnormal genetic testing. The vanishing twin can cause a

discrepancy between the karyotype established by chorionic villous sampling and the fetal karyotype when tissue from the vanished twin is inadvertently sampled. For these reasons, amniocentesis for karyotype may be preferable ([Reddy and associates, 1991](#)). It can also cause an elevated maternal serum alpha-fetoprotein level as well as an elevated amniotic fluid alpha-fetoprotein level and a positive acetylcholinesterase assay ([Winsor and associates, 1987](#)).

Multiple embryos and fetuses may develop ectopically, that is, outside the uterus. Such multiple ectopic pregnancies, as well as combined pregnancies in which there are one or more extrauterine embryos or fetuses as well as one or more intrauterine, are considered in [Chapter 34](#).

RACE. The frequency of multiple fetal births varies significantly among different races and ethnic groups ([Table 30-2](#)). [Myriantopoulos \(1970\)](#) identified the birth of twins in 1 of every 100 pregnancies among white women, compared with 1 of 80 pregnancies for black women. In some areas of Africa the frequency of twinning is very high. [Knox and Morley \(1960\)](#), in a survey of one rural community in Nigeria, found that twinning occurred once in every 20 births! Twinning in Asia is less common. In Japan, for example, among more than 10 million pregnancies analyzed, twinning was identified in only 1 of 155 births. These marked differences in twinning frequency may be the consequence of racial variations in follicle-stimulating hormone levels which can lead to multiple ovulation. In the Nigerian population, mean follicle-stimulating hormone levels are higher at the peak and for four days before and after the peak in women who have had one set of twins than in women who have had only singletons. Women who have had more than one set of twins have even higher follicle-stimulating hormone levels ([Nylander, 1973](#)).

HEREDITY. As a determinant of twinning, the family history of the mother is much more important than that of the father. [White and Wyshak \(1964\)](#), in a study of 4000 records of the General Society of the Church of Jesus Christ of Latter-day Saints, found that women who themselves were a dizygotic twin gave birth to twins at the rate of 1 set per 58 births. Women not a twin, but whose husbands were a dizygotic twin, gave birth to twins at the rate of 1 set per 116 pregnancies. One explanation is that it is the tendency to multiple ovulation which is inherited. A Belgian-Dutch group has reported that dizygotic twinning may be influenced by an autosomal dominant gene carried by approximately 15 percent of the population ([Meulemans and colleagues, 1996](#)). If true, this gene may exert its effects only in women.

MATERNAL AGE AND PARITY. The rate of twinning rises from 0 at puberty, a time of minimal ovarian activity, to a peak at age 37, when maximal hormonal stimulation increases the rate of double ovulation ([Bulmer, 1959](#)). This is in accordance with the first consistently observed sign of reproductive aging, an isolated rise in serum follicle-stimulating hormone ([Klein and co-workers, 1996](#)). The fall in incidence after age 37 probably reflects exhaustion of the Graafian follicles. Fertility, as reflected by any increase in parity up to 7, also increases the twinning rate independent of maternal age. Increasing maternal age and parity have been shown to increase the incidence of twinning in all populations studied. Waterhouse demonstrated that twin pregnancies were a third as common in women under 20 with no previous children, as in women 35 to 40 years old with four or more previous children (1950). In Sweden, [Pettersson and associates \(1976\)](#) determined that the frequency of multiple fetuses in first pregnancies was 1.3 percent, compared with 2.7 percent in the fourth pregnancy. In Nigeria, [Azubuikwe \(1982\)](#) showed that the frequency of twinning increased from 1 in 50 (2 percent) pregnancies among women pregnant for the first time to 1 in 15 (6.6 percent) for women pregnant six or more times!

NUTRITIONAL FACTORS. In animals the litter size increases with the nutritional level. Evidence from a variety of sources indicates that this occurs in humans as well. [Nylander \(1971\)](#) showed a definite gradient in the twinning rate related to nutritional status as reflected by maternal size. Taller, heavier women had a twinning rate 25 to 30 percent higher than short, nutritionally deprived women. [MacGillivray \(1986\)](#) also found that dizygotic twinning is more common in large and tall women than in small women. Evidence that the twinning rate is related more to nutrition than to body size alone was acquired during and after World War II. Widespread undernourishment in Europe during those years was associated with a marked fall in the dizygotic twinning rate ([Bulmer, 1959](#)). More recently, [Czeizel and colleagues \(1994\)](#), in a randomized trial of periconceptional folic acid supplementation, found that women who received folic acid supplementation had an increased incidence of multiple gestations.

PITUITARY GONADOTROPIN. The common factor linking race, age, weight, and fertility to multiple gestation may be follicle-stimulating hormone levels. [Benirschke and Kim \(1973\)](#) presented intriguing reasons for implicating elevated levels of endogenous follicle-stimulating hormone in the genesis of spontaneous dizygous twinning. In addition to the data cited earlier, this theory is supported by the fact that increased fecundity and a higher rate of dizygous twinning have been reported in women who conceive within 1 month after stopping oral contraceptives, but not during subsequent months ([Rothman, 1977](#)). This may be due to the sudden release of pituitary gonadotropin in amounts greater than usual during the first spontaneous cycle after stopping contraception.

INFERTILITY THERAPY. The induction of ovulation by use of gonadotropins (follicle-stimulating hormone plus chorionic gonadotropin) or clomiphene remarkably enhances the likelihood of multiple ovulations. The incidence of multiple gestation following conventional gonadotropin therapy is 16 to 40 percent, with 75 percent being twins ([Schenker and co-workers, 1981](#)). [Tuppin and colleagues \(1993\)](#) reported that in France the incidence of twin and triplet deliveries and the sale of human menopausal gonadotropin rose in parallel between 1972 and 1989, so that by 1989, half of triplet pregnancies resulted from ovulation induction. Superovulation therapy, which increases the chance of pregnancy by recruiting multiple follicles, results in multiple gestation rates of 25 to 30 percent ([Bailey-Pridham and associates, 1990](#)). Therapy with pulsatile gonadotrophin-releasing hormone is associated with a 10 percent incidence of multiple gestation, of which the majority are twins ([Blunt and Butt, 1988](#); [Homburg and co-authors, 1989](#)).

Risk factors for multiple fetuses after ovarian stimulation with human menopausal gonadotropin include increased estradiol levels on the day of chorionic gonadotropin injection and sperm characteristics such as increased concentration and motility ([Dickey and associates, 1992](#); [Pasqualotto and colleagues, 1999](#)). Recognition of these factors plus the ability to sonographically monitor follicle growth and size and cancel cycles likely to lead to a multiple gestation have led to a reduction in the incidence of multiple births. Although clomiphene therapy was previously associated with a lower incidence of multiple gestation than human menopausal gonadotropin, the majority of multiple gestations resulting from ovulation induction are currently caused by clomiphene ([Rein and colleagues, 1990](#)).

Ovulation induction increases both dizygotic and monozygotic twinning. [Derom and colleagues \(1987\)](#) studied the incidence of monozygotic twinning in almost 1000 twin-pairs delivered in East Flanders, Belgium, and reported that the incidence of zygotic splitting was doubled after induced ovulation. Multiple gestation resulting from ovulation induction has also been associated with an increased risk of mendelian, chromosomal, and multifactorial fetal anomalies ([Brambati and associates, 1995](#); [Shoham and colleagues, 1991](#)). This risk is related to the age and family history of the women undergoing therapy, however, and not to the treatment itself.

ASSISTED REPRODUCTION TECHNOLOGIES (ART). Techniques designed to increase the probability of pregnancy increase the probability of multiple gestation as well. Typically, patients undergo superovulation, and in vitro fertilization is attempted in all retrieved ova. Because the likelihood of a successful pregnancy increases according to the number of blastocysts transferred, as many as five blastocysts may be replaced ([Bradshaw and colleagues, 1992](#)). This practice not only increases multiple gestation, it increases the incidence of high-order multiples, that is, pregnancies with four or more fetuses.

High-order multiple gestation entails significant risk to both mother and fetuses (discussed later) and reduces the chances of both a live birth or the birth of a child without significant handicap. The only remedy is a selective reduction procedure, which also increases risk. Additionally, it is expensive. [Goldfarb and colleagues \(1996\)](#) estimated the combined costs of in vitro fertilization plus prenatal care and delivery was \$39,249 for singletons or twins, and this increased to \$342,788 for triplets or higher-order multiple gestations. Most of the costs for singletons or twins were attributed to in vitro fertilization, whereas most of the costs with triplets or more were due to intensive care. [Gleicher and co-workers \(1995\)](#) found that most couples considered the possibility of twins desirable, but higher-order multiple births were typically rejected because of the risks and costs.

The high morbidity and mortality associated with high-order multiples has motivated a concerted effort by the reproductive endocrinology community to reduce the incidence of this outcome, with favorable results. It has been shown that the chances of a live birth increase along with the number of eggs successfully fertilized, presumably because it improves the selection of embryos for transfer ([Templeton and Morris, 1998](#)). Selection is further improved by culturing the embryos for 5 days to the blastocyst stage, because it allows identification of the most viable blastocysts and an acceptable chance of pregnancy with the transfer of fewer embryos ([Scholtes and Zeilmaker, 1996](#)). This and similar data have led to a protocol in which many eggs are retrieved, fertilized, and grown to the blastocyst stage, but then only one to three of the healthiest are transferred. Two-embryo transfer for women with a good prognosis has been advocated as a way to maintain the successful pregnancy rate while decreasing the number of high-order multiples ([Meldrum and Gardner, 1998](#)). This has been promoted by the [American Society for Reproductive Medicine \(1999\)](#). Less intensive gonadotropin stimulation, another strategy to reduce high-order multiple pregnancy, has proved of limited value ([Gleicher and colleagues, 2000](#)).

SEX RATIOS WITH MULTIPLE FETUSES. The percentage of male conceptuses in the human species decreases as the number of fetuses per pregnancy increases. [Strandskov and co-workers \(1946\)](#) found the sex ratio, or percentage of males, for 31 million singleton births in the United States to be 51.6 percent. For twins it was 50.9 percent; for triplets, 49.5 percent; and for quadruplets, 46.5 percent. There is an even greater excess of females in twins resulting from late twinning events. Seventy percent of monozygotic-monoamniotic twins and 75 percent of conjoined twins are female ([Machin, 1996](#)). Two explanations have been offered. First, there is a well-known differential fetal mortality between the sexes, which persists for the newborn infant, child, and adult. Survival is always in favor of the female and against the male. The population pressure with multiple fetuses in utero may exaggerate the biological tendency noted in singleton pregnancies. A second explanation is that the female-producing zygote has a greater tendency to divide into twins, triplets, and quadruplets.

DETERMINATION OF ZYGOSITY. The main reason to determine zygosity antenatally is that it is beneficial in assessing obstetrical risks as well as guiding management of multiple gestations ([Fisk and Bryan, 1993](#)). Twin-specific complications in relation to zygosity are summarized in [Table 30-3](#). Clearly, monozygotic twin gestations are at increased risk for a variety of pregnancy complications, some of which may be minimized by early antepartum diagnosis and treatment. Of particular importance are those monozygotic twins with shared circulation (twin-to-twin transfusion syndrome), shared amniotic sac (cord entanglement), and shared organs (conjoined twins).

Another important reason to encourage determination of zygosity is that this knowledge may facilitate inter-twin organ transplantation later in life. Determination of zygosity frequently requires sophisticated genetic tests because dizygotic twins can look alike, while monozygotic twins are not always identical. Monozygotic twins may actually be discordant for genetic mutations as the result of a postzygotic mutation, or may have the same genetic disease but with marked variability in expression. In female fetuses, skewed lyonization can produce differential expression of X-linked traits or diseases. Most interestingly, monozygotic twins may be discordant for malformations which involve asymmetrical organs. For example, a fetus who is the mirror image of his twin may have a heart defect caused by reversed looping or laterality ([Machin, 1996](#)).

SONOGRAPHIC EVALUATION. Zygosity can be determined prenatally only if the fetuses are monoamniotic or monochorionic. Dichorionic, diamniotic twins may be either dizygotic or monozygotic. A third of monozygotic twins have dichorionic placentas, separate or fused ([Machin, 1996](#)). For obstetrical reasons, it is more important to determine the number of chorions. Chorionicity can be determined as early as the first trimester using multiple sonographic signs. The presence of two separate placental sites and a thick dividing membrane that generally is 2 mm or greater ([Fig. 30-6A](#)) supports dichorionicity. Fetuses of opposite gender are almost always dizygotic as well ([Mahony and co-workers, 1985](#)).

In pregnancies in which there is a single placental mass, it may be difficult to distinguish one large placenta from two placentas lying side by side or "fused." In this situation it is important to examine the point of origin of the dividing membrane on the placental surface. If there is a triangular projection of placental tissue extending beyond the chorionic surface between the layers of the dividing membrane—termed the "twin peak" sign—there are actually two fused placentas present ([Fig. 30-6B](#)).

Monochorionic pregnancies have a dividing membrane that is so thin it may not be visualized at all until the second trimester. The membrane is generally less than 2 mm in thickness, and magnification reveals only two layers ([Scardo and associates, 1995](#)). As shown in [Figure 30-7](#), ultrasonic evaluation of the dividing membrane is easiest and most accurate in the first half of pregnancy when the fetuses are smaller ([Stagiannis and colleagues, 1995](#)). A monochorionic pregnancy with discordant amniotic fluid volume, discordant fetal size, and little or no change in the position of one twin, should raise suspicion of twin-twin transfusion syndrome (discussed later). [Scardo and colleagues \(1995\)](#) used the combination of placental location, dividing membrane thickness, presence or absence of the twin peak sign, and fetal gender to determine the chorionicity, amnionicity, and zygosity in 110 consecutive twins at midgestation. Compared to the pathological diagnosis made by examining the placenta after delivery, the ultrasound determination had 91 percent sensitivity and specificity. In 35 percent of cases, however, zygosity could not be determined even by placental pathology, emphasizing that determination of zygosity often requires sophisticated genetic testing.

PLACENTAL EXAMINATION. A knowledgeably performed examination of the placenta and membranes serves to establish zygosity promptly in about two thirds of cases. The following system for examination is recommended: As the first infant is delivered, one clamp is placed on the portion of the cord coming from the placenta ([Fig. 30-8](#)). Cord blood is not collected until after delivery of the co-twin, unless it has been clearly shown that there are two placentas. As the second infant is delivered, two clamps are placed on that cord. Three clamps are used to mark the cord of a third infant, and so on as necessary. Until the delivery of the last fetus is completed, it is important that each cord segment remain clamped to prevent hemorrhage through anastomoses in the placenta.

Delivery of the placenta should be accomplished with care to preserve the attachment of the amnion and chorion to the placenta, because identification of the relationship of the membranes to each other is critical. With one common amniotic sac, or with juxtaposed amnions not separated by chorion arising between the fetuses, the infants are monozygotic. If adjacent amnions are separated by chorion, the fetuses could be either dizygotic or monozygotic, but dizygosity is more common ([Figs. 30-4, 30-9, and 30-10](#)). If the infants are of the same sex, blood typing of cord blood samples might be helpful. Different blood types confirms dizygosity, although demonstrating the same blood type in each fetus is not enough to confirm monozygosity. For definitive diagnosis, more complicated techniques such as DNA fingerprinting can be used, but these tests are generally not performed at birth unless there is a pressing medical indication ([Azuma and associates, 1989](#)).

INFANT SEX AND ZYGOSITY. Twins of opposite sex are almost always dizygotic. Very rarely, monozygotic twins may be discordant for phenotypic sex. This occurs when one twin is phenotypically female due to Turner syndrome (45,X) and its sibling is 46,XY.

DIAGNOSIS OF MULTIPLE FETUSES

Widespread use of prenatal ultrasound imaging has greatly decreased the incidence of overlooked twin gestations prior to delivery.

ULTRASOUND

By careful ultrasonic examination, separate gestational sacs can be identified very early in twin pregnancy ([Fig. 30-11](#)). Subsequently, the identification of each fetal head should be made in two perpendicular planes so as not to mistake a cross-section of the fetal trunk for a second fetal head. Ideally, two fetal heads or two abdomens should be seen in the same plane, to avoid scanning the same fetus twice and interpreting it as twins. Sonographic scanning should detect practically all sets of twins. Indeed, one argument in favor of routine ultrasound screening is earlier detection of multiple fetuses ([Chap. 41, p. 1113](#)). In the Routine Antenatal Diagnostic Imaging and Ultrasound Study (RADIUS), [LeFevre and co-workers \(1993\)](#) randomized 7617 women to undergo ultrasound examinations at 18 to 20 weeks and again at 31 to 35 weeks. Another 7534 women were randomized to undergo ultrasound scanning only when clinically indicated. Virtually all multiple gestations (99 percent) were diagnosed before 26 weeks when routine ultrasound was used compared with 62 percent in women scanned only for specific indications. A total of 87 percent of multiple gestations were ultimately diagnosed sonographically before labor in these latter women. Higher-order multiple gestations are harder to evaluate. Even in the first trimester it can be difficult to determine the correct number of fetuses and their position, which is important for nonselective pregnancy reduction and essential for selective termination (discussed later).

HISTORY AND CLINICAL EXAMINATION

A maternal family history of twins, older maternal age, high parity, large maternal size, and a previous history of twins provide weak clues, but knowledge of recent administration of either clomiphene or gonadotropins or pregnancy accomplished by assisted reproductive technology provide strong ones.

Clinical examination with accurate measurement of fundal height, as described in [Chapter 10 \(p. 228\)](#), is essential. During the second trimester, the uterine size is larger than expected for gestational age determined from menstrual data. [Rouse and co-workers \(1993\)](#) measured fundal heights in 336 well-dated twin pregnancies. Between 20 and 30 weeks, fundal heights were on average about 5 cm greater than expected for singletons of the same fetal age.

In the case of a woman with a uterus that appears large for gestational age, the following possibilities are considered:

1. Multiple fetuses.
2. Elevation of the uterus by a distended bladder.
3. Inaccurate menstrual history.
4. Hydramnios.
5. Hydatidiform mole.
6. Uterine myomas.
7. A closely attached adnexal mass.
8. Fetal macrosomia late in pregnancy.

OTHER DIAGNOSTIC AIDS

A variety of techniques may be used to clinically suspect or diagnose multifetal gestation.

FETAL PARTS. When uterine palpation leads to diagnosis of twins, it is most often because two fetal heads have been detected, often in different uterine quadrants. In general, however, it is difficult to diagnose twins by palpation of fetal parts before the third trimester. Even late in pregnancy it may be very difficult to identify twins by transabdominal palpation, especially if one twin overlies the other, if the woman is obese, or if hydramnios is present.

FETAL HEART SOUNDS. Late in the first trimester, fetal heart action may be detected with generally available Doppler ultrasonic equipment. Sometime thereafter it becomes possible to identify two fetal hearts if their rates are clearly distinct from each other as well as from that of the mother. It is possible by careful examination to identify fetal heart sounds in twins with the usual aural fetal stethoscopes at 18 to 20 weeks.

RADIOLOGICAL EXAMINATION. A radiograph of the maternal abdomen to try to demonstrate multiple fetuses can be helpful in rare circumstances, usually when there is a high-order multiple gestation and it is unclear how many fetuses are present. Even more rarely, one of the fetuses may be suspected of having a bone dysplasia best visualized radiologically. Radiographs are otherwise frequently not useful and may be responsible for an incorrect diagnosis for the following reasons:

1. The film is taken before 18 weeks when the fetal skeletons are insufficiently radiopaque.
2. The film is of poor quality from inappropriate exposure time or from malposition of the mother so that her upper abdomen and the fetus beneath are excluded from the x-ray.
3. The mother is obese.
4. There is hydramnios.
5. One or more fetuses moves during the exposure.

BIOCHEMICAL TESTS. The amounts of chorionic gonadotropin in plasma and in urine, on average, are higher than those found with a singleton pregnancy, but not so high as to allow a definite diagnosis of multiple fetuses. Twins are frequently diagnosed during an evaluation for an elevated maternal serum alpha-fetoprotein level, although this alone is not diagnostic ([Chap. 37, p. 980](#)). Currently, there is no biochemical test that in any individual case will reliably differentiate between the presence of one and more than one fetus.

MATERNAL ADAPTATION

In general, the degree of maternal physiological change is greater with multiple fetuses than with a single fetus. Beginning in the first trimester, women with multiple gestation often have nausea and vomiting in excess of that characterizing singleton pregnancies, for reasons that are not clear. The normal maternal blood volume expansion is greater in twin pregnancies ([Pritchard, 1965](#)). Whereas the average increase in late pregnancy is about 40 to 50 percent with a single fetus, it is about 50 to 60 percent with twins, which amounts to a maternal blood volume about 500 mL greater. The red cell mass increases as well, but proportionately less in twin pregnancies than in singletons, resulting in a more pronounced "physiological anemia." Women with twins have an average hemoglobin concentration of 10 g/dL from 20 weeks onward ([Campbell, 1986](#)). The average blood loss with vaginal delivery of twins is 935 mL, or nearly 500 mL more than with delivery of a single fetus. Both the remarkable increase in maternal blood volume and the increased iron and folate requirements imposed by a second fetus predispose to a greater prevalence of maternal anemia.

[Veille and associates \(1985\)](#) used M-mode echocardiography to assess cardiac function in women with twin pregnancies. As expected, cardiac output was increased compared with singleton pregnancy, but end-diastolic ventricular dimensions were the same. During the third trimester, cardiac output was increased as a result of both increased heart rate and increased stroke volume. Stroke volume was higher by virtue of increased fractional shortening, which suggests increased contractility. Women carrying twins also have a typical pattern of arterial blood pressure change. Compared with mothers of singletons, their diastolic blood pressure is lower at 20 weeks, and 74 percent have a diastolic pressure less than 80 mm Hg compared with 66 percent of singletons. This is followed by a greater rise in diastolic pressure between midpregnancy and delivery, and 95 percent of women with twins have a 15 mm Hg or greater increase compared with only 54 percent of singleton pregnancies ([Campbell, 1986](#)).

The larger size of the uterus with multiple fetuses intensifies the anatomical changes that occur during pregnancy. The uterus and its contents may achieve a volume of 10 L or more and weigh in excess of 20 pounds! Especially with monozygotic twins, rapid accumulation of grossly excessive amounts of amniotic fluid, that is, acute hydramnios, may develop. In these circumstances it is easy to envision appreciable compression and displacement of many of the abdominal viscera as well as the lungs by the elevated diaphragm. The size and weight of the very large uterus may preclude more than a very sedentary existence for the woman.

In multiple gestation complicated by hydramnios, maternal renal function may become seriously impaired, most likely as the consequence of obstructive uropathy. [Quigley and Cruikshank \(1977\)](#) described two pregnancies with twin fetuses plus acute and severe hydramnios in which oliguria and azotemia developed. Maternal urine output and plasma creatinine levels promptly returned to normal after delivery. In the case of severe hydramnios, therapeutic amniocentesis may be employed to provide relief for the mother and, it is hoped, to allow the pregnancy to continue ([Chap. 31, p. 820](#)). Unfortunately, the hydramnios is often characterized by acute onset remote from term and by rapid reaccumulation following amniocentesis.

The various stresses of pregnancy and the likelihood of serious maternal complications will almost invariably be greater with multiple fetuses than with a singleton. This should be taken into account, especially when counseling the woman whose health is compromised and whose multiple gestation is recognized early. The same is true for a woman who is not pregnant but is considering infertility treatment by ovulation induction or assisted reproductive technology.

PREGNANCY OUTCOME

ABORTION

Spontaneous abortion is more likely with multiple fetuses. Detailed reviews have identified three times more twins among aborted pregnancies when compared with the ratios at term ([Livingston and Poland, 1980](#); [Uchida and co-authors, 1983](#)). Monozygotic twins greatly outnumber dichorial twins by 18 to 1, implicating monozygosity as a risk factor for spontaneous abortion. Anomalies and chromosomal errors, as in singletons, are also often found in twin abortuses.

MALFORMATIONS

The incidence of congenital malformations is appreciably increased in twin and higher-order multiple gestations compared with singletons. Major malformations occur in 2 percent and minor malformations in 4 percent of twins. ([Cameron and colleagues, 1983](#); [Kohl and Casey, 1975](#)). This increase is almost entirely due to the high incidence of structural defects in monozygotic twins. According to [Schinzel and associates \(1979\)](#), anomalies in monozygotic twins generally fall into one of three categories:

1. Defects resulting from twinning itself, which some consider to be a teratogenic event. This category includes conjoined twins, amorphous twins, sirenomelia, neural-tube defects, and holoprosencephaly.
2. Defects resulting from vascular interchange between monochorionic twins. Vascular connections can give rise to reverse flow with acardia in one twin, or if one twin dies, intravascular coagulation with embolization to the living twin can cause defects such as microcephaly, hydranencephaly, intestinal atresia, aplasia cutis, or limb amputation.
3. Defects that occur as the result of crowding. Examples include talipes or congenital hip dislocation.

Dizygotic twins can have malformations of the type that occur in singletons as well as defects due to crowding. [Baldwin \(1991\)](#) has comprehensively reviewed anomalies occurring in twins.

Persistent or chronic hydramnios is more likely to be associated with fetal anomalies of one or both twins. [Hashimoto and colleagues \(1986\)](#) subjectively identified increased amniotic fluid in a fourth of twin pregnancies. In half, hydramnios at midpregnancy was transient, and all of these fetuses were normal. In the 10 pregnancies in which hydramnios persisted, nine fetuses had anomalies.

BIRTHWEIGHT

Multifetal gestations are more likely to be characterized by low birthweight than singletons, due mostly to restricted fetal growth and preterm delivery ([Buekens and Wilcox, 1993](#)). In general, the larger the number of fetuses, the greater the degree of growth restriction. Two thirds of twin and even more triplet pregnancies are complicated by fetal growth restriction. However, this assessment of growth is based on growth curves established for singletons. Several authorities have made the argument that fetal growth in multiple gestation is different from that of singletons, and that abnormal growth should be diagnosed only when fetal size is less than expected for *multiple gestation*. Triplet growth curves have been created for this purpose ([Rodis and associates, 1999](#)). In dizygotic pregnancies, marked size discordance usually results from unequal placentation, with one placental site receiving a better blood supply than the other, but can also reflect different genetic growth potentials. In the third trimester, the larger fetal mass leads to advanced placental maturation and relative placental insufficiency. Size discordance can also be caused by umbilical cord abnormalities such as velamentous or marginal insertion or vasa previa, or discordance for malformations, genetic syndromes, or infection. [Figure 30-12](#) shows dizygotic twins, one of whom weighed 2300 and the other 785 g, delivered at Parkland Hospital. Both survived, but one remains appreciably smaller than the other.

The degree of growth restriction in monozygotic twins is likely to be greater than in dizygotic pairs. For example, the quintuplets shown in [Figure 30-13](#) represent three dizygotic and two monozygotic fetuses. When delivered at 31 weeks, the three infants from separate ova weighed 1420, 1530, and 1440 g, whereas the two derived from the same ovum weighed 990 and 860 g. Monozygotic twins are also more likely to be discordant in size. At the time of the split, the allocation of blastomeres may not be equal between the two embryos, vascular communications within a monochorionic placenta may cause unequal distribution of nutrients and oxygen, and discordant structural anomalies resulting from the twinning event itself may affect growth.

Twin fetuses have been of particular interest to investigators seeking clues on the relative roles of nature versus nurture in human fetal growth. Excluding anomalies, fetal gender influences, and birthweight disparity due to placental insufficiency or vascular communications, restricted fetal growth of twins appears to be primarily a result of diminished nurture during the third trimester. [Figure 30-14](#) compares birthweights in more than 500,000 male singleton infants with more than 10,000 male twin infants. Twin birthweights closely parallel singletons until about 28 to 30 weeks, when twins begin to become progressively smaller than singletons. At approximately 34 to 35 weeks and thereafter, twin birthweights clearly diverge from singletons. Interestingly, it is also at this stage of gestation when the combined weight of twin fetuses reaches 4000 to 5000 g, the latter weight being quite rare in singletons. For example, only 2 per 1000 births at Parkland Hospital in 1999 weighed more than 5000 g.

Thus, the empirical upper fetal growth limit for singletons, and presumably upper limit of maternal support capacity, occurs at about 34 or 35 weeks in twin gestation. Moreover, twin growth restriction intensifies as the third trimester continues, such that at 38 weeks or later, the incidence of overt growth restriction quadruples to include almost half of twin births.

There is other circumstantial evidence that in utero crowding by multiple fetuses affects nurture, presumably by overtaxing the capacity of the mother, the uterus, or both to provide nutrients. For example, both [Lipitz and co-workers \(1996\)](#) and [Smith-Levitin and colleagues \(1996\)](#) have reported that selective reduction of triplets to twins before 12 weeks results in a growth pattern typical of twins rather than triplets, which are typically growth restricted compared with twins. Thus, the number of fetuses residing in the uterus later in pregnancy, and not their embryonic potential, seems to govern growth. Another example that the maternal supply line is affected by the number of fetuses is provided by [Casele and co-authors \(1996\)](#) in their studies of maternal metabolic responses to eating and extended overnight fasting. Women with twins were more vulnerable to starvation ketosis after fasting compared with women with singleton pregnancies. This finding suggests that more maternal metabolic resources are funneled to twin fetuses.

DURATION OF GESTATION

As the number of fetuses increases, the duration of gestation decreases ([Fig. 30-15](#)). Approximately half of twins deliver at 36 weeks or less. The mean age at delivery of triplets is 33.5 weeks, with 90 percent, 24 percent, and 8 percent delivered before 37, 32, and 28 weeks, respectively ([Berkowitz and colleagues, 1996](#)). The average age at delivery was 31 weeks in 37 quadruplet pregnancies ([Barton and colleagues, 1996](#)).

PRETERM BIRTH

Delivery before term is the major reason for the increased risk of neonatal death and morbidity in twins. [Gardner and associates \(1995\)](#) found that the causes of preterm birth differed between twins and singletons. Spontaneous preterm labor accounted for a larger proportion of twins delivered before 37 weeks compared with singletons, whereas the reverse was true for preterm ruptured membranes. Indicated preterm delivery accounted for equal proportions of prematurely delivered twins and singletons. Maternal hypertension, fetal growth restriction, and placental abruption were the main indications for preterm delivery of twins.

Although the causes of preterm delivery in twins and singletons may be different, once delivered the neonatal outcome is generally the same at similar gestational ages. [Gardner and colleagues \(1995\)](#) compared neonatal outcomes of preterm twin infants with preterm singletons delivered at the same gestational ages and found that preterm twins did not have significantly more respiratory distress syndrome, intraventricular hemorrhage, or necrotizing enterocolitis than same-gestational-age singletons. Similar findings were reported by [Kilpatrick and colleagues \(1996\)](#). Thus, the primary neonatal problem with twin gestation is simply more frequent preterm delivery, not increased vulnerability to the morbidity of preterm delivery.

The previous statements apply to twins who are essentially concordant. As one would expect, the neonatal outcome for preterm twins who are markedly discordant may not be comparable to that of singletons because whatever caused the discordance may have long-lasting effects. [Sonntag and co-workers \(1996\)](#) compared 27 weight-discordant twin pairs to 72 concordant twins. They found that the discordant twins had a significantly higher neonatal mortality (19 versus 2 percent), and were more likely to have severe intracranial hemorrhage and persistent ductus arteriosus. Most of the increase in morbidity and mortality was due to the sequelae of chronic twin-twin transfusion, and nearly half of the discordant pairs fulfilled the criteria for this disorder.

PROLONGED PREGNANCY

Is there a safe upper limit of twin gestation? More than 30 years ago [Bennett and Dunn \(1969\)](#) suggested that a twin pregnancy of 40 weeks or more should be considered postterm. This was based on the observation that twin stillborn infants delivered at 40 weeks or beyond had features similar to postmature singletons ([Chap. 28, p. 738](#)). [Kiely \(1990\)](#) later reported that twins born at 40 weeks or more were actually lighter than those born at 38 to 39 weeks, suggesting that intrauterine growth for twins stops after 39 weeks. Similarly, [Luke and colleagues \(1993\)](#) as well as [Minakami and Sato \(1996\)](#) concluded that twins were postterm after 38 weeks. They arrived at this conclusion because the incidence of fetal growth restriction and associated morbidity increased significantly in twins delivered between 39 and 41 weeks compared with delivery at 38 weeks or less. At Parkland Hospital, twin gestations have empirically been considered for many years to be prolonged at about 40 weeks gestation.

SUBSEQUENT DEVELOPMENT

In Norway, [Nilsen and associates \(1984\)](#) evaluated the physical and intellectual development of male twins at 18 years of age. Compared with singletons, twice as many twins were found to be physically unfit for military service. They attributed this to sequelae of preterm delivery such as visual impairment rather than twinning. General intelligence did not appear to differ.

At least one study has suggested that long-term physical development might be different for twins. [Silva and colleagues \(1982, 1985\)](#) carefully monitored 24 twins up to 11 years of age, and compared their outcomes to 1013 singletons who had similar gestational ages and weights at birth and who experienced similar antenatal and neonatal complications. Twins had delays in achieving developmental milestones, and at age 11 years lagged behind singletons in intelligence quotient (IQ) scores. At each age twins were similar in height to singletons 3 months younger, and similar in weight to singletons 6 months younger.

The pattern of subsequent development of discordant twins varies. For example, [Babson and Phillips \(1973\)](#) reported that in monozygotic twins whose birthweights differed on the average by 35 percent, the twin who was smaller at birth remained so into adulthood. Height, weight, head circumference, and intelligence often remained superior in the twin who weighed more at birth. [Fujikura and Froelich \(1974\)](#), however, failed to confirm a significant difference in mental and motor scores.

[Baigts and co-workers \(1982\)](#) studied 17-year-old monozygotic twins who had body frames that were similar, but who were remarkably dissimilar in weight, as they were at birth. The investigators documented hyperplasia of adipocytes in the heavier twin compared with her lighter sister. They suggested that intrauterine nutritional status helps to determine adipocyte numbers and the way the body evolves. Others have concluded that genetic heritage in twins is more important than environment in determining body mass ([Bouchard and co-workers, 1990](#); [Stunkard and co-workers, 1990](#)).

UNIQUE COMPLICATIONS

There are a number of unique complications that occur in multiple fetuses. While these have been best described in twins, they also occur in higher-order multiple gestations.

MONOAMNIONIC TWINS

There is an extremely high fetal death rate with the relatively rare variety of monozygous twinning in which both fetuses occupy the same amniotic sac. A common cause of death is intertwining of their umbilical cords, which has been estimated to complicate at least half of cases. An example is provided in [Figure 30-16](#). Approximately 1 percent of monozygotic twins are monoamniotic. Diamniotic twins can become monoamniotic, and have all the associated morbidity and mortality, if the dividing membrane ruptures ([Gilbert and colleagues, 1991](#)).

Once diagnosed, management of monoamniotic twins is somewhat problematic due to the unpredictability of fetal death resulting from cord entanglement and the lack of an effective means of monitoring for it. There are some data that suggest that morbid cord entanglement is likely to occur early, and that monoamniotic pregnancies that have successfully reached 30 to 32 weeks are at greatly reduced risk. [Carr and co-authors \(1990\)](#) reviewed 24 sets of monoamniotic twins where all the fetuses were known to be alive before 18 weeks. At 30 weeks, 70 percent of the fetuses were alive and there were no additional deaths prior to delivery at an average of 36 weeks. They concluded that the risks due to early delivery to prevent cord accidents outweighed the risks of fetal death from cord entanglement, especially after 30 weeks. A similar experience was reported by Tessin and Zlatnik (1991) in their description of 20 monoamniotic twin pregnancies at the University of Iowa Hospital. There were no fetal deaths after 32 weeks, again suggesting that prophylactic preterm delivery may not be indicated in all cases.

Umbilical cord entanglement occurs frequently, but the factors that lead to pathological umbilical vessel constriction during entanglement are unknown. [Belfort and colleagues \(1993\)](#) and [Aisenbrey and co-workers \(1995\)](#) used color-flow Doppler ultrasonography to diagnose umbilical cord entanglement in 10 monoamniotic twin pregnancies. The recognition of cord entanglement in seven of these pregnancies prompted hospital admission, increased fetal surveillance, or both. Interestingly, only one set of entangled twins required immediate delivery. In fact, the pregnancies continued for an average of 6 weeks after the diagnosis, and one pregnancy continued for 12 weeks!

CONJOINED TWINS

In the United States, united or conjoined twins are commonly referred to as Siamese twins, after Chang and Eng Bunker of Siam (Thailand), who were displayed worldwide by P. T. Barnum. If twinning is initiated after the embryonic disc and the rudimentary amniotic sac have formed, and if division of the embryonic disc is incomplete, conjoined twins result (see [Fig. 30-2](#)). When each of the joined twins is nearly complete, the commonly shared body site may be:

1. Anterior (thoracopagus).
2. Posterior (pyopagus).
3. Cephalic (craniopagus).
4. Caudal (ischiopagus).

The majority are of the thoracopagus variety ([Figs. 30-17](#) and [30-18](#)).

When the bodies are duplicated only partly, the attachment is usually lateral. The incomplete division of the embryonic disc may begin at either or both poles and produce two heads; two, three, or four arms; two, three, or four legs; or some combination thereof. The frequency of conjoined twins is not well established. At Kandang Kerbau Hospital in Singapore, [Tan and co-workers \(1971\)](#) identified seven cases of conjoined twins among somewhat more than 400,000 deliveries (1 in 60,000).

As reviewed by [van den Brand and associates \(1994\)](#), the diagnosis of conjoined twins can frequently be made at midpregnancy using sonography, which allows the parents to decide whether or not to continue the pregnancy. A thorough targeted ultrasound examination, including a careful evaluation of the point of connection and the organs involved, is essential before counseling is provided. Surgical separation of nearly complete conjoined twins may be successful when organs essential for life are not shared. Chang and Eng Bunker, for example, were reportedly connected only by a thin bridge of tissue containing abdominal wall structures and possibly some liver. Consultation with a pediatric surgeon often facilitates parental decision making. It must also be remembered that monozygotic twins are at increased risk to be discordant for structural malformations, most likely because the process of twinning is a teratogenic event which disturbs the timing of normal developmental processes. As a result, conjoined twins may have discordant structural anomalies that further complicate decisions about whether or not to continue the pregnancy. For example, one of the conjoined twins shown in [Figure 30-19](#) was anencephalic. Vaginal delivery of conjoined twins for the purpose of pregnancy termination is possible because the union is most often pliable, although dystocia is common. If the fetuses are mature, vaginal delivery may be traumatic.

ACARDIAC TWIN

Twin reversed-arterial-perfusion (TRAP) sequence is a rare (1 in 35,000 births), but serious complication of monochorionic, monozygotic multiple gestation. In the [TRAP¹](#) sequence, there is usually a normally formed donor twin who has features of heart failure, and a recipient twin without a normal heart (acardius) and missing various other structures ([van Allen and colleagues, 1983](#)). It has been hypothesized that the TRAP sequence is caused in the embryo by a sizable artery-to-artery placental shunt, often accompanied by a vein-to-vein shunt. The perfusion pressure of one twin overpowers the other who then has reverse blood flow from the co-twin ([Jones, 1997](#)). The "used" arterial blood reaching the recipient twin preferentially goes to the iliac vessels and thus perfuses only the lower part of the body, leading to disruption or deterioration of growth and development of the upper body. Failure or disrupted growth of the head is called *acardius acephalus*; a partially developed head with identifiable limbs is called *acardius myelacephalus*; and failure of any recognizable structure to form is *acardius amorphous* ([Robie and colleagues, 1989](#)). An example of an acardiac twin is shown in [Figure 30-20](#). It demonstrates acephalus as well as complete malformation of the upper torso. Without treatment the pump twin dies in 50 to 75 percent of cases ([Moore and colleagues, 1990](#)). Recently, [Norwitz and associates \(2000\)](#) described prenatal planning for neonatal surgery using three-dimensional modeling with magnetic resonance imaging.

[Quintero and colleagues \(1994\)](#) have reviewed methods of in utero treatment of acardiac twinning where the goal is interruption of the vascular communication between the pump and recipient twins. They also have described successful use of transabdominal fetoscopy to ligate the umbilical cord of 11 acardiac twins at approximately 21 weeks ([Quintero and co-authors, 1996](#)).

VASCULAR COMMUNICATIONS BETWEEN FETUSES

With rare exceptions, vascular communications between twins are present only in monochorial placentas ([Baldwin, 1991](#); [Robertson and Neer, 1983](#)). Nearly 100 percent of monochorial placentas have vascular anastomoses, but there is marked variation in the number, size, and direction of these seemingly haphazardly formed connections. Artery-to-artery anastomoses on the chorionic surface of the placenta have been identified in up to 75 percent of monochorial placentas and are the commonest pattern ([Fig. 30-21](#)). Vein-to-vein and artery-to-vein communications are each found in approximately 50 percent of similar placentas. One vessel may have several connections, sometimes to both arteries and veins. In contrast to these vascular connections on the surface of the chorion, there are artery-to-vein communications through the capillary bed of the villous tissue of the placenta. These deep arteriovenous anastomoses create a common villous district or third circulation that has been identified in approximately half of monochorial placentas ([Fig. 30-22](#)).

Most of these vascular communications are hemodynamically balanced and of little fetal consequence. Rarely, however, they can cause hemodynamically significant shunts between fetuses. There are two patterns of hemodynamically significant anastomotic circulations: acardiac twinning (see preceding description) and the twin-to-twin transfusion syndrome. The incidence of the latter syndrome is unclear, but up to approximately a fourth of monochorial twins have some clinical features

of this syndrome ([Galea and co-workers, 1982](#)).

TWIN-TO-TWIN TRANSFUSION SYNDROME. Blood is transfused from the donor twin to its recipient sibling such that the donor becomes anemic and its growth may be restricted, while the recipient becomes polycythemic and may develop circulatory overload manifest as hydrops. As shown in [Figure 30-23](#), the donor twin is pale and its recipient sibling is plethoric. Similarly, one portion of the placenta often appears quite pale compared with the rest of the placenta.

The neonatal period may be complicated by dangerous circulatory overload with heart failure if severe hypervolemia and hyperviscosity are not identified promptly and treated. Occlusive thrombosis is also much more likely to develop in this setting. Polycythemia may lead during the neonatal period to severe hyperbilirubinemia and kernicterus ([Chap. 39, p. 1067](#)).

PATHOPHYSIOLOGY. [Bajoria and colleagues \(1995\)](#) perfused 30 monochorial placentas with anticoagulant solution immediately after delivery and then delineated anastomoses by dye-contrast injection. Ten were from pregnancies with evidence of midtrimester twin-to-twin transfusion syndrome and 10 were from monochorial twin pregnancies without this complication. The vascular communications found in these two groups were remarkably different. Those without twin-to-twin transfusion syndrome had multiple superficial anastomoses. In contrast, those with the twin-to-twin transfusion syndrome had solitary, deep arteriovenous capillary channels within the villous tissue. [Bajoria and colleagues \(1995\)](#) hypothesized that multiple superficial vascular communications were protective against the transfusion syndrome because this arrangement permitted bi-directional, and thus, balanced, blood flow. Conversely, the single deep arteriovenous villous anastomoses without multiple superficial connections were one-way arteriovenous shunts from a donor fetus to its recipient sibling, and thereby hemodynamically imbalanced.

There are other data to suggest that placental pathophysiology may be more complex. [Bendon \(1995\)](#) injected 21 monochorionic placentas from live-born twins, scored surface vessel anastomoses and venous return areas, and correlated them with neonatal birthweight and hematocrit. Birthweight and hematocrit did not correlate with each other or with vessel anastomoses, and only the placental area allotted to each twin correlated with neonatal size.

This pathophysiological scenario does not explain all instances of twin-to-twin transfusion. [Hecher and colleagues \(1994\)](#) described two monochorial twin pregnancies with features of twin-to-twin transfusion syndrome in which Doppler was used to demonstrate artery-to-artery anastomoses and opposing pulsatile blood flows. Although there were intermittent episodes of flow reversal, there was no net forward flow from one fetus to the other that could account for a shift of blood from one fetus to its sibling. They postulated that the intermittent blood flow reversal or sudden hypotension in one twin could cause cerebral damage in the donor twin.

Another hemodynamic explanation for twin-to-twin transfusion syndrome was offered by [Fries and co-workers \(1993\)](#). They postulated that velamentous umbilical cord insertions may contribute to the development of unequal fetal blood volumes because the membranously inserted cord can be easily compressed, restricting blood flow to one twin. [Talbert and colleagues \(1996\)](#) used a computerized model to study the hemodynamics of unidirectional and bi-directional intertwin transfusion via placental anastomoses. They determined that the net direction of blood flow is determined by the donor arterial pressure and not the number of anastomoses, and that the fetal physiological response to the unequal blood volume, primarily relating to changes in urine production and colloid osmotic pressure, determines whether or not blood flow will be equilibrated.

FETAL BRAIN DAMAGE. Cerebral palsy, microcephaly, porencephaly, and multicystic encephalomalacia are serious complications associated with vascular communications in twin gestations. It is most likely that such neurological damage is caused by ischemic necrosis leading to cavitory brain lesions. In the donor twin, ischemia results from hypotension and/or anemia. In the recipient, ischemia is from blood pressure instability and episodes of severe hypotension ([Larroche and colleagues, 1990](#)). [Denbow and colleagues \(1998\)](#) reviewed 17 sets of live-born, monochorionic twins who had twin-to-twin transfusion syndrome and found that one had a cerebral infarction and 10 had other antenatally acquired cerebral lesions; both donors and recipients were affected.

Cerebral pathology may occur after the death of one twin. In this case, damage may be due to emboli of thromboplastic material originating in the dead fetus, but more likely results from acute hypotension at the time of death ([Benirschke, 1993](#)). [Fusi and co-workers \(1990, 1991\)](#) observed that at the time of death of one twin fetus, acute twin-to-twin anastomotic transfusion from the high-pressure vessels of the living twin to the very low resistance vessels of the dead twin leads to rapid hemodynamic changes and ischemic antenatal brain damage in the survivor. This group described eight monochorial twin pregnancies in which one twin died but the pregnancy continued. Careful follow-up showed that none developed disseminated intravascular coagulopathy, and yet there was a high frequency of neurological damage. [Pharoah and Adi \(2000\)](#) surveyed 348 survivors whose co-twin had died in utero. The prevalence of cerebral palsy was 83 per 1000 live births—a 40-fold risk. [Okamura and colleagues \(1994\)](#) performed cordocentesis on seven surviving twin fetuses within 24 hours of sibling death. They found acute anemia in the surviving twin, and hypothesized that cerebral abnormalities in survivors were produced by hypotensive cerebral ischemia due to acute hemorrhage through placental vascular channels. Such sibling brain damage has been reported following death of one fetus as early as 16 weeks ([Anderson and co-workers, 1990](#)).

The pathological importance of hemodynamic fluctuation and fetal response, reflected by urine output, in causing brain damage was shown by [Bejar and co-workers \(1990\)](#). They reviewed neonatal echoencephalographic studies in 89 twins and 12 triplets and diagnosed antenatal necrosis of cerebral white matter in 15 percent of the infants ([Fig. 30-24](#)). The neurological damage was linked to hydramnios, co-twin fetal death, hydrops, and multiple vascular connections. The most important factor in this study appeared to be vein-to-vein anastomosis within the placenta, because 90 percent of such infants had brain damage. [Denbow and colleagues \(2000\)](#) confirmed this and reported that arterioarterial anastomoses are usually harmless.

The acute nature of the twin-to-twin transfusion and hypotension following the death of one twin makes successful intervention after the death nearly impossible. Even with delivery immediately after the demise is recognized, the hypotension that occurs at the moment of death has likely already caused irreversible damage ([Langer and associates, 1997](#); [Wada and co-authors, 1998](#)).

DIAGNOSIS. The diagnosis of twin-to-twin transfusion syndrome, whether made antenatally or postnatally, is problematic. The postnatal diagnosis was classically made based on an intertwin weight discordance of 15 or 20 percent and a hemoglobin difference of 5 g/dL or greater, with the smaller twin being anemic. It is now recognized, however, that significant intertwin weight differences can have a variety of etiologies such as discordance for anomalies, infection, or placental support. Also, hemoglobin discordance can occur acutely at the time of delivery. [Wenstrom and colleagues \(1992\)](#) illustrated this by reviewing the birthweights and hemoglobin concentrations in 97 monochorionic twin pregnancies. They found that 37 percent of weight concordant twins and 50 percent of discordant twins had a significant hemoglobin discordance. Twin B had the higher value in 63 percent, including a third of the discordant twins in which twin B was the smaller, suggesting that the hemoglobin discordance was due to acute transfusion after the delivery of twin A and before the delivery of twin B. Although this pattern met the criteria for twin-to-twin transfusion, it was not clinically important because it was an acute phenomena. Classical features of twin-to-twin transfusion, namely weight discordance with the smaller twin being anemic, occurred in only 11 of these 97 twin pairs. [Danskin and Neilson \(1989\)](#) also concluded that this syndrome cannot be established definitively if based solely upon birthweight or newborn hemoglobin differences.

Clinically important twin-to-twin transfusion syndrome is chronic, and results from significant antenatal vascular volume discrepancies between the twins. The syndrome typically presents in the midtrimester when the donor fetus becomes oliguric due to decreased renal perfusion ([Mari and co-authors, 1993](#)). This fetus develops oligohydramnios, while the recipient fetus develops severe polyhydramnios, presumably due to increased urine production. Virtual absence of amniotic fluid in the donor sac prevents fetal motion, giving rise to the description of **stuck fetus** ([Berry and co-workers, 1995](#)). This polyhydramnios-oligohydramnios combination can lead to growth restriction, contractures, and pulmonary hypoplasia in one twin, and premature rupture of the membranes and heart failure in the other.

The goal of antenatal diagnosis is to prevent fetal morbidity and mortality by selecting candidates for prenatal therapy or delivery. Antenatal criteria recommended for defining the twin-to-twin transfusion syndrome include the following: same sex fetuses, monochorionicity with placental vascular connections, intertwin weight difference greater than 20 percent, hydramnios in the large twin, oligohydramnios or stuck twin in the smaller twin, and hemoglobin difference greater than 5 g/dL ([Bruner and Rosemond, 1993](#)). All of these criteria except hemoglobin levels can be determined sonographically. Cordocentesis is required to measure hemoglobin concentration in each twin antenatally. [Berry and co-workers \(1995\)](#) performed cordocentesis on 38 twin pairs, and found when the intertwin hemoglobin difference was 2.5 g/dL or greater that all cases had stuck twin syndrome.

Shared circulation can also be confirmed in twin-to-twin transfusion syndrome by another invasive technique. Both [Bruner and Rosemond \(1993\)](#) and [Weiner and Ludomirski \(1994\)](#) have used adult red blood cells as a marker injected into the donor twin's umbilical vein, and then performed cordocentesis in the recipient twin to verify the presence of the adult cells.

In situations in which the diagnosis must be confirmed, for example before consideration of a high-risk therapy (see later discussion), such invasive testing is required because the sonographic diagnosis is sometimes incorrect. [Saunders and co-workers \(1991\)](#) used cordocentesis to show that none of four sets of monochorionic twins with all the sonographic features of twin-to-twin transfusion actually had discordant hemoglobin concentrations. [Bruner and Rosemond \(1993\)](#) used cordocentesis and adult red blood cell infusion to show that only four of nine monochorionic twin pregnancies with sonographic features of twin-to-twin transfusion actually had the syndrome. The cause of the discordant amniotic fluid volumes in these cases is unknown. When fetal hemoglobin concentrations have not been

determined antenatally, it may be more accurate to refer to this situation as the "stuck twin" syndrome or the "polyhydramnios-oligohydramnios syndrome," to acknowledge that twin-to-twin transfusion has not been confirmed as the cause of the sonographic findings.

THErapy AND OUTCOME. The prognosis for multiple gestations complicated by twin-to-twin transfusion syndrome is extremely guarded. Not only is brain damage a possibility, but antenatal death of one twin as well as neonatal death due to preterm delivery are other hazards. Generally, the earlier in gestation that twin-to-twin transfusion is diagnosed, the worse the prognosis ([Bebington and Wittmann, 1989](#)). Unfortunately, the most serious form of twin-to-twin transfusion syndrome, with acute hydramnios in one sac and a stuck twin with anhydramnios in the other sac, usually presents between 18 and 26 weeks. The survival rate for those diagnosed before 28 weeks has been reported to be between 20 and 45 percent ([Gonsoulin and co-workers, 1990](#); [Shah and Chaffin, 1989](#)).

Several therapies for twin-to-twin transfusion have been reported. Serial amnioreduction to decompress the hydramnios has the least risk. It is reported to be beneficial for at least two reasons. First, it relieves uterine overdistention and thus forestalls preterm labor ([Mahony and co-workers, 1990](#); [Pinette and colleagues, 1993](#)). Second, there is evidence that it may correct the hemodynamic inequalities by reducing intra-amniotic fluid pressure and placental compression, thus improving perfusion. [Bower and colleagues \(1995\)](#) used color flow Doppler imaging to evaluate uterine artery blood flow before and after amnioreduction in eight twin-to-twin transfusion pregnancies, seven singletons with acute hydramnios, and six controls. They found that quantitative blood flow increased by 75 percent after the procedure. [Garry and associates \(1996\)](#) have reported that use of repetitive decompression amniocentesis significantly reduced amniotic fluid pressure, and [Mari and co-workers \(1996\)](#) concluded, based on their experience in 24 twin pregnancies, that therapeutic amniocentesis was beneficial.

In contrast, [Bruner and Anderson \(1996\)](#) found decompression amniocentesis in eight pregnancies to be of no benefit to donor twins. [Gonsoulin and co-workers \(1990\)](#) also observed that amniocentesis for decompression failed to decrease perinatal mortality. There may be a pathological explanation for these therapeutic failures. For example, [Bajoria \(1998\)](#) correlated placental vascular anatomy with pregnancy outcome in 26 monochorial pregnancies treated by serial amnioreduction. He found that when the placenta had no superficial anastomoses, more procedures were required and were associated with a higher risk of fetal and neonatal death. It may be that amnioreduction improves pressure and blood flow primarily in superficial vessels, and is ineffective in pregnancies in which polyhydramnios-oligohydramnios is due to deeper vascular anastomoses.

Other more invasive therapies have been attempted. [De Lia and associates \(1990\)](#) reported the use of fetoscopic laser occlusion of placental vessels in severe twin-to-twin transfusion syndrome. The theoretical advantage is hemodynamic and hematological isolation of the living fetus, which could obviate embolic and hypotensive injury. The procedure is controversial in part because it results in occlusion of surface vessels only, and thus may not improve hemodynamics in placentas in which the offending anastomoses are deeper (as previously described). [Branisteanu-Demitrascu and co-workers \(1999\)](#), however, used a sheep model to show that laser coagulation of the superficial chorionic vessels leads to complete infarction of all treated cotyledons, and thus does eventually impact the deep vessels.

Laser occlusion entails more risk than amniocentesis and it is technically difficult. Placental vessel perforation was reported by [De Lia and colleagues \(1990\)](#). Their later report of 100 treated cases excluded outcome data from the first 33 procedures which were performed early on the "learning curve" ([De Lia and associates, 1999](#)). Fetal limb necrosis and skin loss have been reported ([Lundvall and co-workers, 1999](#); [Stone and colleagues, 1998](#)).

Despite these early concerns, accumulated data indicate that in experienced hands the procedure may be safe and beneficial. [Ville and colleagues \(1998\)](#) reported the results of a multicenter trial of laser coagulation in 132 pregnancies with severe, early twin-to-twin transfusion syndrome. There was at least one surviving fetus in 73 percent of cases, and at 1 year of age only six survivors were suspected of having a neurological handicap. A descriptive study of severe twin-to-twin transfusion syndrome by [Hecher and co-workers \(1999\)](#) compared 73 women treated with laser coagulation at one center with 43 similar patients treated with serial amnioreduction at another center. Although the overall fetal survival rate was not different, there was a higher proportion of pregnancies with at least one survivor in the laser group. This group also had fewer fetal deaths and abnormal sonographic findings in the brains of survivors. They also had higher birthweights, longer intervals-to-delivery, and longer gestational ages at delivery. [Zikulnig and co-workers \(1999\)](#) evaluated 121 cases treated with laser and found improved outcome with less severe stigmata of twin-to-twin transfusion before the procedure, and Doppler evidence of successful vessel ablation after the procedure. [Ryan \(2000\)](#) cited over 300 cases worldwide in his recent review. Serial amnioreduction is associated with 60 percent average survival, with 20 percent neurological disability in surviving infants. Laser ablation has a 75 to 80 percent survival of at least one twin, 5 to 60 percent for both, and a 5 percent neurological disability at 1 year of age.

Selective fetocide of one twin has also been reported. This has been considered when severe amniotic fluid and growth disturbances occur very early, generally before 20 weeks, and it is likely that both fetuses would die without intervention. Selection of the twin to be sacrificed has been based on evidence of fetal damage and comparison of each twin's prognosis. Because any substance injected into one twin may affect the co-twin, techniques have included saline cardiac tamponade followed by intracardiac potassium chloride, injection of an occlusive substance into the umbilical vein, or fetoscopic ligation, laser coagulation, or monopolar coagulation and bipolar cautery of the umbilical cord ([Challis and co-workers, 1999](#); [Donner and associates, 1997](#); [Weiner, 1987](#); [Wittmann and colleagues, 1986](#)). The complication rate after these procedures is high.

DISCORDANT TWINS. Unequal size of twin fetuses may be a sign of pathological growth restriction in one fetus, and is defined using the larger twin as the index. Generally, as the weight difference within a twin pair increases, perinatal mortality increases proportionately. Restricted growth of one twin fetus usually develops late in the second and early third trimester, and is often asymmetrical ([Leveno and co-workers, 1979](#)). Earlier discordancy is usually symmetrical and indicates higher risk; generally, the earlier in pregnancy discordancy is recognized, the more serious the sequelae. [Weissman and colleagues \(1994\)](#) diagnosed discordancy between 6 and 11 weeks in five twin gestations, and all of the smaller twins had major malformations.

PATHOLOGY. The cause of birthweight inequality in twin fetuses is often unclear, but evidence indicates that the etiology of discordance is different in monochorionic and dichorionic twins. In monochorionic twins, discordancy is usually attributed to placental vascular communications causing hemodynamic imbalance between the twins. Reduced pressure and perfusion of the donor twin may then cause its placental portion to fail to grow ([Benirschke, 1993](#)). Rarely, monochorionic twins are discordant in size because they are discordant for structural anomalies occurring during twinning.

Different etiologies are believed to cause discordance in dichorionic twins. One source of discordance is that dizygous fetuses have different genetic growth potential, especially if they are of opposite genders. It is also possible that, because the placentas are separate and require more implantation space, one of the placentas is likely to have a suboptimal implantation site. The observation that the incidence of discordance doubles in triplets compared with twins lends additional credence to the view that in utero crowding plays a role in fetal growth restriction ([Mordel and colleagues, 1993](#)).

[Eberle and co-workers \(1993\)](#) performed an evaluation of placental pathology in 147 twin gestations that provides important insight into the etiology of discordant twins. They quantified placental lesions usually associated with singleton growth restriction. Placentas from the smaller fetus in discordant dichorionic twin pairs demonstrated the lesions typical of singleton fetal growth restriction, whereas these lesions were not found in discordant monochorionic twin pairs.

Additional evidence supports that discordancy in dichorionic twins is due to placental insufficiency whereas that seen in discordant monochorionic twins is due to hemodynamic imbalance. [Rizzo and colleagues \(1994\)](#) used serial Doppler recordings to evaluate the fetal circulation in 15 women with discordant dichorionic twins compared with 10 discordant monochorionic twin pairs. Discordant dichorionic twins showed Doppler results similar to those described for singleton growth restriction due to placental insufficiency, whereas the smaller of discordant monochorionic twin fetuses had Doppler findings consistent with anemia.

DIAGNOSIS. There are two areas of uncertainty in detection of discordant twins. First, which ultrasonic anatomical measurements most reliably predict discordance? Second, what fetal weight difference is clinically significant?

Size discordancy between twins can be determined in several ways. One common method is to use all fetal measurements to compute the estimated weight of each twin, and then to compare the weight of the smaller twin to that of the larger twin (weight of larger twin minus weight of smaller twin, divided by weight of larger twin). Considering that growth restriction is the primary concern and the abdominal circumference reflects fetal nutrition, some authors diagnose discordance when there is more than 20 mm difference in abdominal circumferences. [Hill and colleagues \(1994\)](#) evaluated the sonographic assessment of twin discordancy and found that abdominal circumference was superior to head circumference, femur length, or transverse cerebellar diameter as the most useful index of unequal size fetuses.

Several different intertwin weight differences have been used to define discordance. Accumulated data suggest that a greater than 25 to 30 percent weight discordance, usually with growth restriction in one or both twins, most accurately predicts an adverse perinatal outcome. [Hollier and co-workers \(1999\)](#) retrospectively evaluated 1370 twin pairs delivered at Parkland Hospital and stratified twin discordance in 5 percent increments from 15 to 40 percent. They found that the incidence of respiratory distress, intraventricular hemorrhage, seizures, periventricular leukomalacia, sepsis, and necrotizing enterocolitis increased directly with the degree of discordance, with a large risk increase beginning at 25 percent discordance. The relative risk of fetal death increased significantly only when there was over 30 percent discordance, which was associated with a relative risk of 5.6 and increased to 18.9 at over 41 percent discordance.

MANAGEMENT. Sonographic monitoring of growth within a twin pair, which provides a means to detect growth disturbance and discordance, has become a mainstay in the management of twin gestations. Other sonographic findings, such as oligohydramnios in the smaller twin, may be helpful in gauging fetal risk. Additionally, discordance with growth restriction should prompt fetal heart rate testing or a biophysical profile to evaluate fetal well being. Delivery is not performed for size discordance alone, but is indicated if there is fetal stress unlikely to respond to intervention and the gestational age is such that survival is expected. Many authorities advise determination of fetal lung maturity before delivery of discordant twin fetuses where the only finding is difference in the ultrasonic estimates of fetal size.

DEATH OF ONE FETUS. On occasion, one fetus succumbs remote from term, but the pregnancy continues with one living fetus. Factors influencing pregnancy loss in twins have been described by [Rydholm \(1994\)](#), who used the Medical Birth Registry in Stockholm to review fetal death in 15,066 twin pairs weighing 500 g or more. Same sex twins were at highest risk. Loss of one or both twins occurred in 1.1 percent of opposite sex twins and 2.6 percent of same sex twins. Size discordance also increased the risk of loss. However, in opposite sex twins the risk of loss remained constant at 1.2 percent or higher until the discordance exceeded 40 to 50 percent or 1000 grams, while anything greater than a 20 percent or 250 g discordance increased the risk in same sex twins. After loss of one twin, the risk of subsequently losing the surviving twin was sixfold greater in same sex twins. Although chorionicity was not known in all cases, the authors estimated that the loss rate for same sex dizygotic twins was the same as for opposite sex twins (0.8 percent), and that monochorionic twins had the greatest risk of loss (3 percent). [Saito and co-workers \(1999\)](#) reviewed 481 twin pregnancies and reported that the risk of single fetal death in a twin pregnancy was 6.2 percent.

At delivery, the dead fetus with placenta and membranes may be identifiable but may be compressed appreciably (fetus compressus) or may be flattened remarkably through loss of fluid and most of the soft tissue (fetus papyraceous). The papyraceous fetus shown in [Figure 30-25](#) died at midpregnancy while the other fetus and placenta thrived. The dead fetus shown in [Figure 30-26](#) has become almost a shadow of itself compressed onto its placenta, which was separate from the placenta of the surviving twin.

Both the maternal risk and the prognosis for the surviving twin depend on the gestational age at the time of the demise, the chorionicity, and the length of time between the demise and delivery of the surviving twin. Early loss such as a "vanishing twin" does not appear to increase the risk of losing the surviving fetus after the first trimester. Selective reduction of a high-order multiple pregnancy (discussed later) increases the risk of losing the entire pregnancy but does not appear to increase the risk of other maternal or fetal complications.

Later in gestation, the death of one of multiple fetuses could theoretically trigger coagulation defects in the mother. Only a few cases of maternal coagulopathy after a single fetal death in a twin pregnancy have been reported, probably because the co-twin is usually delivered within a few weeks of the demise ([Chap. 25, p. 659](#)).

We have observed transient, spontaneously corrected consumptive coagulopathy when one fetus died and was retained in utero along with the other who was alive. The fibrinogen concentration initially dropped but then rose spontaneously and the level of serum fibrinogen-fibrin degradation products fell to normal. At delivery the portions of the placenta that supplied the living fetus appeared quite normal, whereas the part that had once provided for the dead fetus was the site of massive fibrin deposition. This may have accounted directly for the fall in maternal fibrinogen and in turn an increase in fibrin degradation products, or it may have served to block the escape of thromboplastin from fetus and placenta into the maternal circulation and thereby prevented disseminated intravascular coagulation. Both mechanisms may also have been operational until extensive fibrosis was achieved. The surviving fetus continued to thrive in utero and had normal plasma fibrinogen levels, serum fibrinogen-fibrin degradation products, and platelet counts at birth.

Management decisions should be based on the cause of death and the risk to the surviving fetus. The majority of cases of a single fetal death in twin pregnancy involve monochorionic placentation. Evidence indicates that morbidity in the monochorionic survivor is almost always due to vascular anastomoses, which first cause the demise of one twin and then produce sudden hypotension in the other. [Benirschke \(1993\)](#) has concluded that it is implausible that degenerating material from a dead fetus could be transported back to a living sibling. Considering that coagulopathy takes at least 5 weeks to develop, it is unlikely that there would still be shared circulation at that time. [Bajoria and colleagues \(1999\)](#) compared 50 monochorionic and 42 dichorionic twin pregnancies complicated by death of one fetus. The risk of fetal demise was more than 10 times greater in monochorionic twins, and the monochorionic survivors were significantly more likely to be anemic (51 versus 0 percent) and to have intracranial lesions at birth (46 versus 0 percent). The risk was highest if there was twin-to-twin transfusion and the recipient was the one who died. In monochorionic twins without twin-to-twin transfusion, those with superficial artery-to-artery or vein-to-vein anastomoses were at greater risk than those with bi-directional anastomoses. [Yoshida and Matayoshi \(1990\)](#) described 33 pairs of monochorionic twin pregnancies complicated by death of one fetus, in which 8 of 33 survivors had porencephaly, cerebral palsy, or other abnormalities. These complications generally occurred only when the death was in the latter half of pregnancy. As discussed earlier, in this situation delivery does not necessarily prevent morbidity in the survivor.

Less frequently, death results from a maternal complication such as diabetic ketoacidosis or severe preeclampsia with abruption, and pregnancy management is based on the diagnosis and the status of both mother and the surviving fetus. When the death of one dichorionic twin is due to a discordant congenital anomaly, its cause of death should not affect its co-twin. [Santema and co-workers \(1995b\)](#) assessed the cause and outcome of 29 consecutive twin pregnancies where one of the fetuses died after 20 weeks. The causes of fetal death were not clear in all cases; the most common associations were monochorionic placentation and severe preeclampsia. These investigators concluded that in most cases the benefit derived from continuation of multiple pregnancy exceeded the risks of preterm delivery after diagnosis of fetal death, and recommended conservative management of the living fetuses.

IMPENDING DEATH OF ONE FETUS. Abnormal antepartum tests of fetal health in one twin fetus but not the other pose a particular dilemma because delivery may be the best option for the compromised fetus, yet may result in death from immaturity of the second ([Fig. 30-27](#)). When fetal lung maturity is confirmed, salvage of both the healthy fetus and its jeopardized sibling is possible. Unfortunately, ideal management when the healthy fetus is very immature is problematic, but should be based on an estimate of the chances of intact survival in both fetuses. Often the compromised fetus is severely growth restricted or anomalous. An advantage of performing genetic amniocentesis for advanced maternal age in twin pregnancies, even when the mother will continue the pregnancy regardless of the diagnosis, is that the detection of aneuploidy in one fetus allows rational decisions about intervention to be made. In the case of twin-to-twin transfusion syndrome, the stuck twin often decompensates first and in addition to growth restriction has a high risk of pulmonary hypoplasia.

DEATH OF BOTH TWIN FETUSES. Rarely, both twin fetuses will die during the antepartum period. [Rydholm \(1996\)](#) reported that both fetuses died in 0.5 percent of twin pregnancies. Causes implicated in these deaths were monochorionic placentation and discordant fetal growth.

COMPLETE HYDATIDIFORM MOLE AND COEXISTING FETUS. This entity is different from a partial molar pregnancy because there are two separate conceptuses, with a normal placenta in one twin and a complete molar gestation in the other. As discussed in [Chapter 32 \(p. 836\)](#), the distinction between partial and complete mole has important clinical implications because persistent trophoblastic tumor occurs more commonly following complete mole ([Berkowitz and Goldstein, 1992](#)). Approximately 60 percent of women with complete molar twinning will require chemotherapy for persistent gestational trophoblastic tumors ([Fishman and associates, 1998](#); [Steller and colleagues, 1994](#)).

The optimal management of complete mole with coexisting fetus is uncertain. These frequently require preterm delivery because of bleeding complications or severe preeclampsia. [Bristow and colleagues \(1996\)](#) reviewed 26 well-documented cases and found that 73 percent required evacuation before fetal viability, but the remainder continued until fetal viability without serious complications. The pregnancies resulting in live-born infants had evidence of less exuberant tumor growth and their uterine size was only 1 week greater than expected, compared with 8 weeks greater in those requiring evacuation. The mean hCG levels were significantly lower (168,000 mIU/mL) compared with those evacuated early (1,000,000 mIU/mL).

ANTEPARTUM MANAGEMENT OF TWIN PREGNANCY

To reduce perinatal mortality and morbidity in pregnancies complicated by twins, it is imperative that:

1. Delivery of markedly preterm infants be prevented.
2. Failure of one or both fetuses to thrive be identified and fetuses so afflicted be delivered before they become moribund.
3. Fetal trauma during labor and delivery be eliminated.
4. Expert neonatal care be provided.

DIET. The requirements for calories, protein, minerals, vitamins, and essential fatty acids are further increased in women with multiple fetuses. The Recommended Dietary Allowances made by the Food and Nutrition Board of the National Research Council for uncomplicated pregnancy should not only be met but in most

instances exceeded ([Chap. 10](#)). Consumption of energy sources should be increased by another 300 kcal/day. [Brown and Carlson \(2000\)](#) have recommended that weight gain be based in part on prepregnancy weight, but that women with triplet pregnancies should gain 50 pounds. Iron supplementation of 60 to 100 mg/day is recommended. Folic acid, 1 mg/day, is also given.

MATERNAL HYPERTENSION. Hypertensive disorders due to pregnancy are much more likely to develop with multiple fetuses. The exact incidence attributable to twin gestation is difficult to determine because twin pregnancies are more likely to deliver preterm before preeclampsia can develop, and because women with twin pregnancies are often older and multiparous. [Santema and co-workers \(1995a\)](#) performed a case control study in which 187 twin and 187 singleton pregnancies were matched for maternal age, parity, and gestational age at delivery. They found that the incidence of hypertension was significantly higher in the twin pregnancies (15 versus 6 percent). [Coonrad and colleagues \(1995\)](#) reviewed the outcomes of 3407 twin and 8287 singleton pregnancies to determine the contribution of other independent risk factors for preeclampsia. They found that twin pregnancy carries an overall fourfold increased risk of preeclampsia independent of race and parity, and that nulliparous twin pregnancies have a 14-fold increased risk compared with parous singleton pregnancies. [Mastrobattista and colleagues \(1997\)](#) compared 53 triplet with 53 twin pregnancies and observed that the rate of severe preeclampsia was significantly higher in triplets (23 versus 5.7 percent).

These data suggest that fetal number and placental mass are involved in the pathogenesis of preeclampsia ([Chap. 24](#)). Hypertension not only develops more often but also tends to develop earlier and to be more severe. Interestingly, [Hardardottir and colleagues \(1996\)](#) have reported that women with preeclampsia due to high-order multifetal gestations more often develop epigastric pain, hemolysis, and thrombocytopenia as a result of their disease. As shown in [Table 30-1](#), the incidence of pregnancy hypertension in women with twins is 20 percent at Parkland Hospital.

ANTEPARTUM SURVEILLANCE. As discussed earlier, fetal growth is slower in multiple pregnancies than in singleton gestations, and it also may be unequal within a twin pair. For these reasons serial sonography is usually employed throughout the third trimester. Appropriate interval growth is reassuring, and size discordance is a concern primarily when one fetus is growth restricted. Assessment of amniotic fluid volume is also important, as associated oligohydramnios may indicate uteroplacental pathology, and should prompt further evaluation of fetal well being.

[Magann and colleagues \(1995b\)](#), using dye-dilution technique, measured amniotic fluid volumes in each sac in 47 uncomplicated twin gestations between 27 and 38 weeks. The average amniotic fluid volume per twin sac was 877 mL, which is similar to that reported for singletons. The normal range for one fetus was 215 to 2500 mL. These results suggest that in the aggregate, a diamniotic twin gestation has twice the amniotic fluid volume of a singleton.

Quantifying amniotic fluid volume in multiple gestation can be difficult. Some clinicians measure the deepest vertical pocket in each sac, or assess the fluid subjectively. If the sacs are side by side—as opposed to one on top of the other—measurement of the amniotic fluid index (AFI) may be helpful. Using data from 405 normal twin pregnancies, [Porter and associates \(1996\)](#) described a protocol for measuring the AFI in twins and provided normal values. As in singletons, the deepest vertical pocket in each quadrant was measured, regardless of the location of the dividing membrane. An AFI of less than 8 cm (below the 5th percentile) and over 24 cm (above the 95th percentile) were abnormal at all gestational ages from 28 to 40 weeks. If the overall AFI is abnormal, the sonologist must determine which sac is responsible and attempt to quantify the degree of abnormality. Subjective assessment is often required, and is not always accurate. [Magann and co-workers \(1995a\)](#) reported that oligohydramnios, defined as less than 500 mL, is poorly identified by any sonographic method in twin gestations.

TESTS OF FETAL HEALTH. As described in [Chapter 40](#), there are several methods of assessing fetal health in singleton pregnancies. Use of the nonstress test or biophysical profile is common in management of twin or higher-order multiple gestations. The complexity of complications associated with multiple gestations as well as the potential technical difficulties in separating fetuses during antepartum testing appears to limit the usefulness of these methods. For example, [Saacks and co-workers \(1995\)](#) observed that the antepartum death rate of twin fetuses did not change between 1952 to 1962 and 1983 to 1993 despite the availability of fetal testing during the latter decade. [Devoe and Ware \(1995\)](#) evaluated a fetal monitoring protocol for twins that included ultrasound assessment of fetal growth and amniotic fluid, Doppler velocimetry of the umbilical artery, and nonstress and biophysical profile testing. Nonstress testing and Doppler velocimetry were more predictive of fetal well-being than amniotic fluid volume or biophysical profile. In either case, both could be inaccurate because amniotic fluid measurement was difficult. Elliot and Finberg (1995) evaluated the biophysical profile with nonstress testing as a backup for monitoring of high-order multiple gestations. They reported that 4 of 24 monitored pregnancies had a poor outcome despite reassuring biophysical profile scores.

Whatever method is used, care must be taken to evaluate each fetus separately. [Gallagher and colleagues \(1992\)](#) analyzed fetal heart rate accelerations, fetal movement, and other behavioral states in 15 twin pairs. If one twin of a pair was awake or asleep so was its sibling; however, accelerations and movements were usually not coincidental. An example of such asynchrony of accelerations is shown in [Figure 30-28](#).

DOPPLER VELOCIMETRY. As discussed in [Chapters 40](#) and [41](#), Doppler evaluation of vascular resistance may provide a measure of fetal well-being. Increased resistance with diminished diastolic flow velocity often accompanies restricted fetal growth. Doppler values in twins and triplets are the same as in singletons, and can thus be used in a similar manner. [Akiyama and co-workers \(1999\)](#) performed Doppler studies of the descending aorta and the middle cerebral, umbilical, splenic, renal, and femoral arteries of 35 singleton, 52 twin, and 12 triplet fetuses every 2 weeks from 15 weeks to term. They found no differences in absolute values or in the patterns of change in regional arterial vascular resistance between singleton and multiple gestations. As in singletons, however, the clinical utility of these findings is controversial.

[Gerson and co-workers \(1987\)](#) used duplex Doppler ultrasound to measure umbilical venous blood flow and arterial systolic-diastolic velocity ratios in twins. Normal studies correctly predicted 44 of 45 concordant twin pairs, while abnormal values, especially of the umbilical artery, correctly predicted 9 of 11 sets of discordant twins. Conversely, [DiVou and co-workers \(1989\)](#) reported that velocimetry alone was not uniformly successful in identifying twin discordance. [Ezra and colleagues \(1999\)](#) found that in triplets and quadruplets, as in singletons, only absent end-diastolic blood flow in the umbilical artery was associated with low birthweight and perinatal mortality.

PREVENTION OF PRETERM DELIVERY. Several techniques have been applied in attempts to prolong multifetal gestations. These include bed rest, especially through hospitalization, prophylactic administration of beta-mimetic drugs, and prophylactic cervical cerclage.

BED REST. Most evidence suggests that routine hospitalization is not beneficial in prolonging multifetal pregnancy. For example, [Crowther and co-workers \(1990\)](#) randomized hospitalization in 139 Zimbabwean women with twin pregnancies and found that hospitalized bed rest did not prolong pregnancy or improve infant survival, although it did improve fetal growth. [Arabin and colleagues \(1997\)](#) demonstrated sonographically that in multiple gestation the cervix shortens several millimeters and often shows funneling when the woman is in the erect position. In this study, however, bed rest did not improve pregnancy outcome.

At Parkland Hospital, elective hospitalization at 26 weeks was compared longitudinally with outpatient management and no advantages were found for routine hospitalization ([Andrews and colleagues, 1991](#)). Importantly, almost half of the twin pregnancies studied required admission for specific indications such as hypertension or threatened preterm delivery. Similarly, [Adams and colleagues \(1998\)](#) compared 32 triplet pregnancies managed with outpatient bed rest to a historical cohort of 34 triplets managed with routine hospitalization in the third trimester. The outpatient group delivered one week earlier (32.5 versus 33.5 weeks), but neonatal hospitalization was similar between the groups. The outpatient group had a significantly higher rate of preeclampsia (31 versus 9 percent) and significantly more of their neonates had intraventricular hemorrhages (10 versus 1 percent).

Special prenatal clinic sessions, limited physical activity, early work leave, and structured maternal education on the risks of preterm delivery have been advocated to be effective in reducing preterm births in women with multiple fetuses. Unfortunately, there is little evidence that these measures substantially change outcome. For example, [Pons and co-workers \(1998\)](#) found virtually no difference in outcomes of 70 triplet pregnancies managed intensively from 1987 to 1993 and compared with 21 triplet pregnancies managed routinely between 1975 and 1986. The only major difference between these two periods was that neonates in the later group had significantly less hyaline membrane disease (13 versus 31 percent), which these investigators attributed to the use of corticosteroids.

TOCOLYTIC THERAPY. As in singleton pregnancies, most randomized trials of beta-mimetics in twin pregnancies have not shown significant reductions in preterm delivery rates. [Garite and colleagues \(1990\)](#) monitored the contraction patterns of 39 twin, 20 triplet, and 10 quadruplet pregnancies daily and thus diagnosed preterm labor before advanced cervical dilatation had occurred. Despite this, they found that tocolytic therapy was not effective in diminishing the crescendo of uterine activity that preceded preterm labor. [Ashworth and associates \(1990\)](#) were also unable to substantiate any benefits for prophylactic beta-mimetic therapy with salbutamol in twin gestations. As described in [Chapter 27 \(p. 714\)](#), most randomized studies of other tocolytic drugs compared with untreated controls exclude multiple gestation, and few specifically focus on multiple gestation.

Tocolytic therapy in women with multiple gestation entails a higher risk than in singletons, in part because the increased plasma volume and cardiovascular demands make such patients especially susceptible to pulmonary edema after receiving hydration and beta-mimetic therapy. [Gabriel and colleagues \(1994\)](#) compared the outcomes of 26 twin and 6 triplet pregnancies with 51 singletons treated with a beta-mimetic for preterm labor without ruptured membranes. They found that women

with multiple gestation had significantly more cardiovascular complications (43 versus 4 percent), including three cases of pulmonary edema. Magnesium sulfate can also increase risk, especially when used with prolonged bed rest as is commonly prescribed for multiple gestation. [Levav and co-authors \(1998\)](#) reported a case of osteoporosis and bilateral stress fractures of the calcanei in a woman with triplets treated with magnesium sulfate and prolonged bed rest.

CORTICOSTEROIDS FOR FETAL LUNG MATURATION. There is no satisfactory evidence that corticosteroids benefit multiple fetuses. For example, [Turrentine and colleagues \(1996\)](#) found no difference in neonatal outcome between 21 twin pairs who received optimal corticosteroid treatment and 63 pairs who received no treatment. Although acknowledging the preceding, the [Consensus Development Conference on the Effect of Corticosteroids for Fetal Maturation \(1994\)](#) sponsored by the National Institutes of Health essentially recommended treatment for women with multiple gestations and impending delivery.

CERCLAGE. No significant reduction in preterm delivery or perinatal deaths has been demonstrated from prophylactic cervical cerclage in multiple pregnancies. For example, [Elimian and colleagues \(1999\)](#) compared the outcomes of 20 triplet pregnancies managed with prophylactic cerclage and 39 triplet pregnancies managed expectantly. The incidence of low-birthweight infants was higher in the no cerclage group because this group had an increased proportion of deliveries before 31 weeks. Despite this, there was no difference in mean age at delivery (32.8 weeks in the cerclage group versus 31.5 weeks in the control group) or in the incidence of antenatal, perinatal, or neonatal complications.

PRETERM LABOR PREDICTION. [Goldenberg and colleagues \(1996\)](#) prospectively screened 147 twin pregnancies for more than 50 potential risk factors for preterm birth and found that only cervical length and fetal fibronectin predicted preterm birth. At 24 weeks, a cervical length over 25 mm was the best predictor of birth before 32 weeks, and at 28 weeks, a positive fetal fibronectin was the best predictor. Similarly, [Souka and co-workers \(1999\)](#) sonographically measured the cervix of 215 women with twin pregnancies at 23 weeks and found that a length of 25 mm or less had a 100 percent, 80 percent, 47 percent, and 35 percent sensitivity in predicting birth before 28, 30, 32, and 34 weeks, respectively. Conversely, [Imseis and colleagues \(1997\)](#) measured cervical length at 24 to 26 weeks' gestation in 85 twin pregnancies. They found that a cervix measuring 35 mm or less had 49 percent sensitivity, 94 percent specificity, and 97 and 31 percent positive and negative predictive values in identifying women at low risk for delivery before 34 weeks.

PULMONARY MATURATION. As measured by determination of the lecithin-sphingomyelin ratio, pulmonary maturation is usually synchronous in twins ([Leveno and associates, 1984](#)). Moreover, although this ratio usually exceeds 2 by 36 weeks in singleton pregnancies, it often does so by about 32 weeks in multifetal pregnancy. In some cases, however, there may be marked disparity of pulmonary function, with the smallest, most stressed fetus being more mature. We observed the lecithin-sphingomyelin ratio with quintuplets to vary from less than 2 for the largest infant, who weighed 1530 g at 32 weeks and was of appropriate size, to greater than 5 for the severely growth-restricted smallest infant, who weighed 860 g. The largest infant developed appreciable respiratory distress, whereas the smallest infant did not.

[Friedman and co-workers \(1997\)](#) studied 224 twins from 112 otherwise uncomplicated twin pregnancies delivered before 35 weeks because of refractory preterm labor. When compared to 224 normal singleton fetuses from similarly uncomplicated pregnancies who were matched for gestational age at birth, gender, and mode of delivery, there was no difference in the incidence of respiratory distress syndrome, grades 3 and 4 intraventricular hemorrhage, grades 2 and 3 necrotizing enterocolitis, or neonatal death. However, significantly more twins required admission to the neonatal intensive care unit (88 versus 72 percent).

EXPECTANT MANAGEMENT OF RUPTURED MEMBRANES. Twin gestations with preterm ruptured membranes are managed expectantly much like singleton pregnancies ([Chap. 27, p. 704](#)). [Mercer and colleagues \(1993\)](#) compared outcomes of twin and singleton pregnancies with prematurely ruptured membranes at 19 to 36 weeks and found that labor ensued earlier in twins. Specifically, the median time from rupture to delivery was 1.1 days in twins compared with 1.7 days in singletons. Over 90 percent in both groups delivered within 7 days of ruptured membranes. Similarly, [Hsieh and colleagues \(1999\)](#) studied 131 twins and 48 singletons with preterm premature rupture and found that the latency in twins was 1.2 days shorter when rupture was at 30 weeks or sooner. Regardless of the gestational age at rupture, 50 percent of twins compared with 27 percent of singletons delivered within 48 hours, and 92 percent of twins and 86 percent of singletons delivered within 7 days.

DELAYED DELIVERY OF SECOND TWIN. Cases have been reported in which one or more of multiple fetuses was expelled very preterm, and because uterine activity then ceased the pregnancy was allowed to continue with delivery of another fetus days to even many weeks later. [Trivedi and Gillett \(1998\)](#) reviewed the English literature and found 45 case reports of asynchronous birth in multiple gestation. Most often, the first birth resulted from preterm rupture of the membranes, and the survival rate for these infants was very poor. However, the pregnancies with a surviving twin or triplet continued for an average of 49 days. Management with tocolytics, prophylactic antibiotics, and cerclage, appeared to make no difference. If asynchronous birth is attempted, there must be careful evaluation for infection, abruption, and congenital anomalies, and the woman is counseled thoroughly about these risks.

DELIVERY OF TWIN FETUSES

LABOR

Many complications of labor and delivery, including preterm labor, uterine dysfunction, abnormal presentations, prolapse of the umbilical cord, premature separation of the placenta, and immediate postpartum hemorrhage, are encountered much more often with multiple fetuses. For these reasons, certain precautions and special arrangements are prudent when delivery of two or more fetuses is expected. Recommendations for intrapartum management follow.

1. An appropriately trained obstetrical attendant should remain with the mother throughout labor. Continuous external electronic monitoring or, if the membranes are ruptured and the cervix dilated, evaluation of both fetuses by simultaneous internal and external electronic monitoring, is typically employed.
2. Blood transfusion products should be readily available.
3. An intravenous infusion system capable of delivering fluid rapidly should be established. In the absence of hemorrhage or metabolic disturbance during labor, lactated Ringer with aqueous dextrose solution is infused at a rate of 60 to 120 mL/hr.
4. Ampicillin, 2 g intravenously, is administered every 6 hours for prevention of group B *Streptococcus* neonatal infection when preterm labor is diagnosed.
5. An obstetrician skilled in intrauterine identification of fetal parts and intrauterine manipulation of the fetus should be present.
6. If possible, an ultrasound machine should be available in the delivery room to facilitate evaluation of position and status of the second twin after delivery of the first.
7. An experienced anesthesiologist should be immediately available in the event that intrauterine manipulation or cesarean delivery is necessary.
8. For each fetus, two people, one of whom is skilled in resuscitation and care of newborns, are appropriately informed of the case and remain immediately available.
9. The delivery area should provide adequate space for all members of the team to work effectively. Moreover, the site should be appropriately equipped to take care of all possible maternal problems plus resuscitation and maintenance of each infant.

PRESENTATION AND POSITION. With twins, all possible combinations of fetal positions may be encountered. Either or both fetuses may present cephalic, breech, or shoulder. As shown in [Figure 30-29](#), the most common presentations at admission for delivery are cephalic-cephalic, cephalic-breech, and cephalic-transverse. Importantly, these presentations, especially those other than cephalic-cephalic, are unstable before and during labor or delivery. Compound, face, brow, and footling breech presentations are relatively common, especially when the fetuses are quite small, there is excess amniotic fluid, or maternal parity is high. Prolapse of the cord is fairly common in these circumstances.

The presentation can often be ascertained by sonography. If any confusion about the relationship of the twins to each other or to the maternal pelvis persists, a single anteroposterior x-ray of the abdomen may be helpful.

INDUCTION OR STIMULATION OF LABOR. Labor is generally shorter with twins ([Schiff and associates, 1998](#)), but rupture of the membranes without effective labor, and prolonged inefficient labor with or without previous rupture of the membranes, do develop. These problems are often handled better by cesarean delivery unless there is little hope of salvaging the infants because of their gross immaturity. Termination of pregnancy is occasionally desirable before the spontaneous onset of labor, as with severe pregnancy-induced hypertension. In these circumstances, if the presenting part is well fixed in the pelvis and the cervix dilated somewhat, amniotomy will often initiate labor and effect delivery. If the woman meets all criteria for administration of oxytocin for labor initiation ([Chap. 20, p. 477](#)), the [American](#)

[College of Obstetricians and Gynecologists \(1995\)](#) has stated that multifetal gestation is not a contraindication to labor induction, but is a condition that warrants special attention. There is no reluctance by some obstetricians to give oxytocin by dilute intravenous infusion to initiate or to stimulate labor in pregnancies complicated by multiple fetuses. [Satin and co-workers \(1996\)](#) compared outcomes in 55 women with twins who were given oxytocin for augmentation or induction for labor with 55 matched singleton pregnancies. Women with twin pregnancies responded similarly to women with singletons.

ANALGESIA AND ANESTHESIA. During labor and delivery of multiple fetuses, deciding what to use for analgesia and for anesthesia is unusually difficult because of the frequency of and problems imposed by:

1. Prematurity.
2. Maternal hypertension.
3. Desultory labor.
4. Need for intrauterine manipulation.
5. Uterine atony and hemorrhage after delivery.

Epidural analgesia is recommended by some clinicians because it provides: (1) pain relief, (2) skeletal muscle relaxation that would be required for internal podalic version, and (3) it can be rapidly extended cephalad if cesarean delivery is required ([Koffel, 1999](#)). Special care must be taken in hypertensive women or those who have hemorrhaged because epidural analgesia may cause hypotension with inadequate perfusion of vital organs, especially the placenta.

Therefore, placement and maintenance of continuous epidural analgesia should be by someone knowledgeable in obstetrics and preceded by adequate hydration, and the block should be allowed to come up slowly to avoid a hypotensive episode. Because the woman pregnant with multiple fetuses is even more vulnerable to supine hypotension during labor and delivery, she should be placed in full lateral position during and after induction of epidural analgesia, and left uterine displacement should be maintained for cesarean delivery.

It is likely that the effects of epidural analgesia on the progress of labor seen in singleton pregnancy would also be found in twins, but few studies include multiple gestations. These effects are discussed in [Chapter 15 \(p. 374\)](#). [Crawford \(1987\)](#) described 105 women with twins delivered vaginally who were given epidural analgesia. It prolonged the interval from complete dilatation until delivery by approximately 60 minutes. Interestingly, the mean delivery intervals between delivery of the first and second twins were not altered by epidural analgesia.

Either balanced general anesthesia or regional epidural or subarachnoid analgesia has proved satisfactory at Parkland Hospital for cesarean delivery of twins. When general anesthesia is used, the increased oxygen demand and decreased functional residual capacity associated with multiple gestation increase the risk of hypoxemia, thus making adequate preoxygenation essential. Pudendal block skillfully administered along with nitrous oxide plus oxygen can provide relief of pain for spontaneous delivery. When intrauterine manipulation is necessary, as with internal podalic version, uterine relaxation can also be accomplished rapidly with isoflurane. Although these agents provide effective relaxation for intrauterine manipulation, they also cause an increase in blood loss during the third stage. Some use intravenous or sublingual nitroglycerine for relaxation ([Vinatier and associates, 1996](#)).

VAGINAL DELIVERY

The presenting twin typically bears the major brunt of dilating the cervix and the remaining soft tissues of the birth canal. When the first twin is cephalic, delivery is usually uncomplicated, and can be accomplished spontaneously or with outlet forceps. As in singletons, when the first fetus presents as a breech, major problems are most likely to develop if:

1. The fetus is unusually large and the aftercoming head taxes the capacity of the birth canal.
2. The fetus is quite small so that the extremities and trunk are delivered through a cervix inadequately effaced and dilated for the head to escape easily.
3. The umbilical cord prolapses.

When these problems are anticipated or identified, cesarean delivery will often be the better way to effect delivery, except in those instances in which the fetuses are so immature that they will not survive. Otherwise, breech delivery may be accomplished as described in [Chapter 22](#).

The phenomenon of locked twins is rare, and according to [Cohen and co-workers \(1965\)](#) occurred only once in 817 twin gestations. For locking to occur, the first fetus must present by the breech and the second as cephalic. With descent of the breech through the birth canal, the chin of the first fetus locks in the neck and chin of the second cephalic fetus. Cesarean delivery is recommended when the potential for locking is identified.

Many obstetricians plan vaginal delivery for cephalic-cephalic presenting twins if satisfactory labor has been established. The optimal delivery route for cephalic-noncephalic twins is controversial, particularly when very-low-birthweight is a concern ([American College of Obstetricians and Gynecologists, 1998](#)). Many of the issues involved in vaginal delivery of breech second twins are similar to those for singletons, with the added concern that second-born twins have historically fared worse than their first-born siblings. [Kurzel and colleagues \(1997\)](#) reviewed the delivery events of 541 twin pregnancies at the University of California in Los Angeles from 1987 to 1995. The overall cesarean delivery rate was 35 percent, including 5 percent solely for twin B. Cesareans were performed in 14 percent of twins in which twin A was cephalic, compared with 67 percent when twin A was breech and 100 percent when twin A was transverse. The proportion of primary cesarean deliveries when twin B was breech or transverse was similar. Of the twins who were cephalic-cephalic, cesarean delivery of the second twin was performed in 26 percent, primarily for cord prolapse. Of the cephalic-noncephalic twins, cesarean delivery of twin B was done in 52 percent, primarily for failed internal podalic version and extraction when twin B was transverse.

There are several reports attesting to the safety of vaginal delivery of second noncephalic twins who are larger than 1500 g ([Blickstein, 1987](#); [Chervanuk, 1985](#); [Gocke, 1989](#), and their associates) as well as those weighing less than 1500 g ([Davidson and co-workers, 1992](#); [Rydhstrom, 1990](#)). More recently, [Mauldin and colleagues \(1998\)](#) retrospectively reviewed the delivery courses of 84 cephalic-noncephalic twins, and found that vaginal delivery of twin A with breech extraction of twin B resulted in significantly shorter maternal and neonatal hospital stays and lowered hospital charges than either vaginal delivery of A with external version of B or cesarean delivery. Hospital stays were shorter for both mother and infant in part because vaginally extracted breech twins had less respiratory disease and infections. Unfortunately, and as emphasized by [Chauhan and colleagues \(1995\)](#), there are no large randomized trials to help resolve the uncertainty about vaginal or cesarean delivery for noncephalic second twins.

When the first twin is breech, most clinicians plan a cesarean delivery. The [American College of Obstetricians and Gynecologists \(1998\)](#) has concluded that, in general, cesarean delivery is the method of choice when the first twin is noncephalic, such as breech or transverse presentation. More recently, however, [Blickstein and colleagues \(2000\)](#) reported the collective experience from 1990 to 1997 of 13 European centers that allowed vaginal delivery in 239 of 613 twin pairs when twin A was breech. Although twin A breech infants weighing less than 1500 g were more likely to suffer neonatal death (45 versus 8 percent), the death rates were not significantly different in those weighing more than 1500 g (0.3 versus 0.2 percent).

VAGINAL DELIVERY OF THE SECOND TWIN. As soon as the first twin has been delivered, the presenting part of the second twin, its size, and its relationship to the birth canal are quickly ascertained by careful combined abdominal, vaginal, and at times intrauterine examination. Sonography also has proven quite valuable in some cases.

If the fetal head or the breech is fixed in the birth canal, moderate fundal pressure is applied and membranes are ruptured. Immediately afterward, the examination is repeated to identify prolapse of the cord. Labor is allowed to resume while the fetal heart rate is monitored. With re-establishment of labor there is no need to hasten delivery unless there is a nonreassuring fetal heart rate or bleeding. Hemorrhage indicates placental separation, which can be deleterious to both the fetus and the mother. If contractions do not resume within approximately 10 minutes, dilute oxytocin may be used to stimulate appropriate myometrial activity, leading to spontaneous delivery or delivery assisted by outlet forceps.

If the occiput or the breech presents immediately over the pelvic inlet but is not fixed in the birth canal, the presenting part can often be guided into the pelvis with a

vaginal hand while a hand on the uterine fundus exerts moderate pressure. Alternatively, an assistant can direct the presenting part into the pelvis using ultrasound for guidance and to monitor heart rate. Intrapartum external version of the noncephalic second twin has also been described ([Chervanek and co-workers, 1983](#)). Using the method shown in [Figure 30-30](#), the fetus who presents as breech or shoulder may be gently converted into a cephalic presentation. Once the presenting part is fixed in the pelvic inlet, membranes are ruptured and delivery is carried out as described earlier.

If the occiput or the breech is not over the pelvic inlet and cannot be so positioned by gentle pressure on the presenting part, or if appreciable uterine bleeding develops, delivery of the second twin can be problematic. So as to take maximum advantage of the dilated cervix before the uterus contracts and the cervix retracts, procrastination must be avoided. An obstetrician skilled in intrauterine fetal manipulation and an anesthesiologist skilled in providing anesthesia to effectively relax the uterus are essential for vaginal delivery with a favorable outcome. Prompt delivery of the second fetus by cesarean delivery is the better choice if no one present is skilled in the performance of internal podalic version (described in the following section) or if anesthesia that will provide effective uterine relaxation is not immediately available.

INTERNAL PODALIC VERSION. In internal podalic version, the fetus is turned so as to deliver the feet first, which then enables the obstetrician to effect delivery by breech extraction. [Chauhan and colleagues \(1995\)](#) compared outcomes of 23 second twins delivered by podalic version and breech extraction with 21 who underwent external cephalic version. Breech extraction was considered superior to external version because there was less fetal distress.

Through careful abdominal, vaginal, and intrauterine examinations, the various parts of the fetus can be identified. A hand is used to rupture the membranes and both feet are identified and grasped, and only then are they gently pulled toward the birth canal ([Fig. 30-31](#)). With the other hand applied to the abdomen, or with the help of an assistant, the head simultaneously is elevated gently ([Fig. 30-32](#)). An episiotomy is made or extended whenever more room is needed for uterine and vaginal manipulation. The legs are drawn slowly through the birth canal until the buttocks are visible anteriorly just beyond the maternal symphysis. A moist, warm towel is applied to the buttocks, and gentle traction is continued until the lower thirds of both scapulas are visible. Next, the trunk is slowly rotated with gentle traction until the shoulder and arm on one side of the fetus are delivered. Rotation of the fetal trunk now is gently reversed to deliver the other arm and shoulder into the vagina. Care must be taken to avoid or at least recognize the presence of a nuchal arm ([Chap. 22, p. 524](#)). A nuchal arm can be reduced by rotating the trunk 90 degrees or more in the direction of the trapped arm (for example, if the left arm is trapped, rotate the trunk to the patient's left), bringing the arm into extension in front of the trunk where it can be grasped and gently pulled down. The aftercoming head may then be delivered either by simultaneous suprapubic external pressure to flex the head and gentle traction applied to the trunk, or by use of Piper forceps ([Chap. 22, p. 524](#)).

The cord is clamped promptly with two clamps on the placental side to identify it as the cord of the second infant. The placenta or placentas are delivered immediately by manual removal, if necessary. The uterus is promptly explored for defects and for retained pregnancy products. As these steps are being carried out, the uterine-relaxing anesthetic agent is discontinued, and as soon as uterine exploration has been completed, oxytocin is administered through an intravenous infusion system. Fundal massage or, preferably, manual compression of the uterus with one hand in the vagina against the lower uterine segment and the other transabdominally over the uterine fundus is applied to hasten and enhance myometrial contraction.

The cervix, vagina, periurethral region, vulva, and perineum are inspected carefully. Lacerations likely to bleed are repaired along with the episiotomy.

INTERVAL BETWEEN FIRST AND SECOND TWINS. In the past, the interval between delivery of the first and second twins was commonly cited to be safest if less than 30 minutes. Subsequently, as shown by [Rayburn and colleagues \(1984\)](#) as well as others, if continuous fetal monitoring is employed, there is a good outcome even if this interval is longer. Of 115 twin pairs at 34 weeks or more, the mean interval between delivery of twins was 21 minutes, but it ranged from 1 to 134 minutes. In 60 percent, the interval was 15 minutes or less. Importantly, there was no excess trauma or evidence for fetal depression in those born after the 15-minute interval. As expected, the cesarean delivery rate was much higher if the interval was more than 15 minutes (18 percent) than if the interval was less than 15 minutes (3 percent). [Saacks and co-workers \(1995\)](#) found that the time interval between delivery of twin A and twin B increased significantly between 1952 and 1993. The median interval was 11 minutes in the most recent years they studied, however, probably indicating that the spontaneous delivery interval between twins is typically quite brief. The [American College of Obstetricians and Gynecologists \(1998\)](#) has determined that the interval between delivery of twins is not critical in determining the outcome of twin B.

CESAREAN DELIVERY

Twin fetuses create unusual intraoperative problems. The mother is likely to be even less tolerant of the supine position, and therefore it is important to rotate her position so as to deflect the uterus off the aorta ([Chap. 8, p. 182](#)). Hypotension can be detected with simultaneous monitoring of brachial and popliteal blood pressures. The incision should be large enough to allow atraumatic delivery of both fetuses. In some cases, a vertical incision in the lower uterine segment may be advantageous. For example, if a fetus is in transverse position, with the back down, and the arms are inadvertently delivered first, it is much easier and safer to extend a vertical uterine incision upward than to extend a transverse incision. If twin B is breech and delivery of the head is obstructed, Piper forceps can be used just as for a vaginal delivery.

It is important that the uterus be well contracted during completion of the cesarean delivery and thereafter. Remarkable blood loss may be concealed within the uterus and vagina and beneath the drapes during the time taken to close the incisions.

At times, attempts to deliver the second twin vaginally after delivery of the first twin are not only unwise but also impossible, and prompt cesarean delivery is required. Cesarean delivery of twin B may be necessary, for example, when the second fetus is much larger than the first, and is in a breech position or in a transverse lie. Even more perplexing, cesarean delivery may be required because the cervix promptly contracts and thickens after delivery of the first infant and does not dilate subsequently.

TRIPLETS OR MORE

All of the problems of twin gestation are remarkably intensified by the presence of additional fetuses. Improved neonatal care has led to the expectation of 95 percent infant survival, but triplets still suffer morbidity. [Kaufman and colleagues \(1998\)](#) compared the outcomes of 55 triplet pregnancies with 357 twin and 959 singleton pregnancies delivered from 1992 to 1996. They reported that the survival rates were similar at 95, 95, and 97 percent, respectively. Compared with singletons, however, triplets were at significantly higher risk to have mild intraventricular hemorrhage (RR 6.2), mild retinopathy of prematurity (RR 20.0), and severe retinopathy (RR 46.7). The mortality rate for triplets was 121 per 1000, regardless of birth order.

Labor and delivery entails increased risk as well. Fetal heart rate monitoring during labor is challenging. A scalp electrode can be attached to the presenting fetus, but it is difficult to assure that the other two triplets are each being monitored separately. With vaginal delivery, the first infant is usually born spontaneously or with little manipulation. However, subsequent infants are delivered according to the presenting part, which often requires complicated obstetrical maneuvers such as total breech extraction with or without internal podalic version, or may even necessitate cesarean delivery. Associated with malposition of the fetuses is an increased incidence of cord prolapse and fetal collision. Moreover, reduced placental perfusion and hemorrhage from separating placentas are more likely during delivery.

For all these reasons, many clinicians believe that delivery of pregnancies complicated by three or more fetuses is best accomplished by cesarean section. Vaginal delivery is reserved for those circumstances in which survival is not expected because the fetuses are markedly immature, or maternal complications make cesarean delivery hazardous to the mother. There are other clinicians who believe that vaginal delivery is safe under certain circumstances. For example, [Alamia and colleagues \(1998\)](#) evaluated a protocol for vaginal delivery of triplet pregnancies in which the presenting fetus was cephalic, and all three fetuses could be continuously monitored. A total of 23 sets of triplets were analyzed and a third were delivered vaginally. Neonatal outcomes were the same in the vaginal and cesarean groups, with no morbidity and 100 percent survival. As in any obstetrical procedure, the safety of vaginal triplet delivery depends on the skill and experience of the operator.

SELECTIVE REDUCTION OR TERMINATION

In some cases of higher-order multifetal gestations, reduction in the number of fetuses to two or three will improve survival for the remaining fetuses. Selective reduction implies early pregnancy intervention whereas selective termination is done later.

SELECTIVE REDUCTION

Reduction of a selected fetus or fetuses in a multiple gestation may be chosen as a therapeutic intervention to enhance survivability of the co-fetuses. Multifetal pregnancy reduction was developed at Mount Sinai Medical Center in New York in an effort to improve the poor prognosis of pregnancies with three or more fetuses

that typically resulted from assisted reproduction technologies ([Berkowitz and associates, 1988](#)). Pregnancy reduction can be performed transcervically, transvaginally, or transabdominally, but the transabdominal route is easiest. Transabdominal reductions are typically performed between 10 and 13 weeks. This time was chosen because any spontaneous fetal losses have already occurred, the remaining fetuses are big enough to be evaluated sonographically, the amount of devitalized fetal tissue remaining after the procedure is small, and the risk of losing the entire pregnancy as a result of the procedure is low. The smallest fetuses and any anomalous fetuses are targeted for reduction and potassium chloride is then injected into the heart or thorax of each selected fetus under ultrasound guidance, taking care not to enter or traverse the sacs of the fetuses selected for retention. In most cases, pregnancies are reduced to twins in order to increase the chances of delivering at least one viable fetus.

[Berkowitz and co-workers \(1996\)](#), in describing their experience with 400 reductions performed by very experienced operators, reported a pregnancy loss rate of 8 percent. The remaining 92 percent delivered one or more viable fetus after 24 weeks. [Evans and associates \(1996\)](#) described a multicenter collaborative experience with this procedure in 1789 patients. They reported an overall pregnancy loss rate of 12 percent, which varied from a low of 8 percent for triplets reduced to twins, and increased with each additional starting fetus to 23 percent for sextuplets or higher. The loss rate early on was higher than for the last two years, attesting to the importance of operator skill and experience. Early preterm deliveries were more likely in pregnancies starting as higher-order gestations, reinforcing the concept that higher-order multiple gestations are hazardous to both the fetuses and the mothers ([Fig. 30-33](#)).

SELECTIVE TERMINATION

With the identification of multiple fetuses discordant for structural or genetic abnormalities, three options are available:

1. Abortion of all fetuses.
2. Selective termination of the abnormal fetus.
3. Continuation of the pregnancy.

Because anomalies are typically not discovered until the second trimester, selective termination is performed later in gestation than selective reduction and entails more risk. This procedure is therefore usually not performed unless the anomaly is severe but not lethal, meaning that the anomalous fetus would survive and require lifetime care, or the estimated risk of continuing the pregnancy is greater than the risk of the procedure. For example, a triplet pregnancy in which one fetus has Down syndrome might be a candidate for selective termination, while a twin pregnancy in which one has trisomy 18 might not. In some cases, termination is considered because the abnormal fetus may jeopardize the normal one. For example, pathological hydramnios developing in a twin with esophageal atresia could lead to preterm birth of its sibling. Prerequisites to selective termination include a precise diagnosis for the anomalous fetus and absolute certainty as to its location. In the case of an aneuploidy detected after genetic amniocentesis for advanced maternal age, for example, a map of the uterus with the locations of all the fetuses clearly labeled should be made at the time of the diagnostic procedure.

[Evans and co-workers \(1999\)](#) have provided the most comprehensive results to date on second-trimester selective termination for fetal abnormalities. A total of 402 cases from the eight most experienced centers worldwide were analyzed. Included were 345 twins, 39 triplets, and 18 quadruplets. Selective termination using potassium chloride resulted in the delivery of a viable infant in more than 90 percent of cases, with a mean age at delivery of 35.7 weeks. The loss rate was 7.1 percent in pregnancies reduced to singletons and was 13 percent in those reduced to twins, again attesting to the increased risk of higher-order multiples. The gestational age at the time of the procedure did not appear to affect the outcome—the rate was 5.4 percent when the procedure was performed at 9 to 12 weeks; 8.7 percent at 13 to 18 weeks; 6.8 percent at 19 to 24 weeks; and 9.1 percent at 25 weeks. Several losses occurred because the pregnancy was actually monochorionic and potassium chloride killed the normal fetus through placental vascular shunts. [Lynch and colleagues \(1996\)](#) reported that termination of the presenting fetus or selective termination after 20 weeks significantly increased the risk of preterm prematurely membrane rupture and delivery.

ETHICS

The ethical issues associated with these techniques are almost limitless. The interested reader is referred to the excellent reviews by [Evans and co-workers \(1988\)](#) and [Simpson and Carson \(1996\)](#).

INFORMED CONSENT

Prior to initiation of infertility therapy or any attempt to perform selective termination or reduction, the couple should be counseled about the risks and benefits and informed consent obtained. Counseling should include a discussion of the morbidity and mortality expected if the pregnancy is continued, according to the number of fetuses; the morbidity and mortality expected with twins or triplets, whichever the couple would reduce to; and the risks of the procedure itself. Specific risks that are common to selective termination or reduction include:

1. Abortion of the remaining fetuses.
2. Abortion of the wrong (normal) fetus in twins.
3. Retention of genetic or structurally abnormal fetuses after a reduction in number.
4. Damage without death to a fetus.
5. Preterm labor complicating pregnancies with the remaining fetuses.
6. Development of discordant twins or growth restricted fetuses.
7. Maternal infection, hemorrhage, or possible disseminated intravascular coagulopathy owing to retained products of conception.

The procedure should be performed by an operator skilled and experienced in ultrasound-guided procedures. Because selective reduction will increase the maternal serum alpha-fetoprotein level, the couple should be informed that this screening test will not be helpful to them after the procedure ([Lynch and Berkowitz, 1993](#)). Instead, they are offered a second-trimester targeted ultrasound evaluation.

PSYCHOLOGICAL REACTIONS

Women and their spouses who elect to undergo selective termination or reduction find this decision highly stressful. [Schreiner-Engel and associates \(1995\)](#) retrospectively studied the emotional reactions of 100 women following selective reduction. Although 70 percent of the women mourned for their lost fetus(es), most grieved only for 1 month. Persistent depressive symptoms were mild, although moderately severe sadness and guilt continued for many. Fortunately, the large majority were reconciled to the termination of some fetuses to preserve the lives of a remaining few. Indeed, 93 percent of the women would have made the same decision again.

TABLE 30-1. Selected Outcomes in Twin Pregnancies Compared with Singletons Delivered at Parkland Hospital in 1999

Outcome	Singletons	Twins^a
Women delivered	14,503	162
Births	14,503	324
Stillbirths (per 1000)	85 (6)	8 (25)
Neonatal deaths (per 1000)	57 (4)	6 (18)
Perinatal deaths (per 1000)	142 (10)	14 (43)
Very-low birthweight (< 1500 g)	1.4%	12%
Pregnancy hypertension	12%	20%
Cesarean delivery	19%	60%

^a Represented 1 in 44 births and 1 in 8 perinatal deaths.

SECTION VIII - PLACENTAL DISORDERS

31. Abnormalities of the Fetal Membranes and Amnionic Fluid

Fetal membranes include the amnion and chorion. Their development, physiology, and histology are detailed in [Chapter 5 \(p. 86\)](#). A number of physiological and pathological events cause perceptible anatomical changes in the amnion, chorion, or both.

ABNORMALITIES OF THE CHORIOAMNION

MECONIUM STAINING

The presence of meconium is relatively common. In a summary of 17 series, [Katz and Bowes \(1992\)](#) reported that the incidence of meconium passage ranged from 7 to 22 percent. [Wiswell and associates \(1990\)](#) identified it in 12 percent of more than 175,000 live-born infants. [Benirschke and Kaufmann \(2000\)](#) identified visible meconium staining in 18 percent of nearly 13,000 consecutive placentas. It has been remarkably constant over the past 16 years at Parkland Hospital. Of almost 200,000 women delivered during this period, about 20 percent had amnionic fluid that contained some meconium identified during labor or at delivery.

Meconium passage is seldom seen in preterm fetuses, and it may be confused with pigments arising from fetal hemolysis. It is uncommon prior to 38 weeks, and it increases after 40 weeks ([Table 31-1](#)). Staining of the amnionic membranes is obvious within 1 to 3 hours after meconium passage ([Miller and colleagues, 1985](#)). Although more prolonged exposure results in staining of the chorion, umbilical cord, and decidua, according to [Benirschke and Kaufmann \(2000\)](#), it cannot be dated accurately.

In a global sense, meconium passage is associated with increased perinatal morbidity and mortality. [Fujikura and Klionsky \(1975\)](#) identified meconium-stained membranes or fetuses in about 10 percent of 43,000 live-born infants in the Collaborative Study of Cerebral Palsy. The neonatal mortality rate was 3.3 percent in the group with meconium-stained membranes compared with 1.7 percent in those without such staining. [Nathan and co-workers \(1994\)](#) retrospectively compared perinatal outcomes in over 8000 women delivered at Parkland Hospital in whom meconium was identified intrapartum. The control group consisted of over 34,500 similar pregnancies with clear amnionic fluid. Perinatal mortality was increased significantly in the meconium group (1.5 versus 0.3 per 1000). Likewise, severe fetal acidemia—cord arterial pH less than 7.0—was significantly more common with meconium-stained births (7 versus 3 per 1000). Finally, cesarean delivery was doubled in the meconium group (14 versus 7 percent). These global findings are not applicable in individual cases. Despite this, according to [Benirschke and Kaufmann \(2000\)](#), meconium has assumed great importance in many medicolegal pursuits.

Neonatal mortality associated with meconium is primarily the result of aspiration of thick, tenacious meconium ([Chap. 39, p. 1044](#)). [Houlihan and Knuppel \(1994\)](#) and [Cleary and Wiswell \(1998\)](#) have reviewed this subject.

CHORIOAMNIONITIS

Inflammation of the fetal membranes is a manifestation of an intrauterine infection, and it is frequently associated with prolonged membrane rupture and long labors ([Fox, 1978](#)). When mononuclear and polymorphonuclear leukocytes infiltrate the chorion, the resulting microscopical finding is designated chorioamnionitis ([Fig. 31-1](#)). If they are found in amnionic fluid, it is termed *amnionitis*. Inflammation of the umbilical cord is *funisitis* and placental infection is manifest by *villitis* ([Goldenberg and co-workers, 2000](#)). According to some investigators, these findings may be nonspecific and are not always associated with other evidence for fetal or maternal infection. For example, [Yamada and colleagues \(2000\)](#) found that meconium-stained fluid is a chemoattractant for leukocytes. Conversely, [Benirschke and Kaufmann \(2000\)](#) believe that microscopic chorioamnionitis is always due to infection. Before 20 weeks, almost all polymorphonuclear leukocytes are maternal in origin, but later the inflammatory response is primarily fetal ([Sampson and colleagues, 1997](#)).

Management of clinical chorioamnionitis is antimicrobial administration and expedient delivery ([Chap. 27, p. 707](#)). Occult chorioamnionitis, caused by a wide variety of microorganisms, has recently emerged as a possible explanation for many heretofore unexplained cases of ruptured membranes, preterm labor, or both ([Chaps. 11, p. 282 and 27, p. 696](#)).

OTHER ABNORMALITIES

Small **amnionic cysts** lined by typical amnionic epithelium are occasionally formed. The common variety results from fusion of amnionic folds, with subsequent retention of fluid.

Amnion nodosum are nodules in the amnion that are sometimes called squamous amnionic metaplasia or amnionic caruncles. They are most commonly seen in the amnion in contact with the chorionic plate, but they may also be found elsewhere. They usually appear near the insertion of the cord as shiny grayish-yellow opaque elevations that are multiple, rounded, or oval, and they vary from 1 mm to 5 mm in diameter. The nodules are made up of fetal ectodermal debris, including vernix caseosa with hair, squames, and sebum. They are associated with oligohydramnios and are most commonly found in fetuses with renal agenesis or prolonged prematurely ruptured membranes or in the placenta of the donor fetus with twin-twin transfusion syndrome ([Benirschke and Kaufmann, 2000](#)).

Amnionic bands are caused when disruption of the amnion leads to formation of bands or strings that adhere to the fetus and impair growth and development of the involved structure. Some conditions that appear to be the consequence of this phenomenon, including intrauterine amputations, are considered in [Chapter 39 \(p. 1082\)](#).

DISORDERS OF AMNIONIC FLUID VOLUME

Normally, amnionic fluid volume increases to about 1 L, or somewhat more by 36 weeks, but decreases thereafter ([Table 31-2](#)). Postterm, there may be only 100 to 200 mL or less. Diminished fluid volume is termed *oligohydramnios*. Somewhat arbitrarily, more than 2000 mL of amnionic fluid is considered excessive and is termed *hydramnios* and sometimes called *polyhydramnios*. In rare instances, the uterus may contain an enormous quantity of fluid, with reports of as much as 15 L. In most instances, chronic hydramnios develops, which is the gradual increase of excessive fluid. In acute hydramnios, the uterus may become markedly distended within a few days.

MEASUREMENT OF AMNIONIC FLUID. Over the past two decades, a number of ultrasonic methods have been used to measure the amount of amnionic fluid. Limitations of using a single pocket of amnionic fluid to determine accurate quantification of fluid were obvious. Accordingly, [Phelan and colleagues \(1987\)](#) described the clinical utility of quantification using the **amnionic fluid index**. This is calculated by adding the vertical depths of the largest pocket in each of four equal uterine quadrants. According to their calculations, significant hydramnios is defined by an index greater than 24 cm. [Moore and Cayle \(1990\)](#) reported normal values for 791 normal pregnancies from 16 to 42 weeks ([Table 31-3](#)). [Hallak and colleagues \(1993\)](#) studied 892 normal pregnancies and reported similar trends, but lower absolute numbers ([Fig. 31-2](#)). [Porter and associates \(1996\)](#) and [Hill and co-workers \(2000\)](#) have provided normal values for twin pregnancies ([Chap. 30, p. 794](#)).

The group from the University of Mississippi has performed several investigations to correlate ultrasonic accuracy of predicting abnormal amnionic fluid volume with actual measurement by dye dilution. [Magann and associates \(1992\)](#) used the dye-dilution technique to measure amnionic fluid in 40 women undergoing amniocentesis in late pregnancy. They found that the amnionic fluid index was reasonably reliable in determining normal or increased amnionic fluid, but was inaccurate in diagnosing oligohydramnios. In a later study, [Chauhan and co-workers \(1997\)](#) evaluated 144 women and found a poor correlation of fluid volume with both the amnionic fluid index and the 2-diameter fluid pocket method.

[Williams \(1993\)](#) reviewed techniques and concluded that there is good inter- and intra-observer variability. In a preliminary study, [Bootstaylor and associates \(1996\)](#) found that assessment of the index with the woman in the lateral decubitus position correlated well with supine values. [Peedicayil and colleagues \(1994\)](#) emphasized that borderline values should be repeated before interventions are undertaken.

Importantly, several factors may modulate the amnionic fluid index. [Yancey and Richards \(1994\)](#) reported that high altitude (6000 ft) was associated with an increased index. [Bush and associates \(1996\)](#) and [Kilpatrick and Safford \(1993\)](#), but not [Kerr and associates \(1996\)](#), showed that maternal hydration increased the index. Conversely, fluid restriction or dehydration may lower the index. Ross and colleagues (1996) administered 1-deamino-[8-D-arginine] vasopressin to women with oligohydramnios. The resulting maternal serum hypo-osmolality (285 to 265 mOsm/kg) was associated with an increased amnionic fluid index from 4 to 8 cm within 8

hours.

HYDRAMNIOS

Minor to moderate degrees of hydramnios—2 to 3 L—are rather common. Because of the difficulty of complete collection and measurement of fluid, the diagnosis is usually clinical ([Fig. 31-3](#)) and confirmed by sonographic estimation. The frequency of the diagnosis varies appreciably with different observers.

INCIDENCE. Hydramnios is identified in around 1 percent of all pregnancies. Most clinical studies define hydramnios as an amniotic fluid index of greater than 24 to 25 cm—corresponding to greater than either the 95th or 97.5th percentiles. Using an index of 25 cm or greater, [Biggio and colleagues \(1999\)](#) at the University of Alabama reported a 1 percent incidence in nearly 36,450 women examined.

In an earlier study by [Hill and associates \(1987\)](#) from the Mayo Clinic, more than 9000 prenatal patients underwent routine ultrasonic evaluation near the beginning of the third trimester. The incidence of hydramnios was 0.9 percent. Mild hydramnios—defined as pockets measuring 8 to 11 cm in vertical dimension—was present in 80 percent of cases with excessive fluid. Moderate hydramnios—defined as a pocket containing only small parts and measured 12 to 15 cm deep—was found in 15 percent. Only 5 percent had severe hydramnios defined by a free-floating fetus found in pockets of fluid of 16 cm or greater. Although two thirds of all cases were idiopathic, the other third were associated with fetal anomalies, maternal diabetes, or multifetal gestation. [Golan and co-workers \(1993\)](#) reported remarkably similar findings in nearly 14,000 women.

CAUSES OF HYDRAMNIOS. The degree of hydramnios, as well as its prognosis, is related to the cause. Many reports are significantly biased because they consist of observations from women referred for targeted ultrasonic evaluation. Others are population based, but still may not reflect an accurate incidence unless universal ultrasonic screening is done. In either case, obvious pathological hydramnios is frequently associated with fetal malformations, especially of the central nervous system or gastrointestinal tract. For example, hydramnios accompanies about half of cases of anencephaly and esophageal atresia. In the study cited earlier by [Hill and associates \(1987\)](#) of nonreferred Mayo Clinic prenatal patients, the cause of mild hydramnios was identified in only about 15 percent of cases. Conversely, with moderately or severely increased amniotic fluid, the cause was identified in more than 90 percent of cases. Specifically, in almost half of cases with moderate and severe hydramnios, a fetal anomaly was identified. The opposite is not true, however, and in the Spanish Collaborative Study of Congenital Malformations (ECEMC) with over 27,000 anomalous fetuses, only 3.7 percent had hydramnios ([Martinez-Frias and colleagues, 1999](#)). Another 3 percent had oligohydramnios.

In another population-based study, [Biggio and co-workers \(1999\)](#) reviewed sonographic examinations in over 40,000 women at the University of Alabama at Birmingham. They identified 370 women with hydramnios defined as an index of 25 cm or greater, largest vertical pocket of 8 cm or more, or subjective impression by an experienced sonographer. Using over 36,000 women with a normal index as controls, hydramnios was found to portend a significantly increased risk for a number of adverse outcomes as shown in [Table 31-4](#). One quite interesting finding was that most perinatal adverse outcomes were in nondiabetic women with hydramnios.

[Damato and colleagues \(1993\)](#) reported results from 105 women referred for evaluation of excessive fluid. Using definitions similar to those described by [Hill and associates \(1987\)](#), these investigators observed that almost 65 percent of the 105 pregnancies were abnormal ([Table 31-5](#)). There were 47 singletons with one or more anomalies: gastrointestinal (15), nonimmune hydrops (12), central nervous system (12), thoracic (9), skeletal (8), chromosomal (7), and cardiac (4). Among 19 twin pregnancies, only two were normal. Twelve of the remaining 17 had twin-twin transfusion.

Using an amniotic fluid index of greater than 24 or 25 cm to define hydramnios, most studies indicate that perinatal mortality is increased substantively. In a report by [Carlson and associates \(1990\)](#) of 49 women with an index of 24 cm or more, 22 (44 percent) had fetal malformations and six of these also had aneuploidy. There were 14 perinatal deaths among these 49 women. [Brady and colleagues \(1992\)](#) used an index of 25 cm or greater in 5000 nonreferred women and found unexplained or idiopathic hydramnios in 125 cases. They identified two fetuses with trisomy 18 and two with trisomy 21. [Panting-Kemp and co-workers \(1999\)](#) found that idiopathic hydramnios was not associated with increased adverse outcomes except for cesarean delivery.

PATHOGENESIS. Early in pregnancy, the amniotic cavity is filled with fluid very similar in composition to extracellular fluid. During the first half of pregnancy, transfer of water and other small molecules takes place not only across the amnion but through the fetal skin. During the second trimester, the fetus begins to urinate, swallow, and inspire amniotic fluid ([Abramovich and colleagues, 1979](#); [Duenhoelter and Pritchard, 1976](#)). These processes almost certainly have a significant modulating role in the control of fluid volume. Although the major source of amniotic fluid in hydramnios has most often been assumed to be the amniotic epithelium, no histological changes in amnion or chemical changes in amniotic fluid have been found.

Because the fetus normally swallows amniotic fluid, it has been assumed that this mechanism is one of the ways by which the volume is controlled. The theory gains validity by the nearly constant presence of hydramnios when swallowing is inhibited, as in cases of esophageal atresia. Fetal swallowing is by no means the only mechanism for preventing hydramnios. Both [Pritchard \(1966\)](#) and [Abramovich \(1970\)](#) quantified this and found in some instances of gross hydramnios that appreciable volumes of fluid were swallowed.

In cases of anencephaly and spina bifida, increased transudation of fluid from the exposed meninges into the amniotic cavity may be an etiological factor. Another possible explanation in anencephaly, when swallowing is not impaired, is excessive urination caused either by stimulation of cerebrospinal centers deprived of their protective coverings, or lack of antidiuretic effect because of impaired arginine vasopressin secretion. The converse is well established—that fetal defects that cause anuria are nearly always associated with oligohydramnios.

In hydramnios associated with monozygotic twin pregnancy, the hypothesis has been advanced that one fetus usurps the greater part of the circulation common to both twins and develops cardiac hypertrophy, which in turn results in increased urine output ([Chap. 30, p. 777](#)). [Naeye and Blanc \(1972\)](#) identified dilated renal tubules, enlarged bladder, and an increased urinary output in the early neonatal period, suggesting that increased fetal urine production is responsible for hydramnios. Conversely, donor members of paratibiotic transplacental transfusion pairs had contracted renal tubules with oligohydramnios.

Hydramnios that rather commonly develops with maternal diabetes during the third trimester remains unexplained. One explanation is that maternal hyperglycemia causes fetal hyperglycemia that results in osmotic diuresis. [Bar-Hava and associates \(1994\)](#) have provided evidence that third-trimester amniotic fluid volume in 399 gestational diabetes reflected recent glycemic status. [Yasui and co-workers \(1994\)](#) reported increased fetal urine production in fasted diabetic women compared with nondiabetic controls. Of interest, fetal urine production increased in nondiabetic women after eating, but this was not observed in diabetic women.

SYMPTOMS. Major symptoms accompanying hydramnios arise from purely mechanical causes and result principally from pressure exerted within and around the overdistended uterus upon adjacent organs. When distention is excessive, the mother may suffer from severe dyspnea and, in extreme cases, she may be able to breathe only when upright. Edema, the consequence of compression of major venous systems by the very large uterus, is common, especially in the lower extremities, the vulva, and the abdominal wall. Rarely, severe oliguria may result from ureteral obstruction by the very large uterus ([Chap. 47, p. 1252](#)).

With chronic hydramnios, the accumulation of fluid takes place gradually and the woman may tolerate the excessive abdominal distention with relatively little discomfort. In acute hydramnios, however, distention may lead to disturbances sufficiently serious to be threatening. Acute hydramnios tends to develop earlier in pregnancy than does the chronic form—often as early as 16 to 20 weeks—and it may rapidly expand the hypertonic uterus to enormous size. As a rule, acute hydramnios leads to labor before 28 weeks, or the symptoms become so severe that intervention is mandatory. In the majority of cases of chronic hydramnios, and thus differing from acute hydramnios, the amniotic fluid pressure is not appreciably higher than in normal pregnancy.

DIAGNOSIS. The primary clinical finding with hydramnios is uterine enlargement in association with difficulty in palpating fetal small parts and in hearing fetal heart tones. In severe cases, the uterine wall may be so tense that it is impossible to palpate any fetal parts ([Fig. 31-3](#)).

The differentiation between hydramnios, ascites, or a large ovarian cyst can usually be made without difficulty by ultrasonic evaluation. Large amounts of amniotic fluid can nearly always be readily demonstrated as an abnormally large, echo-free space between the fetus and the uterine wall or placenta ([Fig. 31-4](#)). At times, a fetal abnormality such as anencephaly or other neural-tube defects, or a gastrointestinal tract anomaly, may be seen.

PREGNANCY OUTCOME. In general, the more severe the degree of hydramnios, the higher the perinatal mortality rate. The outlook for the infant in pregnancies with marked hydramnios is poor. Even when sonography and x-ray show an apparently normal fetus, the prognosis is still guarded, because fetal malformations and chromosomal abnormalities are common. [Furman and co-workers \(2000\)](#) described substantively increased adverse perinatal outcomes if fetal growth restriction accompanies hydramnios. Perinatal mortality is increased further by preterm delivery, even with a normal fetus. [Many and colleagues \(1995\)](#) reported that 20 percent of 275 women with an amniotic fluid index of at least 25 cm delivered preterm. Moreover, preterm delivery was more common in women with an anomalous fetus (40 percent). Erythroblastosis, difficulties encountered by infants of diabetic mothers, prolapse of the umbilical cord when the membranes rupture, and placental abruption

as the uterus rapidly decreases in size, add still further to bad outcomes.

The most frequent maternal complications associated with hydramnios are placental abruption, uterine dysfunction, and postpartum hemorrhage. Extensive premature separation of the placenta sometimes follows escape of massive quantities of amniotic fluid because of the decrease in the area of the emptying uterus beneath the placenta ([Chap. 25 p. 621](#)). Uterine dysfunction and postpartum hemorrhage result from uterine atony consequent to overdistention. Abnormal fetal presentations and operative intervention are also more common.

MIDTRIMESTER HYDRAMNIOS. The prognosis of midtrimester hydramnios depends on the severity. Mild hydramnios has a reasonably good outcome. [Glantz and co-workers \(1994\)](#) studied 47 consecutive singleton pregnancies with a single deepest pocket of 6 to 10 cm that was identified at 14 to 27 weeks. Excessive fluid resolved spontaneously in three fourths and perinatal outcomes were similar to matched controls without hydramnios. In the group in which hydramnios persisted, 2 of 10 had fetal aneuploidy.

MANAGEMENT. Minor degrees of hydramnios rarely require treatment. Even moderate degrees with some discomfort can usually be managed without intervention until labor ensues or until the membranes rupture spontaneously. If there is dyspnea or abdominal pain, or if ambulation is difficult, hospitalization becomes necessary. Bed rest rarely has any effect, and diuretics and water and salt restriction are likewise ineffective. Recently, indomethacin therapy has been used for symptomatic hydramnios.

AMNIOCENTESIS. The principal purpose of amniocentesis is to relieve maternal distress, and to that end it is transiently successful. Amniotic fluid can also be tested to predict fetal lung maturity as described in [Chapter 39 \(p. 1042\)](#). [Piazzze and co-workers \(1998\)](#) showed that dilution may cause false-negative results. Therapeutic amniocentesis appears at times to initiate labor even though only a part of the fluid is removed. [Elliott and associates \(1994\)](#) reported results from 200 therapeutic amniocenteses in 94 women with hydramnios. Common causes included twin-twin transfusion (38 percent), idiopathic (26 percent), fetal or chromosomal anomalies (17 percent), and diabetes (12 percent). They removed a mean of 1650 mL of fluid at each procedure and gained an average duration of 7 weeks to delivery. Only three procedures were complicated: one woman had ruptured membranes, one developed chorioamnionitis, and another suffered placental abruption after 10 L of fluid was removed.

TECHNIQUE To remove amniotic fluid, a commercially available plastic catheter that tightly covers an 18-gauge needle is inserted through the locally anesthetized abdominal wall into the amniotic sac, the needle is withdrawn, and an intravenous infusion set is connected to the catheter hub. The opposite end of the tubing is dropped into a graduated cylinder placed at floor level, and the rate of flow of amniotic fluid is controlled with the screw clamp so that about 500 mL/h is withdrawn. After about 1500 to 2000 mL have been collected, the uterus has usually decreased in size sufficiently so that the catheter may be withdrawn from the amniotic sac. At the same time, maternal relief is dramatic and the danger of placental separation from decompression is very slight. Using strict aseptic technique, this procedure can be repeated as necessary to make the woman comfortable. [Elliott and colleagues \(1994\)](#) used wall suction and removed 1000 mL over 20 minutes (50 mL/min); however, we prefer more gradual removal.

AMNIOTOMY. The disadvantages inherent in rupture of the membranes through the cervix is the possibility of cord prolapse and especially of placental abruption. Slow removal of the fluid by amniocentesis helps to obviate these dangers.

INDOMETHACIN THERAPY. In their review of several studies, [Kramer and colleagues \(1994\)](#) concluded that indomethacin impairs lung liquid production or enhances absorption, decreases fetal urine production, and increases fluid movement across fetal membranes. Doses employed by most investigators range from 1.5 to 3 mg/kg per day.

[Cabrol and associates \(1987\)](#) treated eight women with idiopathic hydramnios from 24 to 35 weeks with indomethacin for 2 to 11 weeks. Hydramnios, defined by at least one 8-cm fluid pocket, improved in all cases. There were no serious adverse effects and the outcome was good in all cases. [Kirshon and associates \(1990\)](#) treated eight women (three sets of twins) with hydramnios from 21 to 35 weeks. In all of these, two therapeutic amniocenteses had been done before indomethacin was given. Of 11 fetuses, three were stillborn associated with twin-twin transfusion syndrome and one newborn died at 3 months of age. The remaining seven infants did well. [Mamopoulos and colleagues \(1990\)](#) treated 15 women—11 were diabetic—who had hydramnios at 25 to 32 weeks. Indomethacin was given and amniotic fluid volume decreased in all women, from a mean of 10.7 cm at 27 weeks to 5.9 cm after therapy. The outcome was good in all 15 newborns.

A major concern for the use of indomethacin is the potential for closure of the fetal ductus arteriosus ([Chap. 38, p. 1027](#)). [Moise and colleagues \(1988\)](#) reported that 50 percent of 14 fetuses whose mothers received indomethacin had ductal constriction detected by Doppler ultrasound. Persistent constriction was not demonstrated in the studies described earlier, nor has it been described in studies in which indomethacin was given for tocolysis ([Kramer and colleagues, 1994](#)).

OLIGOHYDRAMNIOS

In rare instances, the volume of amniotic fluid may fall far below the normal limits and occasionally be reduced to only a few mL of viscid fluid. The cause of this condition is not completely understood. In general, oligohydramnios developing early in pregnancy is less common and frequently has a bad prognosis. By contrast, diminished fluid volume may be found relatively often with pregnancies that continue beyond term. [Marks and Divon \(1992\)](#) found oligohydramnios—defined as an amniotic fluid index of 5 cm or less—in 12 percent of 511 pregnancies of 41 weeks' duration or greater. In 121 women studied longitudinally, there was a mean decrease in the amniotic fluid index of 25 percent per week beyond 41 weeks. The risk of cord compression, and in turn fetal distress, is increased as the consequence of diminished fluid in all labors, but especially in postterm pregnancy ([Grubb and Paul, 1992](#); [Leveno and colleagues, 1984](#)).

EARLY-ONSET OLIGOHYDRAMNIOS. A number of conditions have been associated with diminished amniotic fluid ([Table 31-6](#)). Oligohydramnios is almost always evident when there is either obstruction of the fetal urinary tract or renal agenesis. Therefore, anuria almost certainly has an etiological role in such cases. A chronic leak from a defect in the membranes may reduce the volume of fluid appreciably, but most often labor soon ensues. Exposure to angiotensin-converting enzyme inhibitors has been associated with oligohydramnios ([Chap. 38, p. 1014](#)). Anywhere from 15 to 25 percent of cases are associated with the fetal anomalies shown in [Table 31-7](#). [Pryde and co-workers \(2000\)](#) were able to visualize fetal structures in only half of women referred for ultrasonic evaluation of midtrimester oligohydramnios. They performed amniocentesis and were then able to visualize 77 percent of routinely imaged structures. Identification of associated anomalies increased from 12 to 31 percent.

PROGNOSIS. Fetal outcome is poor with early-onset oligohydramnios. [Shenker and colleagues \(1991\)](#) described 80 such pregnancies and only half of these fetuses survived. [Mercer and Brown \(1986\)](#) described 34 midtrimester pregnancies complicated by oligohydramnios diagnosed ultrasonically by the absence of amniotic fluid pockets greater than 1 cm in any vertical plane. Nine of these fetuses (26 percent) had anomalies, and 10 of the 25 who were phenotypically normal either aborted spontaneously or were stillborn because of severe maternal hypertension, restricted fetal growth, or placental abruption. Of the 14 live-born infants, eight were preterm and seven died. The six infants who were delivered at term did well. [Garnel and co-workers \(1997\)](#) observed that appropriately grown fetuses associated with oligohydramnios prior to 37 weeks had a significant threefold increase in preterm birth, but not growth restriction or fetal death.

[Newbould and colleagues \(1994\)](#) described autopsy findings in 89 infants with the oligohydramnios sequence. Only 3 percent had a normal renal tract; 34 percent had bilateral renal agenesis; 34 percent bilateral cystic dysplasia, 9 percent unilateral agenesis with dysplasia, and 10 percent minor urinary abnormalities.

Otherwise normal infants may suffer the consequences of early-onset severely diminished amniotic fluid. Adhesions between the amnion and fetal parts may cause serious deformities including amputation. Moreover, subjected to pressure from all sides, the fetus assumes a peculiar appearance, and musculoskeletal deformities such as clubfoot are observed frequently.

PULMONARY HYPOPLASIA. The incidence of pulmonary hypoplasia at birth has been unchanged and ranges from 1.1 to 1.4 per 1000 infants ([Moessinger and colleagues, 1989](#)). When amniotic fluid is scant, pulmonary hypoplasia, such as that shown in [Figure 31-5](#), is common. [Winn and associates \(2000\)](#) performed a prospective cohort study in 163 cases of oligohydramnios that followed prematurely ruptured membranes at 15 to 28 weeks. Almost 13 percent of fetuses developed pulmonary hypoplasia. This was more common as gestational age decreased. [Kilbride and co-workers \(1996\)](#) studied 115 women with prematurely ruptured membranes before 29 weeks. There ultimately were seven stillbirths and 40 neonatal deaths for a perinatal mortality of 409 per 1000. The risk of lethal pulmonary hypoplasia was 20 percent. Adverse outcomes were more likely with earlier rupture as well as duration exceeding 14 days.

According to [Fox and Badalian \(1994\)](#) and [Lauria and colleagues \(1995\)](#), there are three possibilities that account for pulmonary hypoplasia. First, thoracic compression may prevent chest wall excursion and lung expansion. Second, lack of fetal breathing movements decreases lung inflow. The third and most widely accepted model involves a failure to retain amniotic fluid or increased outflow with impaired lung growth and development.

The appreciable volume of amniotic fluid demonstrated by [Duenhoelter and Pritchard \(1976\)](#) to be inhaled by the normal fetus is suggestive of a role for the inspired fluid in expansion, and in turn growth, of the lung. [Fisk and colleagues \(1992\)](#), however, concluded that fetal breathing impairment does not cause pulmonary hypoplasia with oligohydramnios. In a unique experiment, [McNamara and associates \(1995\)](#) described findings from two sets of monoamniotic twins with discordant renal anomalies. They provided evidence that normal amniotic fluid volume in the presence of fetal renal obstruction allows normal lung development.

OLIGOHYDRAMNIOS IN LATE PREGNANCY. As shown in [Table 31-3](#) and [Figure 31-2](#), amniotic fluid volume diminishes normally after 35 weeks. Using an amniotic fluid index of less than 5 cm, [Casey and co-workers \(2000\)](#) found an incidence of oligohydramnios of 2.3 percent in over 6400 pregnancies undergoing sonography after 34 weeks at Parkland Hospital. They confirmed previous observations that this is associated with an increased risk of adverse perinatal outcomes ([Table 31-8](#)). In pregnancies selected because of "high risk," [Magann and co-workers \(1999\)](#) did not find that associated oligohydramnios (amniotic fluid index of less than 5 cm) increased risks for intrapartum complications such as thick meconium, variable heart-rate decelerations, cesarean delivery for fetal distress, or neonatal acidemia.

[Chauhan and associates \(1999\)](#) performed meta-analysis of 18 studies with over 10,500 pregnancies in which the intrapartum amniotic fluid index was less than 5 cm. Compared with controls whose index was over 5 cm, women with oligohydramnios had significantly increased risks for cesarean delivery for fetal distress risk ratio [RR] 2.2) and 5-minute Apgar of less than 7 (RR 5.2).

Cord compression during labor is common with oligohydramnios. [Sarno and co-workers \(1989, 1990\)](#) reported that an index of 5 cm or less was associated with a fivefold increased cesarean delivery rate. [Baron and colleagues \(1995\)](#) reported a 50 percent increase in variable decelerations during labor and a sevenfold increased cesarean delivery rate in these women. By contrast, Casey and co-workers (1999) showed a 25 percent increase in nonreassuring fetal heart rate patterns when women with oligohydramnios were compared with normal controls; however, the cesarean rate for this increased only from 3 to 5 percent ([Table 31-8](#)).

[Divon and associates \(1995\)](#) studied 638 postterm pregnancies in labor and observed that only women whose amniotic fluid index was 5 cm or less had fetal heart rate decelerations and meconium. Interestingly, [Chauhan and collaborators \(1995\)](#) showed that diminished amniotic fluid index increased the cesarean delivery rate only in women whose labor attendants were made aware of the findings!

AMNIOINFUSION. Infusion of crystalloid to replace pathologically diminished amniotic fluid has most often been used during labor to prevent umbilical cord compression ([Chap. 14, p. 345](#)). Results with intrapartum amnioinfusion to prevent fetal morbidity from meconium-stained fluid—often associated with oligohydramnios—are mixed. [Pierce and colleagues \(2000\)](#) performed meta-analysis of 13 studies with 1924 such women randomized to amnioinfusion or no treatment. They found significantly decreased adverse outcomes: meconium beneath the cords (OR 0.18), meconium aspiration syndrome (OR 0.30), neonatal acidemia (OR 0.42), and cesarean delivery rate (0.74). [Wenstrom and associates \(1995\)](#) surveyed academic obstetrical departments and reported that amnioinfusion is widely performed with relatively few complications. It is discussed in greater detail in [Chapter 39 \(p. 1045\)](#) and the technique is described in [Chapter 14 \(p. 345\)](#).

32. Diseases and Abnormalities of the Placenta

With the basic understanding of the process of implantation and placental development presented in [Chapter 5 \(p. 87\)](#), it is much easier to visualize the development of abnormal placental types. In addition to these, there are a number of tumors that involve the placenta. These include trophoblastic tumors such as hydatidiform mole, stromal tissue tumors such as chorioangiomas, and tumors metastatic to the placenta.

ABNORMALITIES OF PLACENTATION

ABNORMAL SHAPES

There are a number of normal placental shape variations.

MULTIPLE PLACENTAS WITH A SINGLE FETUS. Occasionally, the placenta may be separated into lobes. When the division is incomplete and the vessels of fetal origin extend from one lobe to the other before uniting to form the umbilical cord, the condition is termed *placenta bipartita* or *bilobata* ([Fig. 32-1](#)). Its reported incidence varies widely, and [Fox \(1978\)](#) cited it at about 1 of 350 deliveries. If the two lobes are separated entirely and the vessels remain distinct, the condition is designated *placenta duplex*. Occasionally, there is *placenta triplex*, with three distinct lobes.

SUCCENTURIATE PLACENTA. This variation results when one or more small accessory lobes are developed in the membranes at a distance from the periphery of the main placenta, to which they usually have vascular connections of fetal origin (see [Fig. 5-15](#)). It is a smaller version of the bilobed placenta and its incidence is about 5 percent ([Benirschke and Kaufmann, 2000](#)). The accessory lobe may sometimes be retained in the uterus after expulsion of the main placenta, and may subsequently give rise to serious hemorrhage. If, on placental examination, defects are seen in the membranes a short distance from the placental margin, retention of a succenturiate lobe should be suspected. The suspicion is confirmed if vessels extend from the placenta to the margins of the tear.

RING-SHAPED PLACENTA. This is a rare anomaly seen in fewer than 1 in 6000 deliveries. The placenta is annular in shape and sometimes a complete ring of placental tissue is present, but because of atrophy of a portion of the tissue of the ring, a horseshoe shape is more common. These abnormalities appear to be associated with a greater likelihood of antepartum and postpartum bleeding and fetal growth restriction. This anomaly may be a variant of membranaceous placenta ([Fox, 1978](#)).

MEMBRANACEOUS PLACENTA. In rare circumstances, all of the fetal membranes are covered by functioning villi, and the placenta develops as a thin membranous structure occupying the entire periphery of the chorion. *Placenta membranacea* ([Fig. 32-2](#)) is also referred to as *placenta diffusa*. It may occasionally give rise to serious hemorrhage because of associated placenta previa, and diagnosis can often be made using sonography. After delivery, the placenta may not separate readily. Bleeding resembles that seen in central placenta previa, and it may be necessary to perform a hysterectomy to control bleeding from the large area of implantation.

FENESTRATED PLACENTA. This is a rare anomaly in which the central portion of a discoidal placenta is missing. In some instances, there is an actual hole in the placenta, but more often the defect involves villous tissue only, and the chorionic plate is intact. The clinical significance of this anomaly is that it may be mistakenly considered to represent a missing portion that has been retained in the uterus.

EXTRACHORIAL PLACENTA. This is a common variation and [Benirschke and Kaufmann \(2000\)](#) found it in 5.3 percent of over 13,500 consecutive placentas. It forms when the chorionic plate, which is on the fetal side of the placenta, is smaller than the basal plate, which is located on the maternal side. If the fetal surface of such a placenta presents a central depression surrounded by a thickened, grayish-white ring, it is called a *circumvallate placenta*. When the ring coincides with the placental margin, the condition is sometimes described as a *circummarginate placenta*. Within the ring, the fetal surface presents the usual appearance, gives attachment to the umbilical cord, and shows the usual large vessels, which terminate abruptly at the margin of the ring. In a circumvallate placenta, the ring is composed of a double fold of amnion and chorion, with degenerated decidua and fibrin in between. In a marginate placenta, the chorion and amnion are raised at the margin by interposed decidua and fibrin, without folding of the membranes ([Fig. 32-3](#)). The cause of circumvallate and circummarginate placentation is not completely understood. Antepartum hemorrhage—both from placental abruption and fetal hemorrhage, preterm delivery, perinatal deaths, and fetal malformations are reported to be increased with circumvallate placentas ([Benirschke, 1974](#); [Lademacher and co-workers, 1981](#)).

PLACENTA ACCRETA, INCRETA, AND PERCRETA. In these cases, trophoblastic tissues invade the myometrial tissues. Because of their importance clinically, these are discussed in [Chapter 25 \(p. 632\)](#).

CIRCULATORY DISTURBANCES

PLACENTAL INFARCTS. The most common placental lesions, though of diverse origin, are referred to collectively as placental infarcts. [Fox \(1978\)](#) found that about a fourth of placentas from uncomplicated term pregnancies have infarcts, while pregnancies complicated by severe hypertensive disease are infarcted in about two thirds of cases. They result from occlusion of the maternal vascular supply, that is, the intervillous circulation ([Benirschke and Kaufmann, 2000](#)). The principal histopathological features include fibrinoid degeneration of the trophoblast, calcification, and ischemic infarction from occlusion of spiral arteries. Overclassification of these infarcts has led to unnecessary confusion. Small subchorionic and marginal foci of degeneration are present in almost every term placenta. In simplest terms, degenerative lesions of the placenta have two etiological factors in common:

1. Changes associated with aging of the trophoblast.
2. Impairment of the uteroplacental circulation causing infarction.

Although the placenta is by no means a dying organ at term, there are morphological indications of aging. During the latter half of pregnancy, syncytial degeneration begins and *syncytial knots* are formed. The villous stroma usually undergoes hyalinization. The syncytium may then break away, exposing the connective tissue directly to maternal blood. Clotting occurs as a result, and propagation of the clot may result in the incorporation of other villi. Macroscopically, such a focus closely resembles an ordinary blood clot, but if not observed until it has become thoroughly organized, on section a firm, white island of tissue is seen.

Around the edge of nearly every term placenta there is a dense yellowish-white fibrous ring representing a zone of degeneration and necrosis, which usually is termed a *marginal infarct*. Underneath the chorionic plate, there are nearly always similar lesions, most often pyramidal shaped, ranging from 2 mm to 3 cm across the base, and extending downward with their apices in the intervillous space (*subchorionic infarcts*). Similar lesions may be noted about the intercotyledonary septa. Occasionally, these lesions meet and form a column of cartilage-like material extending from the maternal surface to the fetal surface. Less frequently, round or oval islands of similar tissue occupy the central portions of the placenta ([Fig. 32-4](#)).

PLACENTAL CALCIFICATION. Small calcareous nodules or plaques are frequently observed on the maternal surface of the placenta. An extensive deposition of calcium is shown in [Figure 32-5](#). Placental calcification may be visualized using sonography, and [Spirit and colleagues \(1982\)](#) reported that by 33 weeks more than half of placentas have some degree of calcification, which increases substantively until term. Placental calcification graded ultrasonically has been correlated with fetal lung maturity ([Grannum and co-workers, 1979](#)); however, this correlation is not of sufficient strength to justify elective delivery.

VILLOUS (FETAL) ARTERY THROMBOSIS. Thrombosis of a stem artery produces a sharply demarcated area of avascularity. [Fox \(1978\)](#) found single-artery thrombosis in 4.5 percent of placentas from normal pregnancies and in 10 percent of those involving diabetic women. He estimated that thrombosis of a single fetal stem artery will deprive only 5 percent of the villi of their blood supply. However, he also observed a few placentas from recent stillbirths in which 40 to 50 percent of the villi were so deprived. According to [Benirschke and Kaufmann \(2000\)](#), these lesions indicate a pathological prenatal environment.

CLINICAL SIGNIFICANCE. In general, placental infarcts, caused either by local deposition of fibrin or by the more acute process of intervillous thrombosis, have little clinical significance. Nonetheless, in certain maternal diseases, notably severe hypertension, the reduction in functioning placenta through infarction, coupled with reduced blood flow to the uterus, may be sufficient to cause fetal growth restriction or death.

Villous (fetal) vessels may show endarteritic thickening and obliteration in association with fetal death. This is termed *hemorrhagic endovasculitis (HEV)*. When the placental villi are excluded from their supply of maternal blood by fibrin deposits, hematomas, or direct blockage of the decidual circulation, they become infarcted and

die. Histologically, the compromised villi are characterized by fibrosis, obliteration of fetal vessels, and gradual disappearance of the syncytium. [Shen-Schwarz and associates \(1988\)](#) described hemorrhagic endovasculitis in less than 1 percent of placentas.

HYPERTROPHIC LESIONS OF THE CHORIONIC VILLI. Striking enlargement of the chorionic villi is commonly seen in association with severe erythroblastosis and fetal hydrops. It has also been described in diabetes and occasionally in severe fetal congestive heart failure.

MICROSCOPIC PLACENTAL ABNORMALITIES. Beginning after 32 weeks, clumps of syncytial nuclei are found to project into the intervillous space, and these are called *syncytial knots*. By term, up to 30 percent of villi may be involved; however, formation of knots by more than one third of villi is considered abnormal ([Fox, 1978](#)). In prolonged pregnancies there are marked increases in syncytial knots and avascular villi as the consequence of fetal artery thrombosis. Generally, increased numbers of syncytial knots are found in placentas in which there may have been reduced uteroplacental blood flow, as with preeclampsia.

It is well recognized that the number of *cytotrophoblastic* cells becomes progressively reduced as pregnancy advances. In a normal mature placenta, cytotrophoblastic cells are found in about 20 percent of the villi ([Fox, 1978](#)). Most often, at this stage of pregnancy such cells are few and inconspicuous. However, numerous cytotrophoblastic cells are found in placentas of pregnant women with diabetes mellitus, erythroblastosis fetalis, and pregnancy-induced hypertension.

PLACENTAL INFLAMMATION. Changes that are now recognized as various forms of degeneration and necrosis were formerly described under the term *placentitis*. For example, small placental cysts with grumous contents were formerly thought to be abscesses. Nonetheless, especially in cases of prolonged rupture of the membranes, pyogenic bacteria do invade the fetal surface of the placenta, and after gaining access to the chorionic vessels, give rise to fetal infection.

ABNORMALITIES OF THE UMBILICAL CORD (FUNIS)

The cord develops in close association with the amnion ([Chap. 5, p. 105](#)).

LENGTH. Umbilical cord length varies appreciably, with the mean length at term being about 55 to 60 cm ([Benirschke and Kaufmann, 2000](#)). Extremes in cord length in abnormal instances range from apparently no cord (achordia) to lengths up to 300 cm. Vascular occlusion by thrombi and true knots are more common in excessively long cords, and they are more likely to prolapse through the cervix. Rarely, excessively short umbilical cords may be instrumental in abruptio placentae and uterine inversion.

Determinants of cord length are intriguing. Studies performed on animals and experiments of nature in human pregnancy support the concept that cord length is positively influenced by the volume of amniotic fluid and by fetal mobility. [Miller and associates \(1981\)](#) identified the human umbilical cord to be shortened appreciably when there had been either chronic fetal constraint from oligohydramnios or decreased fetal movement because of limb dysfunction. Excessive cord length may be the consequence of entanglement of cord and fetus with stretching during fetal movement. [Soernes and Bakke \(1986\)](#) reported that the mean cord length in fetuses with breech presentations was about 5 cm shorter than those with vertex presentations.

SINGLE UMBILICAL ARTERY. The absence of one umbilical artery, according to [Benirschke and Dodds \(1967\)](#), characterized 0.85 percent of all cords in singletons and 5 percent of the cords of at least one twin. **About 30 percent of all infants with only one umbilical artery had associated congenital anomalies.** The incidence ranged from 18 to 68 percent ([Herrmann and Sidiropoulos, 1988](#); [Leung and Robson, 1989](#)). [Bryan and Kohler \(1975\)](#) identified single-artery umbilical cords of 143 infants out of nearly 20,000 examined (0.72 percent). Infants with a single-artery cord had an 18 percent incidence of major malformations, 34 percent were growth-restricted, and 17 percent delivered preterm. The authors followed 90 infants and found previously unrecognized malformations in another 10.

The incidence of a single umbilical artery is increased considerably in newborns of women with diabetes, epilepsy, preeclampsia, antepartum hemorrhage, oligohydramnios, and hydramnios ([Leung and Robson, 1989](#)). Most of these conditions are associated with a threefold increase in anomalous fetuses.

Two-vessel cords are more frequently identified in fetuses aborted spontaneously. For example, [Byrne and Blanc \(1985\)](#) studied 879 consecutively aborted fetuses and identified a single umbilical artery in 1.5 percent. Eight of these 13 fetuses had serious malformations, most associated with chromosomal abnormalities.

[Parilla and colleagues \(1995\)](#) reviewed 50 neonates with a two-vessel umbilical cord as an isolated finding on prenatal ultrasound. They reported that as an isolated finding, a single umbilical artery was not associated with adverse outcomes. All 17 women who underwent amniocentesis had a fetus with a normal karyotype. [Catanzarite \(1995\)](#), however, cautioned that an isolated single umbilical artery may be associated with adverse outcomes. Two fetuses were reported with lethal chromosomal abnormalities and one fetus with a tracheoesophageal fistula out of 46 infants with a single umbilical artery.

[Pavlopoulos and colleagues \(1998\)](#) found an increase in renal aplasia, limb-reduction defects, and atresia of hollow organs in such fetuses, suggesting a vascular etiology. In a Doppler velocimetry study of 45 fetuses with single umbilical arteries compared with 124 normal controls, [Goldkrand and colleagues \(1999\)](#) found indices in the normal range but lower than in normal cords beginning at 26 weeks. Congenital anomalies were present in approximately 10 percent of fetuses with a single umbilical artery and fetal growth restriction was present in 20 percent of such fetuses. [Raio and colleagues \(1999\)](#) reported an association between single umbilical artery and a reduction of Wharton jelly. They postulated that such reduction may be responsible, at least in part, for the increased morbidity and mortality in these fetuses.

CORD COILING. In most cases, the umbilical vessels course through the umbilical cord in a spiraled manner. Several authors have observed a significant increase in various indices of adverse perinatal outcome in fetuses with hypocoiled cords, including meconium staining, preterm birth, and operative delivery for fetal distress ([Strong and colleagues, 1993, 1994](#)). [Shen-Schwarz and associates \(1996\)](#) reported an association between "absent" cord twist and marginal and velamentous cord insertion. [Rana and associates \(1995\)](#) also demonstrated a higher incidence of preterm delivery and cocaine abuse in women with hypercoiled cords.

FOUR-VESSEL CORD. Additional umbilical vessels are rarely apparent on casual inspection; however, careful inspection may disclose a venous remnant in 5 percent of cases ([Fox, 1978](#)). Its significance is unknown.

CORD INSERTION. The umbilical cord usually, but not always, is inserted at or near the center of the fetal surface of the placenta.

MARGINAL INSERTION. Cord insertion at the placental margin is sometimes referred to as a *Battledore placenta*. It is found in about 7 percent of term placentas ([Benirschke and Kaufmann, 2000](#)). With the exception of the cord being pulled off during delivery of the placenta, it is of little clinical significance.

VELAMENTOUS INSERTION. This type of cord insertion is of considerable practical importance because the umbilical vessels separate in the membranes at a distance from the placental margin, which they reach surrounded only by a fold of amnion ([Figs. 32-1 and 32-6](#)). In a review of the literature totaling almost 195,000 cases, [Benirschke and Kaufmann \(2000\)](#) found an average of 1.1 percent of singleton deliveries to have velamentous insertion. It occurs much more frequently with twins, and it is almost the rule with triplets.

VASA PREVIA. This is associated with velamentous insertion when some of the fetal vessels in the membranes cross the region of the internal os and occupy a position ahead of the presenting part. At times, the careful examiner will be able to palpate a tubular fetal vessel in the membranes overlying the presenting part. Compression of the vessels between the examining finger and the presenting part is likely to induce changes in the fetal heart rate. At times, the vessels may be visualized directly, or they may be seen on ultrasonic examination ([Fig. 32-7](#)). With vasa previa, there is considerable potential danger to the fetus, for rupture of the membranes may be accompanied by rupture of a fetal vessel, causing exsanguination.

[Fung and Lau \(1998\)](#) described three cases of vasa previa and reviewed the literature of other cases reported since 1980. These authors reported a significantly decreased fetal mortality associated with antenatal diagnosis. They also found that a low-lying placenta was a risk factor in 80 percent of cases. In another review by [Oyelese and colleagues \(1999\)](#), transvaginal ultrasound with color Doppler was recommended for antenatal diagnosis in women with risk factors such as a bilobed or succenturiate placenta, low-lying placenta, multiple pregnancy, or pregnancy resulting from in vitro fertilization. In a prospective study of 45 women with placenta previa in the third trimester, [Megier and colleagues \(1999\)](#) found 20 previas over the internal cervical os and three of these had vasa previa.

In an 8-year survey of over 90,000 women who had gray-scale ultrasonography, [Lee and colleagues \(2000\)](#) utilized endovaginal and Doppler studies to confirm vasa previa in women whose initial ultrasound demonstrated an "echogenic parallel or circular line near the cervix." These authors were able to detect vasa previa in asymptomatic women as early as the midtrimester. Likewise, [Nomiyama and colleagues \(1998\)](#) were able to diagnose two cases of vasa previa at 18 weeks with transvaginal color Doppler imaging.

Whenever there is hemorrhage antepartum or intrapartum, the possibility of vasa previa and a ruptured fetal vessel exists. Unfortunately, the amount of fetal blood that can be shed without killing the fetus is relatively small. A quick, readily available approach to detecting fetal blood is to smear the blood on glass slides, stain the smears with Wright stain, and examine for nucleated red cells, which normally are present in cord blood but not maternal blood.

CORD ABNORMALITIES CAPABLE OF IMPEDING BLOOD FLOW. Several mechanical and vascular abnormalities of the umbilical cord are capable of impairing fetal-placental blood flow.

KNOTS. *False knots*, which result from kinking of the vessels to accommodate to the length of the cord, should be distinguished from *true knots*, which result from active fetal movements. In nearly 17,000 deliveries in the Collaborative Study on Cerebral Palsy, [Spellacy and co-workers \(1966\)](#) found an incidence of true knots of 1.1 percent. Perinatal loss was 6 percent in the presence of true knots. The incidence of true knots is especially high in monoamniotic twins.

LOOPS. The cord frequently becomes coiled around portions of the fetus, usually the neck. In 1000 consecutive deliveries studied by [Kan and Eastman \(1957\)](#), the incidence of the umbilical cord around the neck ranged from one loop in 21 percent to three loops in 0.2 percent. Fortunately, coiling of the cord around the neck is an uncommon cause of fetal death. Typically, as labor progresses and the fetus descends the birth canal, contractions compress the cord vessels, which cause fetal heart rate deceleration that persists until the contraction ceases. [Hankins and colleagues \(1987a\)](#) reported 110 pregnancies in which labor at term was complicated by a nuchal cord. Compared with control infants, those with a nuchal cord had more moderate or severe variable fetal heart rate decelerations (20 versus 5 percent). They also were more likely to have a lower umbilical artery pH. Interestingly, none of the newborns had pathological fetal acidemia (pH less than 7.00).

TORSION. As a result of fetal movements, the cord normally becomes twisted. Occasionally, the torsion is so marked that fetal circulation is compromised. Extreme degrees may occur after the death of the fetus by a mechanism that is not understood. In monoamniotic twinning, a significant fraction of the high perinatal mortality rate is attributed to entwining of the umbilical cords before labor.

STRICTURE. Most, but not all, infants with cord stricture are stillborns; the stricture probably has a role in fetal death. Cord stricture, for unknown reasons, is associated with an extreme focal deficiency in Wharton jelly. Stricture is commonly and causally associated with torsion.

HEMATOMA. These occasionally result from the rupture of a varix, usually of the umbilical vein, with effusion of blood into the cord ([Fig. 32-8](#)). Cord hematomas have also been described as resulting from ultrasound-directed umbilical vessel venipuncture.

CYSTS. Occasionally found along the course of the cord, cysts are designated true and false, according to their origin. True cysts are quite small and may be derived from remnants of the umbilical vesicle or of the allantois. False cysts, which may attain considerable size, result from liquefaction of Wharton jelly. Such cysts may be detected by sonography but are difficult to identify precisely. For example, the cyst demonstrated in [Figure 32-9](#) was thought to possibly be a meningocele when detected by sonography, because the cyst maintained a close and constant relationship over time with the lower spine of the fetus.

EDEMA. Placental and cord edema are rarely seen alone, but are frequently associated with edema of the fetus. They are very common with macerated fetuses.

PATHOLOGICAL EXAMINATION

The [College of American Pathologists \(1991\)](#) recommends routine pathological examination of the placenta with certain obstetrical and neonatal conditions. Conversely, the [American College of Obstetricians and Gynecologists \(1993a\)](#) feels that there are insufficient data to support this recommendation, which is costly and time consuming. Certainly, the placenta and cord—including the number of vessels—should be grossly examined following all deliveries. Although pathological examination may be useful in the diagnosis of some unusual conditions, such as microabscesses seen with listeriosis, the possible correlation of specific placental findings with both short- and long-term neonatal outcome is still unclear. Currently, routine placental examination in all births does not appear to be justified on either a scientific or cost-effective basis. Pathological placental examination, however, as well as fetal autopsy, frequently prove useful in determining the cause of stillbirth ([Chap. 39, p. 1074](#)).

GESTATIONAL TROPHOBLASTIC DISEASE

There is a spectrum of pregnancy-related trophoblastic proliferative abnormalities, the classification of which for many years was based principally on histological criteria and included hydatidiform mole, invasive mole, and choriocarcinoma. Subsequently, a classification was proposed based principally upon clinical findings and serial determinations of serum levels of chorionic gonadotropin which is secreted by the abnormal tissue ([Hammond and colleagues, 1973](#)). Although these two classifications have caused some confusion, the clinical approach is now accepted.

In 1983, the [World Health Organization Scientific Group on Gestational Trophoblastic Diseases](#) published specific recommendations regarding terminology for the definition, classification, and staging of trophoblastic disease. Basically, gestational trophoblastic disease can be divided into **hydatidiform mole** and **gestational trophoblastic tumors** ([Table 32-1](#)). The term *gestational trophoblastic neoplasia* is no longer employed because invasive moles are not true neoplasms ([Miller and Lurain, 1988](#)). As shown in [Table 32-1](#), gestational trophoblastic tumors can be classified clinically as nonmetastatic and metastatic, and the latter are subdivided into low risk and high risk.

HYDATIDIFORM MOLE (MOLAR PREGNANCY)

Molar pregnancy is characterized histologically by abnormalities of the chorionic villi consisting of varying degrees of trophoblastic proliferation and edema of villous stroma. Moles usually occupy the uterine cavity; however, they may occasionally be located in the oviduct and even the ovary ([Stanhope and associates, 1983](#)). The absence or presence of a fetus or embryonic elements has been used to classify them into *complete* and *partial* moles ([Table 32-2](#)). As emphasized by [Benirschke and Kaufmann \(2000\)](#), in many cases this is difficult.

COMPLETE HYDATIDIFORM MOLE. The chorionic villi are converted into a mass of clear vesicles ([Fig. 32-10](#)). The vesicles vary in size from barely visible to a few centimeters in diameter and often hang in clusters from thin pedicles. The histological structure demonstrated in [Figure 32-11](#) is characterized by:

1. Hydropic degeneration and swelling of the villous stroma.
2. Absence of blood vessels in the swollen villi.
3. Proliferation of the trophoblastic epithelium to a varying degree.
4. Absence of fetus and amnion.

Hydropic or molar degeneration, which may be confused with a true mole, is not classified as trophoblastic disease ([Berkowitz and associates, 1991](#)).

Cytogenetic studies of complete molar pregnancies have identified the chromosomal composition most often (85 percent or more) to be 46, XX, with the chromosomes completely of paternal origin ([Wolf and Lage, 1995](#)). This phenomenon is referred to as *androgenesis*. Typically, the ovum has been fertilized by a haploid sperm, which then duplicates its own chromosomes after meiosis, and thus the chromosomes are homozygous. The chromosomes of the ovum are either absent or inactivated. Occasionally, the chromosomal pattern in a complete mole may be 46,XY, that is, heterozygous due to dispermic fertilization ([Bagshawe and Lawler, 1982](#); [Lawler and colleagues, 1991](#)).

[Lawler and colleagues \(1991\)](#) described 202 hydatidiform moles; 151 were complete and 49 partial moles. The genetic ploidy of these moles is summarized in [Table 32-3](#). The majority (85 percent) of complete moles are diploid whereas most partial moles (86 percent) are triploid. Other variations have been described, such as 45,X. Thus, a morphologically complete mole can result from a variety of chromosomal patterns ([Wolfe and Lage, 1995](#)). The risk of trophoblastic tumors developing from a complete mole is approximately 20 percent ([Table 32-2](#)).

PARTIAL HYDATIDIFORM MOLE. When the hydatidiform changes are focal and less advanced, and maybe some fetal tissues, usually at least an amniotic sac, is seen, the condition is classified as a partial hydatidiform mole. There is slowly progressing hydatidiform swelling of some usually avascular villi, while other vascular villi with a functioning fetal-placental circulation are spared. Trophoblastic hyperplasia is focal rather than generalized.

As shown in [Table 32-3](#), the karyotype typically is triploid—69,XXX, 69,XXY, or 69,YYY—with one maternal but usually two paternal haploid complements ([Berkowitz and colleagues, 1986, 1991](#); [Wolfe and Lage, 1995](#)). The fetus of a partial mole typically has stigmata of triploidy, which includes multiple congenital malformations and growth restriction, and it is nonviable. In the report by [Lawler and colleagues \(1991\)](#), 86 percent of partial moles were triploid and 2 percent were diploid. [Jauniaux \(1999\)](#), in a review of partial moles, reported that 82 percent of fetuses with triploid karyotypes had symmetrical growth restriction. [Jauniaux and colleagues \(1998\)](#) also reported a case of partial mole with trisomy 13. [Lembet and colleagues \(2000\)](#) recently reported a case of partial hydatidiform mole with a diploid karyotype and a live fetus.

A twin gestation of a complete mole and a normal fetus and placenta is sometimes misdiagnosed as a diploid partial mole ([Fig. 32-12](#)). It is important to attempt to distinguish between the two, because twin pregnancies consisting of a normal fetus and a complete mole have a 50 percent chance of subsequent persistent trophoblastic disease compared with a much lower rate with triploid partial moles ([Bruchim and associates, 2000](#)). [Van de Kaa and colleagues \(1995\)](#) described the use of interphase cytogenetics and DNA cytometric analysis to help distinguish between these two entities.

Nonmetastatic trophoblastic tumors may follow hydatidiform mole in 4 to 8 percent of cases ([Berkowitz and colleagues, 1986](#); [Szulman and Surti, 1982](#)). The risk of choriocarcinoma arising from a partial mole is very low. [Seckl and associates \(2000\)](#) described 3000 cases of partial mole and documented only three cases of choriocarcinoma.

[Veierslev \(1991\)](#) reviewed the outcomes of pregnancies reported with a hydatidiform mole coexistent with a normal fetus. Of 113 pregnancies, 52 (45 percent) of fetuses progressed to 28 weeks, and survival was 70 percent. Thus, when providing counseling for women with a coexistent mole and a fetus, both cytogenetic and high-resolution ultrasound studies are of paramount importance.

HISTOLOGICAL DIAGNOSIS. Attempts to relate the histological structure of individual complete hydatidiform moles to their subsequent malignant tendencies have generally been disappointing. [Novak and Seah \(1954\)](#), for example, were unable to precisely establish such a relation in 120 cases of hydatidiform mole or in the molar tissue in 26 cases of choriocarcinoma following hydatidiform mole.

THECA-LUTEIN CYSTS. In many cases of hydatidiform mole, the ovaries contain multiple theca-lutein cysts ([Fig. 35-10](#)). These may vary from microscopic size to 10 cm or more in diameter. The surfaces of the cysts are smooth, often yellowish, and lined with lutein cells. The incidence of obvious cysts in association with a mole is reported to be from 25 to 60 percent. These cysts are thought to result from overstimulation of lutein elements by large amounts of chorionic gonadotropin secreted by proliferating trophoblast. In general, extensive cystic change is usually associated with larger hydatidiform moles and a long period of stimulation. [Montz and colleagues \(1988\)](#) reported that persistent trophoblastic disease was more likely in women with theca-lutein cysts, especially if bilateral. Cysts are not limited to cases of hydatidiform mole, and are associated with placental hypertrophy with fetal hydrops or multifetal pregnancy. Some of these, especially very large cysts, may undergo torsion, infarction, and hemorrhage. Because the cysts regress after delivery, oophorectomy should not be performed unless the ovary is extensively infarcted.

INCIDENCE. Hydatidiform mole develops in approximately 1 in 1000 pregnancies in the United States and Europe. Although it has been reported to be more frequent in other countries, especially in parts of Asia, much of this information was based on hospital studies ([Schorge and associates, 2000](#)). Based on population studies, the incidence in most of the world is probably similar to that in the United States ([Miller and colleagues, 1989](#); [Semer and Macfee, 1995](#)).

AGE. There is a relatively high frequency of hydatidiform mole among pregnancies at the beginning or end of the childbearing period ([Semer and Macfee, 1995](#)). The most pronounced effect is seen in women over 45, when the relative frequency of the lesion is more than 10 times greater than at ages 20 to 40 ([Schorge and colleagues, 2000](#)). There are numerous authenticated cases of hydatidiform mole in women 50 years old and older.

PREVIOUS MOLE. Recurrence of hydatidiform mole is seen in about 1 to 2 percent of cases ([Miller and co-workers, 1989](#)). In a review of 12 series totaling almost 5000 deliveries, the frequency of recurrent moles was 1.3 percent ([Loret de Mola and Goldfarb, 1995](#)). [Kim and associates \(1998\)](#) found a 4.3 percent recurrence rate in 115 women followed in Seoul, Korea. In a review of repetitive hydatidiform moles with different partners, [Tuncer and colleagues \(1999\)](#) concluded that there may be "a primary oocyte problem."

OTHER FACTORS. The role of gravidity, parity, other reproductive factors, estrogen status, oral contraceptives, and dietary factors in the risk of gestational trophoblastic disease is unclear ([Semer and Macfee, 1995](#)).

CLINICAL COURSE. The clinical presentation of most molar pregnancies has changed appreciably over 20 years because use of transvaginal ultrasound and quantitative serum hCG have led to earlier diagnosis ([Coukos and colleagues, 1999](#)). Later in the first trimester and during the second trimester, a number of changes are often evident. Symptoms are more likely to be dramatic with a complete mole. [Schlaerth and colleagues \(1988\)](#) reported complications in two thirds of 381 women with molar pregnancies.

BLEEDING. Uterine bleeding is almost universal, and may vary from spotting to profuse hemorrhage ([Rose, 1995](#)). It may begin just before abortion or, more often, it may occur intermittently for weeks or even months. A dilutional effect from appreciable hypervolemia has been demonstrated in some women with larger moles. At times there may be considerable hemorrhage concealed within the uterus. Iron-deficiency anemia is a common finding and infrequently megaloblastic erythropoiesis is evident, presumably as a result of poor dietary intake because of nausea and vomiting coupled with increased folate requirement imposed by rapidly proliferating trophoblast.

UTERINE SIZE. The growing uterus often enlarges more rapidly than usual. It is the most common finding, and in about half of cases, uterine size clearly exceeds that expected from the duration of gestation. The uterus may be difficult to identify precisely by palpation, particularly in the nulliparous woman, because of its soft consistency beneath a firm abdominal wall. At times ovaries appreciably enlarged by multiple theca-lutein cysts may be difficult to distinguish from the enlarged uterus.

FETAL ACTIVITY. Even though the uterus is enlarged sufficiently to reach well above the symphysis, typically no fetal heart action is detected. Rarely, there may be twin placentas with a complete molar pregnancy developing in one, while the other placenta and its fetus appear normal ([Fig. 32-12](#)). Also, very infrequently there may be extensive but incomplete molar change in the placenta accompanied by a living fetus.

PREGNANCY-INDUCED HYPERTENSION. Of special importance is the possible association of preeclampsia with molar pregnancies that persist into the second trimester. Because pregnancy-induced hypertension is rarely seen before 24 weeks, preeclampsia that develops before this time should at least suggest hydatidiform mole or extensive molar change.

HYPEREMESIS. Significant nausea and vomiting may occur. Of interest, none of the 24 complete moles reported by [Coukos and colleagues \(1999\)](#) had preeclampsia, hyperemesis, or clinical hyperthyroidism.

THYROTOXICOSIS. Plasma thyroxine levels in women with molar pregnancy are often elevated, but clinically apparent hyperthyroidism is unusual. [Amir and colleagues \(1984\)](#) and [Curry and associates \(1975\)](#) identified hyperthyroidism in about 2 percent of cases. Plasma thyroxine elevation may be the effect primarily of estrogen, as in normal pregnancy, in which case free thyroxine levels are not elevated. As discussed in [Chapter 6 \(p. 113\)](#), serum free thyroxine is elevated as the consequence of either the thyrotropin-like effect of chorionic gonadotropin or its variants ([Amir and co-workers, 1984](#); [Mann and colleagues, 1986](#)). [Miller and Seifer \(1990\)](#) reviewed the endocrinological aspects of gestational trophoblastic diseases.

EMBOLIZATION. Variable amounts of trophoblast with or without villous stroma escape from the uterus in the venous outflow at evacuation. The volume may be such as to produce signs and symptoms of acute pulmonary embolism and even a fatal outcome ([Fig. 32-13](#)). Such fatalities are rare. [Hankins and colleagues \(1987b\)](#) obtained hemodynamic measurements using a pulmonary artery catheter in six women with large molar pregnancies. They also searched for evidence of **trophoblastic deportation** before and during molar evacuation. Only small numbers of multinucleated giant cells and mononuclear cells, presumably trophoblasts, were identified. They found no evidence for acute cardiorespiratory changes, and concluded that massive trophoblastic embolization with molar evacuation was probably infrequent.

Some, but not most, practitioners believe that medical induction prior to evacuation of a hydatidiform mole may increase the risk of trophoblast embolization or persistent trophoblastic disease. [Schlaerth and co-workers \(1988\)](#) identified respiratory complications in 15 percent of women with a mole larger than 20 weeks' size. In many of these, pregnancy was terminated by hysterectomy or labor induction.

Even though trophoblast, with or without villous stroma, embolizes to the lungs in volumes too small to produce overt blockade of the pulmonary vasculature, these can subsequently invade the pulmonary parenchyma to establish metastases that are evident radiographically. The lesions may consist of trophoblast alone (metastatic choriocarcinoma) or trophoblast with villous stroma (metastatic hydatidiform mole). The subsequent course of such lesions is unpredictable, and some have been observed to disappear spontaneously either soon after uterine evacuation or even weeks to months later, while others proliferate and cause death without treatment.

DIAGNOSTIC FEATURES. In some cases, hydatid vesicles that resemble grapes are passed before the mole is aborted spontaneously or removed by operation (Rose, 1995). Spontaneous expulsion is most likely around 16 weeks and is rarely delayed beyond 28 weeks. Clinical findings of persistent bleeding and a uterus larger than the expected size arouse suspicion for a molar pregnancy. Consideration must be given to an error in menstrual data or a pregnant uterus further enlarged by myomas, hydramnios, or especially multiple fetuses. The greatest diagnostic accuracy is obtained from the characteristic ultrasonic appearance of hydatidiform mole (Fig. 32-14). Occasionally, other structures may have an appearance similar to that of a mole, including uterine myoma and pregnancies with multiple fetuses.

In summary, the clinical and diagnostic features of a complete hydatidiform mole are the following:

- Continuous or intermittent bloody discharge evident by about 12 weeks, usually not profuse, and often more nearly brown rather than red.
- Uterine enlargement out of proportion to the duration of pregnancy in about half of the cases.
- Absence of fetal parts and fetal heart sounds even though the uterus may be enlarged to the level of the umbilicus or higher.
- Characteristic ultrasonic appearance.
- Serum chorionic gonadotropin level higher than expected for the stage of gestation.
- Preeclampsia-eclampsia developing before 24 weeks.
- Hyperemesis gravidarum.

PROGNOSIS. Current mortality from moles has been practically reduced to zero by more prompt diagnosis and appropriate therapy. With advanced molar pregnancies, these women are usually anemic and bleeding acutely. Infection and sepsis in these cases may cause serious morbidity (Schlaerth and colleagues, 1988).

Earlier evacuation unfortunately has not diminished the development of persistent tumors (Schorge and co-workers, 2000).

Nearly 20 percent of complete moles progress to gestational trophoblastic tumor. Lurain and colleagues (1983) reported follow-up results of 738 patients from 1962 to 1978 following evacuation of a hydatidiform mole. Spontaneous regression occurred in 596 women (81 percent), while gestational trophoblastic tumors developed in 142 (19 percent). Of this latter group, 125 (17 percent) had an invasive mole and 17 (2 percent) had choriocarcinoma. All 142 women with trophoblastic tumors were cured and all 738 patients were free of disease at 4 to 18 years follow-up.

TREATMENT. Hydatidiform mole treatment consists of two phases: immediate evacuation of the mole, and subsequent follow-up for detection of persistent trophoblastic proliferation or malignant change. Initial evaluation prior to evacuation or hysterectomy includes at least a cursory search for metastatic disease. A chest radiograph should be done to look for pulmonary lesions. Although Mutch and colleagues (1986) showed that using computed tomography increased the likelihood of detecting metastatic disease, its routine use has not been evaluated and did not affect prognosis. Unless there is other evidence of extrauterine disease, computed tomography or magnetic resonance imaging to evaluate the liver or brain is not done routinely.

The rare circumstance of twinning with a complete hydatidiform mole plus a fetus and placenta presents an unusual therapeutic dilemma, especially in the absence of karyotypic aberrations or gross fetal anomalies. Neither the risks to the mother nor the likelihood of a healthy offspring have been established. Suzuki and associates (1980) and Vejerslev (1991) reviewed cases in which the outcome was good for both infant and mother.

TERMINATION OF MOLAR PREGNANCY. Because of greater awareness, and certainly because of better technique for diagnosis, moles now are terminated more often when they are still small, and under controlled circumstances rather than the chaos common when they abort spontaneously. Thus, there is time for adequate evaluation of the woman who may be anemic, hypertensive, or fluid depleted.

PROPHYLACTIC CHEMOTHERAPY. The role of prophylactic chemotherapy for women with a hydatidiform mole is controversial (Bloss and Miller, 1995; Goldstein and Berkowitz, 1995). There is no evidence, however, that such therapy improves the long-term prognosis. Not only will the majority of women experience a spontaneous regression of disease following evacuation, but the follow-up of all patients, including those receiving chemotherapy, is essentially the same. Moreover, the toxicity from prophylactic chemotherapy may be significant, including death (Bloss and Miller, 1995).

VACUUM ASPIRATION. Suction evacuation is the treatment of choice for hydatidiform mole, regardless of uterine size (Bloss and Miller, 1995; Miller and colleagues, 1989). For large moles, compatible blood is made ready and an intravenous system is established for its rapid infusion, if needed. Cervical dilating agents described in Chapter 20 (p. 470) are used if the cervix is long, very firm, and closed. Further dilatation can be safely accomplished under anesthesia to a diameter sufficient to allow insertion of a plastic suction curet.

After the great bulk of the mole has been removed by aspiration and oxytocin is given, and the myometrium has contracted, *thorough but gentle* curettage with a large sharp curet is usually performed. Evacuation of all the contents of a large mole is not always easily accomplished, and intraoperative ultrasonic examination may be helpful to establish that the uterine cavity is empty. Facilities and personnel for immediate laparotomy are mandatory in case there is uncontrollable hemorrhage or serious trauma to the uterus.

OXYTOCIN, PROSTAGLANDINS, AND HYSTEROTOMY. Labor induction rarely is used in this country for evacuation of hydatidiform moles, and there are many who feel that medical termination and hysterotomy have no role in the management (Miller and co-workers, 1989; Stone and Bagshawe, 1979).

HYSTERECTOMY. If age and parity are such that no further pregnancies are desired, then hysterectomy may be preferred to suction curettage. Hysterectomy is a logical procedure in women of 40 or over, because of the frequency with which malignant trophoblastic disease ensues in this age group. Tow (1966) reported that 37 percent of women over age 40 with a complete mole went on to develop gestational trophoblastic tumor. Although hysterectomy does not eliminate trophoblastic tumor, it does appreciably reduce the likelihood of recurrent disease.

FOLLOW-UP PROCEDURES. The prime objective of follow-up is prompt detection of any change suggestive of malignancy. A general method of follow-up is the following:

- Prevent pregnancy during the follow-up period—at a minimum, for 1 year.
- Measure serum chorionic gonadotropin (hCG) levels every 2 weeks. Although weekly assays are recommended by some, no distinct benefit has been demonstrated.
- Withhold therapy as long as these serum levels continue to regress. A rise or persistent plateau in the level demands evaluation and usually treatment.
- Once the level is normal—that is, once it has reached the lower limit of measurement—then test monthly for 6 months, and then every 2 months for a total of 1 year.
- Follow-up may be discontinued and pregnancy allowed after 1 year.

Thus current follow-up and management centers on serial measurement of serum hCG values to detect persistent trophoblastic tumor. As shown in Figure 32-15, chorionic gonadotropin levels should progressively fall to undetectable levels, otherwise trophoblast persists. An increase signifies trophoblastic proliferation that is most likely malignant unless the woman is again pregnant. Treatment of suspected persistent trophoblastic tumor is discussed subsequently.

Estrogen-progestin contraceptives have often been used to prevent a subsequent pregnancy and to suppress pituitary luteinizing hormone that cross-reacts with some tests for chorionic gonadotropin. [Yuen and Burch \(1983\)](#) reported that neither the duration that chorionic gonadotropin persisted nor the frequency of invasive complications was increased in women who used oral contraceptives after molar evacuation. [Deicas and associates \(1991\)](#) studied the effect of contraception on subsequent development of postmolar tumor in 162 women with hydatidiform mole and 137 with trophoblastic tumor. Of the women using oral contraceptives, 33 percent developed tumors compared with 57 percent who did not.

TREATMENT OF PERSISTENT TROPHOBLASTIC TUMOR. Following evacuation of a hydatidiform mole, about 20 percent of women will subsequently undergo further treatment for suspected persistent gestational trophoblastic tumor ([Lurain and co-workers, 1983](#)). If serum chorionic gonadotropin values have plateaued or are rising, if there is no evidence for disease beyond the uterus, and if the uterus is not important for future reproduction, hysterectomy will effect a cure in most cases. Often chorionic gonadotropin will disappear and the woman remains well. However, if the uterus is to be preserved, if there is radiographic evidence of lung lesions, or if there are vaginal metastases, chemotherapy is started. Most often, such treatment has been successful. Very small amounts of viable trophoblastic tumor can be detected by hCG assay. Once gonadotropin activity has decreased to the limit of measurement, therapy can be stopped safely without likelihood of recurrence.

GESTATIONAL TROPHOBLASTIC TUMOR

This term refers to the pathological entities of invasive mole, choriocarcinoma, and placental site trophoblastic tumor. It may follow molar pregnancy or normal pregnancy, or develop after abortive outcomes, including ectopic pregnancy. As shown in [Table 32-1](#), malignant gestational trophoblastic disease is divided into two clinical categories, nonmetastatic and metastatic. The latter is further divided into those women who are at high risk and low risk with regard to prognosis.

ETIOLOGY. Gestational trophoblastic tumor most always develops with or follows some form of pregnancy. Very rarely, choriocarcinoma may arise from a teratoma. Approximately half of cases follow a hydatidiform mole, 25 percent follow an abortion, and 25 percent develop after an apparently normal pregnancy. Of 48 fatal cases from the Brewer Trophoblastic Disease Center, only 14 (30 percent) developed in association with a hydatidiform mole ([Lurain and co-workers, 1982](#)). The remainder were associated with term or near-term pregnancies, abortions, or ectopic pregnancies. [Tanos and associates \(1994\)](#) described a woman who developed recurrence of gestational trophoblastic disease after two attempts at in vitro fertilization.

Malignancy has rarely been identified in the placenta of a seemingly normal pregnancy. In a case described by [Brewer and Mazur \(1981\)](#), widespread malignant trophoblast was evident at 18 weeks, and a primary choriocarcinoma of the placenta was detected. A case in which malignant trophoblast metastasized to the fetus has also been described ([Kruseman and colleagues, 1977](#)). Others have reported intraplacental choriocarcinoma associated with a live fetus ([Aonahata and co-workers, 1998](#); [Jacques and associates, 1998](#)). [Lele and colleagues \(1999\)](#) presented another case and a review of the literature.

PATHOLOGY. In most cases of gestational trophoblastic tumor, the diagnosis is made primarily by persistent serum chorionic gonadotropin. **Clinical management is no longer dictated by histological findings.** In fact, in most cases, no tissue is submitted for pathological study. In those cases with tissue submitted, either choriocarcinoma or invasive mole are most often found.

CHORIOCARCINOMA. This extremely malignant form of trophoblastic tumor may be considered a carcinoma of the chorionic epithelium, although in its growth and metastasis it often behaves like a sarcoma. Factors involved in malignant transformation of the chorion are unknown. In choriocarcinoma, the predisposition of normal trophoblast to invasive growth and erosion of blood vessels is greatly exaggerated. The characteristic gross picture is that of a rapidly growing mass invading both uterine muscle and blood vessels, causing hemorrhage and necrosis ([Fig. 32-16A](#)). The tumor is dark red or purple and ragged or friable. If it involves the endometrium, then bleeding, sloughing, and infection of the surface usually occur early. Masses of tissue buried in the myometrium may extend outward, appearing on the uterus as dark, irregular nodules that eventually penetrate the peritoneum.

Microscopically, columns and sheets of trophoblast penetrate the muscle and blood vessels, sometimes in plexiform arrangement and at other times in complete disorganization, interspersed with clotted blood ([Fig. 32-16B](#)). An important diagnostic feature of choriocarcinoma, in contrast to hydatidiform mole or invasive mole, is absence of a villous pattern. Both cytotrophoblast and syncytial elements are involved, although one or the other may predominate. Cellular anaplasia exists, often in marked degrees, but is less valuable as a criterion of trophoblastic malignancy than in other tumors. The difficulty of cytological evaluation is one of the factors leading to error in the diagnosis of choriocarcinoma from examination of uterine curettings. Cells of normal trophoblast at the placental site have been erroneously diagnosed as choriocarcinoma.

Metastases often develop early and are generally blood-borne because of the affinity of trophoblast for blood vessels. The most common sites of metastasis are the lungs (over 75 percent) and the vagina (about 50 percent). The vulva, kidneys, liver, ovaries, brain, and bowel also contain metastases in many cases ([Fig. 32-17](#)). Ovarian theca-lutein cysts are identified in over a third of cases.

INVASIVE MOLE. The distinguishing features of invasive mole are excessive trophoblastic overgrowth and extensive penetration by the trophoblastic elements, including whole villi, into the depths of the myometrium, sometimes to involve the peritoneum or the adjacent parametrium or vaginal vault. Such moles are locally invasive, but generally lack the pronounced tendency to widespread metastasis characteristic of choriocarcinoma.

PLACENTAL SITE TROPHOBLASTIC TUMOR. Very rarely, a trophoblastic tumor arises from the placental implantation site following either a normal term pregnancy or abortion. This tumor is characterized histologically by predominantly cytotrophoblastic cells, and immunohistochemical staining reveals many prolactin-producing cells and few gonadotropin-producing ones ([Miller and associates, 1989](#)). Thus, gonadotropin levels may be normal to elevated. Bleeding is the main presenting symptom. [Brewer and colleagues \(1992\)](#) described erythrocytosis associated with a placental-site trophoblastic tumor. Polycythemia resolved after hysterectomy. Disease confined to the uterus can usually be cured by hysterectomy, although women with metastatic disease have a much worse progress. [Randall and colleagues \(2000\)](#) described a woman with prolonged remission following recurrent metastatic placental site tumor and chemotherapy. [Gillespie and colleagues \(2000\)](#) reviewed their experience with seven women with placental site tumor. Three were treated successfully with hysterectomy for tumor confined to the uterus, two are doing well following chemotherapy for pulmonary metastases, and two have died from metastatic disease despite therapy.

CLINICAL COURSE. Gestational trophoblastic tumor may follow hydatidiform mole, abortion, ectopic pregnancy, or normal pregnancy. The most common, though not constant sign, is irregular bleeding after the immediate puerperium in association with uterine subinvolution. The bleeding may be continuous or intermittent, with sudden and sometimes massive hemorrhages. Uterine perforation by the growth may cause intraperitoneal hemorrhage.

In many cases, the first indication may be a metastatic lesion. Vaginal or vulvar tumors may be found. The woman may complain of cough and have bloody sputum from pulmonary metastases. In a few cases it has been impossible to find choriocarcinoma in the uterus or pelvis, the original lesion having disappeared, leaving only distant metastases growing actively. If untreated, choriocarcinoma is rapidly progressive, and death usually follows within a few months in the majority of cases. The most common cause of death is hemorrhage in various locations.

DIAGNOSIS. All women with a hydatidiform mole are at risk and need to be followed as described. **Recognition of the possibility of the lesion is the most important factor in diagnosis.** Any case of unusual bleeding after term pregnancy or abortion should be investigated by curettage, but especially by measurements of chorionic gonadotropin, because absolute reliance cannot be placed on histological findings. Solitary or multiple nodules present in the chest radiograph ([Fig. 32-17](#)) that cannot be otherwise explained are suggestive of the possibility of choriocarcinoma. Persistent or rising gonadotropin levels in the absence of pregnancy are indicative of trophoblastic tumor. Occasionally, some nontrophoblastic tumors secrete small amounts of chorionic gonadotropin ([Shane and Naftolin, 1975](#)).

Other evaluation before treatment is given includes computed tomography to evaluate the brain, lungs, liver, and pelvis. [Hricak and colleagues \(1986\)](#) reported the use of magnetic resonance imaging in nine women with trophoblastic tumor and concluded that this method was superior to sonography and computed tomography to evaluate the degree of uterine involvement. [Yamashita and co-workers \(1995\)](#) recently reported that contrast-enhanced magnetic resonance imaging was superior to conventional spin-echo imaging for demonstrating myometrial involvement of postmolar trophoblastic tumor.

TREATMENT. Single-agent chemotherapy is given for nonmetastatic or low-risk metastatic disease ([Table 32-1](#)). Methotrexate and other agents effective against malignant tumors, especially actinomycin D, have been widely used with considerable success. In some cases, such as with brain metastases, chemotherapy is given along with radiotherapy ([Evans and associates, 1995](#)).

The pharmacology and clinical use of methotrexate have been reviewed extensively by [Jolivet and colleagues \(1983\)](#). The overall cure rate in past years for persistent gestational trophoblastic tumor of all severities has been about 90 percent ([American College of Obstetricians and Gynecologists, 1993b](#)). Patients classified as having nonmetastatic tumors or good-prognosis gestational trophoblastic tumors have been cured virtually 100 percent of the time. ([Schorge and colleagues, 2000](#)). Cure has usually been achieved for these low-risk women following single-agent chemotherapy. Such treatment reduces serious toxicity.

A number of regimens have been used with success. [Barter and associates \(1987\)](#) reported success with methotrexate given orally. [Homesley and associates \(1988\)](#) reported similar results with weekly intramuscular methotrexate. [Petrilli and colleagues \(1987\)](#) found that single-dose actinomycin D given every 2 weeks was highly effective in women with nonmetastatic disease. [Lurain and Elfstrand \(1995\)](#) reported similar results from the Brewer Trophoblastic Disease Center at Northwestern Medical School. A total of 253 women with nonmetastatic disease were treated with 5-day intravenous methotrexate repeated every 14 days. Additional therapy was required in about 10 percent and all eventually were cured.

HIGH-RISK TROPHOBLASTIC TUMOR. Patients are classified as high risk because they have metastatic trophoblastic tumor that is unlikely to be cured with single-agent chemotherapy based on the following risk factors: disease for more than 4 months, serum gonadotropin levels greater than 40,000 mIU/mL, liver or brain metastases, tumor following term pregnancy, or previous chemotherapy without success. In these women, combination chemotherapy, in spite of increased toxicity, has produced the highest cure rate. According to Schorage and colleagues (2000), the EMA-CO regimen results in response rates of about 90 percent and survival rates of 80 to 100 percent. This combination employs etoposide, methotrexate, actinomycin, cyclophosphamide, and vincristine.

PLACENTAL SITE TUMORS. The most efficacious treatment for placental site trophoblastic tumor is unknown, although [Miller and colleagues \(1989\)](#) recommend that most women are best treated by hysterectomy. Although chemotherapy is recommended for metastatic disease, it does not appear to be as effective as for other gestational trophoblastic tumors ([Gillespie and colleagues, 2000](#); [Randall and associates, 2000](#)).

PROGNOSIS. Women with nonmetastatic malignant trophoblastic disease have an extremely good prognosis if single-agent chemotherapy is started as soon as persistent disease is identified. Previously cited were the remarkable results of [Lurain and colleagues \(1983\)](#) of women with molar pregnancies from the Brewer Trophoblastic Disease Center of Northwestern University. From 1962 to 1978, 738 women with molar pregnancy were managed as generally outlined above. Chemotherapy was given for persistent disease in 19 percent, and all were living and disease-free 4 to 18 years later.

Women with low-risk malignant metastatic gestational disease who are treated aggressively with single- or multiagent chemotherapy in general do almost as well as those with nonmetastatic disease ([DuBeshter and associates, 1987](#); [Hammond and colleagues, 1980](#); [Jones, 1987](#)). Women with high-risk metastatic disease have appreciable mortality that depends on which factors were considered "high risk" ([Soper and associates, 1988](#)). Remission rates have been reported to vary from about 45 to 65 percent. [Lurain \(1987\)](#) analyzed 53 deaths from the Brewer Trophoblastic Center and concluded that the three factors primarily responsible were:

1. Extensive choriocarcinoma at initial diagnosis.
2. Lack of appropriately aggressive initial treatment.
3. Failure of currently used chemotherapy.

There have been several prognostic scoring systems and an anatomical staging system reported ([Bagshawe, 1976](#); [Pettersson and colleagues, 1985](#); [World Health Organization, 1983](#)). [Lurain and associates \(1991\)](#) presented a simplified prognostic scoring system based on multivariate analysis of almost 400 women treated for gestational trophoblastic tumor. This system, known as the Brewer Score, is summarized in [Table 32-4](#). This score is derived by adding the component scores for the three significant variables from the multivariate analysis. In the 168 women with metastatic trophoblastic tumors, survival was 100 percent with a score of 1, 88 percent for a score of 2, 63 percent for a score of 3, and only 30 percent for a score of 4.

PREGNANCY AFTER TROPHOBLASTIC DISEASE. There is no difficulty with fertility or normal pregnancy outcome following trophoblastic disease, even if standard chemotherapy was given ([Schorage and associates, 2000](#); [Woolas and co-workers, 1998](#)). Women who had trophoblastic disease are at increased risk for developing trophoblastic disease in a subsequent pregnancy. [Berkowitz and colleagues \(1987\)](#) reported that 1.3 percent of 1048 women treated at the New England Trophoblastic Disease Center for gestational trophoblastic disease had a recurrent molar pregnancy. [Kim and associates \(1998\)](#) reported a 4.3 percent recurrence in 115 Korean women. Importantly, women who have been given chemotherapy do not have an increased risk for anomalous fetuses in subsequent pregnancies ([Rustin and colleagues, 1984](#); [Song and associates, 1988](#)).

OTHER TUMORS OF THE PLACENTA

CHORIOANGIOMA (HEMANGIOMA). Various angiomatous tumors of the placenta ranging widely in size have been described. Because of the resemblance of their components to the blood vessels and stroma of the chorionic villus, the term *chorioangioma*, or *chorangioma*, has been considered the most appropriate designation. These are the only benign tumors of the placenta ([Benirschke and Kaufmann, 2000](#)). The tumors are most likely hamartomas of primitive chorionic mesenchyme. Their incidence has been reported to be about 1 percent. Larger chorioangiomas may be strongly suspected on the basis of sonographic changes within the placenta. A dramatic example is provided in [Figure 32-18](#).

Small growths are essentially asymptomatic, but large tumors may be associated with hydramnios or antepartum hemorrhage. Fetal death and malformations are uncommon complications, although there may be a positive correlation with low birthweight. [Stiller and Skafish \(1986\)](#) described a case with multiple placental chorioangiomas in which a blood group A fetus bled acutely into her O group mother. The mother showed evidence of acute hemolysis without anemia, and the fetus developed a sinusoidal heart rate pattern frequently seen in severe anemia. We have identified severe iron-deficiency anemia in the neonate as the consequence of chronic fetal to maternal hemorrhage associated with multiple small chorioangiomas. Large chorioangiomas provide an arteriovenous shunt in the fetal circulation that can lead to heart failure with all of its complications. Chorioangiomas may result in fetal anemia even without hydrops fetalis. [Haak and colleagues \(1999\)](#) described a case of severe anemia requiring intrauterine transfusion in a fetus with a placental chorioangioma but without hydrops fetalis. With a large chorioangioma, consumptive coagulopathy and microangiopathic hemolytic anemia have also been observed in the fetus-infant. [Figure 32-18](#) shows a placenta and a very large, discrete chorioangioma that led to heart failure, consumptive coagulopathy, and microangiopathic hemolysis in the fetus.

TUMORS METASTATIC TO THE PLACENTA. Metastases of malignant tumors are rare. This was reviewed by [Read and Platzer \(1981\)](#) and [Dildy and associates \(1989\)](#), who reported that malignant melanoma is the most common malignancy metastatic to the placenta; it makes up nearly a third of reported cases. Leukemias and lymphomas comprise another third. In most cases, tumor cells are in the intervillous space; however, as shown in [Table 32-5](#), the fetus is involved with malignant tumor in about a fourth of cases. Despite this, malignant cells seldom proliferate in the fetus to cause clinical disease ([Baergen and colleagues, 1997](#)). Any tumor with hematogenous spread is a potential source of placental metastases, as evidenced by the case of large-cell undifferentiated lung carcinoma metastatic to the placenta ([Fig. 32-19](#)). The mother succumbed but the child remained healthy by 16 months. [Eltorky and colleagues \(1995\)](#) reported two breast cancers and one pancreatic cancer with placental metastasis.

TABLE 32-1. Classification of Gestational Trophoblastic Disease

Hydatidiform Mole

Complete

Partial

Gestational trophoblastic tumors

Nonmetastatic

Metastatic

Low risk—no risk factors

High risk—any risk factor

Pretherapy hCG level > 40,000 mIU/mL

Duration > 4 months

Brain or liver metastases

Prior chemotherapy failure

Antecedant term pregnancy

hCG = human chorionic gonadotropin.

TABLE 32-2. Features of Partial and Complete Hydatidiform Moles

Feature	Partial Mole	Complete Mole
Karyotype	Most commonly 69,XXX or 69,XXY	46,XX or 46,XY
Pathology		
Fetus	Often present	Absent
Amnion, fetal red blood cells	Often present	Absent
Villous edema	Variable, focal	Diffuse
Trophoblastic proliferation	Variable, focal, slight to moderate	Variable, slight to severe
Clinical presentation		
Diagnosis	Missed abortion	Molar gestation
Uterine size	Small for dates	50% large for dates
Theca-lutein cysts	Rare	25-30%
Medical complications	Rare	Frequent
Postmolar disease	Less than 5-10%	20%

SECTION IX - REPRODUCTIVE SUCCESS AND FAILURE

33. Abortion

The definition of *abortion* is the termination of pregnancy by any means before the fetus is sufficiently developed to survive. In the United States this definition is confined to the termination of pregnancy before 20 weeks based upon the date of the first day of the last normal menses. Another commonly used definition is the delivery of a fetus-neonate that weighs less than 500 g.

SPONTANEOUS ABORTION

When abortion occurs without medical or mechanical means to empty the uterus, it is referred to as spontaneous. Another widely used term is *miscarriage*.

PATHOLOGY

Hemorrhage into the decidua basalis and necrotic changes in the tissues adjacent to the bleeding usually accompany abortion. The ovum becomes detached, and this stimulates uterine contractions that result in expulsion. When the sac is opened, fluid is commonly found surrounding a small macerated fetus, or alternatively there may be no visible fetus in the sac, the so-called *blighted ovum*.

Blood or carneous mole is an ovum that is surrounded by a capsule of clotted blood. The capsule is of varying thickness, with degenerated chorionic villi scattered through it. The small, fluid-containing cavity within appears compressed and distorted by thick walls of old blood clot.

In later abortions, several outcomes are possible. The retained fetus may undergo *maceration*. The bones of the skull collapse and the abdomen becomes distended with blood-stained fluid. The skin softens and peels off in utero or at the slightest touch, leaving behind the corium. Internal organs degenerate and undergo necrosis. Amniotic fluid may be absorbed when the fetus becomes compressed upon itself and desiccated to form a *fetus compressus*. Occasionally, the fetus eventually becomes so dry and compressed that it resembles parchment, so-called *fetus papyraceous*.

RESUMPTION OF OVULATION. Ovulation may resume as early as 2 weeks after an abortion. [Lahteenmaki and Luukkainen \(1978\)](#) detected a surge of luteinizing hormone (LH) 16 to 22 days after abortion in 15 of 18 women studied. Moreover, plasma progesterone level, which had plummeted after the abortion, increased soon after the LH¹ surge. These hormonal events are in temporal agreement with histological changes observed in endometrial biopsies as described by [Boyd and Holmstrom \(1972\)](#). **Therefore, it is important that effective contraception be initiated soon after abortion.**

ETIOLOGY

More than 80 percent of abortions occur in the first 12 weeks, and the rate decreases rapidly thereafter ([Harlap and Shiono, 1980](#)). Chromosomal anomalies cause at least half of these early abortions, and their incidence likewise decreases thereafter ([Fig. 33-1](#)). The risk of spontaneous abortion increases with parity as well as with maternal and paternal age ([Warburton and Fraser, 1964](#); [Wilson and associates, 1986](#)). The frequency of clinically recognized abortion increases from 12 percent in women less than 20 years old to 26 percent in those over age 40. The effect of advancing maternal age is illustrated in [Figure 33-2](#). For the same paternal ages, the increase is from 12 to 20 percent. Finally, the incidence of abortion is increased if a woman conceives within 3 months of a term birth ([Harlap and Shiono, 1980](#)).

The exact mechanisms responsible for abortion are not always apparent, but in the very early months of pregnancy, spontaneous expulsion of the ovum is nearly always preceded by death of the embryo or fetus. For this reason, etiological considerations of early abortion involve ascertaining whenever possible the cause of fetal death. In the subsequent months, the fetus frequently does not die in utero before expulsion, and other explanations for its expulsion must be invoked.

FETAL FACTORS ABNORMAL ZYGOTE DEVELOPMENT. The most common morphological finding in early spontaneous abortions is an abnormality of development of the zygote, embryo, early fetus, or at times the placenta. In an analysis of 1000 spontaneous abortions, [Hertig and Sheldon \(1943\)](#) observed pathological ("blighted") ova in which the embryo was degenerated or absent in half. Such an abnormal ovum can be seen in [Figure 33-3](#).

[Poland and co-workers \(1981\)](#) identified morphological disorganization of growth in 40 percent of abortuses that were expelled spontaneously before 20 weeks. Among embryos of less than 30 mm crown-rump length, the frequency of abnormal morphological development was 70 percent. Of the embryos on which tissue culture and chromosomal analyses were performed, 60 percent had chromosomal abnormalities. For fetuses of 30 to 180 mm crown-rump length, the frequency of chromosomal abnormalities was 25 percent.

ANEUPLOID ABORTION. Chromosomal abnormalities are common among embryos and early fetuses that are aborted spontaneously, and account for much or most of early pregnancy wastage. Approximately 50 to 60 percent of early spontaneous abortions are associated with a chromosomal anomaly of the conceptus ([Table 33-1](#)). [Jacobs and Hassold \(1980\)](#) reported that approximately one fourth of chromosomal abnormalities were due to maternal gametogenesis errors and 5 percent to paternal errors. In a study of fetuses and newborns with trisomy 13, [Robinson and colleagues \(1996\)](#) reported that in 21 of 23 cases, the extra chromosome was of maternal origin.

Autosomal trisomy is the most frequently identified chromosomal anomaly associated with first-trimester abortions ([Table 33-1](#)). As discussed in [Chapter 36](#), trisomies can be the result of an **isolated nondisjunction**, maternal or paternal **balanced translocation**, or **balanced chromosomal inversion**. Balanced structural chromosomal rearrangements are present in 2 to 3 percent of couples with a history of recurrent abortions ([American College of Obstetricians and Gynecologists, 1995](#)). Translocations may be identified in either parent. Balanced chromosomal inversions may also be identified in couples with recurrent abortions. Trisomies for all autosomes except chromosome number 1 have been identified in abortuses, but autosomes 13, 16, 18, 21, and 22 are most common.

Monosomy X (45,X) is the next most common chromosomal abnormality and is compatible with live-born females (Turner syndrome). **Triploidy** is often associated with hydropic placental degeneration. Incomplete hydatidiform moles may have fetal development that is triploid or trisomic for chromosome number 16. Fetuses associated with these frequently abort early, and the few carried longer are all grossly malformed. Advanced maternal and paternal age are not associated with this abnormality. **Tetraploid abortuses** are rarely live born and are most often aborted very early in gestation.

Chromosomal structural abnormalities are unusual causes of abortion and have been identified only since the development of banding techniques. Some of these infants are live born with balanced translocations and can be normal. **Autosomal monosomy** is extremely rare and is incompatible with life. **Sex chromosomal polysomy (47,XXX or 47,XXY)** is unusual in abortus material but is commonly seen in live births.

EUPLOID ABORTION. [Kajji and co-workers \(1980\)](#) reported that three fourths of aneuploid abortions were before 8 weeks, while euploid abortions peaked at about 13 weeks. [Stein and associates \(1980\)](#) presented evidence that the incidence of euploid abortions increases dramatically after the maternal age of 35 years. The reasons for euploid abortions are generally unknown, but the following are possibilities:

1. A genetic abnormality such as an isolated mutation or polygenic factors.
2. Various maternal factors.
3. Possibly some paternal factors.

[Simpson \(1980\)](#) observed that approximately 0.5 percent of live births have chromosomal abnormalities, while at least 2 percent of live births have diseases associated with a single-gene mutation or a polygenic mechanism of inheritance.

MATERNAL FACTORS. A variety of medical disorders, environmental conditions, and developmental abnormalities have been implicated in euploidic abortion.

INFECTIONS. Some chronic infections have been implicated in causing abortion. *Brucella abortus* and *Campylobacter fetus* are well-known causes of chronic abortion in cattle, but they are not a significant cause in humans ([Sauerwein and associates, 1993](#)). Evidence that *Toxoplasma gondii* causes abortion in humans is

inconclusive. There is no evidence in humans that either *Listeria monocytogenes* or *Chlamydia trachomatis* produce abortions ([Feist and associates, 1999](#); [Osser and Persson, 1996](#); [Paukku and associates, 1999](#)). Herpes simplex, however, has been associated with an increased incidence of abortion following genital infection in early pregnancy. [Temmerman and colleagues \(1992\)](#) reported that spontaneous abortion was independently associated with maternal human immunodeficiency virus-1 (HIV-1) antibody, with maternal syphilis seroreactivity, and with vaginal colonization with group B streptococci. Serological evidence supportive of a role for *Mycoplasma hominis* and *Ureaplasma urealyticum* in abortion was provided by [Quinn and co-workers \(1983\)](#). Conversely, [Temmerman and associates \(1992\)](#) found no association between genital mycoplasma and spontaneous abortion. Interestingly, [Berg and associates \(1999\)](#) reported that erythromycin treatment for women with mycoplasma culture-positive amniotic fluid undergoing genetic amniocentesis resulted in a significant decrease in midtrimester losses (11 versus 44 percent).

CHRONIC DEBILITATING DISEASES. In early pregnancy, chronic wasting diseases such as tuberculosis or carcinomatosis have seldom caused abortion. Hypertension is seldom associated with abortion before 20 weeks, but rather may lead to fetal death and preterm delivery. Celiac sprue has been reported to cause both male and female infertility and recurrent abortions ([Sher and colleagues, 1994](#)).

ENDOCRINE ABNORMALITIES HYPOTHYROIDISM There does not appear to be an increased incidence of abortion associated with clinical hypothyroidism ([Montoro and associates, 1981](#)). Thyroid autoantibodies were associated with an increased incidence of abortion despite the lack of overt hypothyroidism ([Dayan and Daniels, 1996](#); [Stagnaro-Green and associates, 1990](#)). Conversely, others have found no increase in the incidence of antithyroid antibodies in women who have recurrent abortions when compared with normal controls ([Esplin and colleagues, 1998](#); [Pratt and associates, 1994](#)).

DIABETES MELLITUS. As reviewed recently by [Greene \(1999\)](#), spontaneous abortion and major congenital malformations are both increased in women with insulin-dependent diabetes. The risk is related to the degree of metabolic control in the first trimester. In a prospective study, [Mills and associates \(1988\)](#) reported that early glucose control (within 21 days of conception) resulted in a similar spontaneous abortion rate compared with nondiabetic controls. Lack of glucose control, however, resulted in a marked increase in the abortion rate. In a study from the Children's Hospital of Pittsburgh, [Dorman and associates \(1999\)](#) reported a significantly higher rate of spontaneous abortion (27 versus 8 percent) for diabetic women compared with nondiabetic partners of type I diabetic men. There was a temporal decline in the spontaneous abortion rate in these diabetic women from 26 percent before 1969 to 5.7 percent from 1980 to 1989. These authors postulated that this decrease may be secondary to changes in medical care such as glucose self-monitoring.

PROGESTERONE DEFICIENCY. Insufficient progesterone secretion by the corpus luteum or placenta has been associated with an increased incidence of abortion. It has been suggested that abnormal levels of one or more hormones might help to forecast abortion. Unfortunately, reduced levels of these hormones are usually the consequence rather than the cause ([Salem and co-workers, 1984](#)). There are well-documented cases of luteal phase defects, but they are uncommon.

NUTRITION. There is no conclusive evidence that dietary deficiency of any one nutrient or moderate deficiency of all nutrients is an important cause of abortion. The nausea and vomiting that develop rather commonly during early pregnancy, and any inanition so induced, are rarely followed by spontaneous abortion.

DRUG USE AND ENVIRONMENTAL FACTORS. A variety of different agents has been reported, but not confirmed, to be associated with an increased incidence of abortion.

TOBACCO. Smoking has been associated with an increased risk for euploidic abortion ([Harlap and Shiono, 1980](#)). For women who smoked more than 14 cigarettes a day, the risk was approximately twofold compared with controls ([Kline and associates, 1980](#)). [Armstrong and associates \(1992\)](#) calculated that the abortion risk increased in a linear fashion by a factor of 1.2 for each 10 cigarettes smoked per day.

ALCOHOL. Both spontaneous abortion and fetal anomalies may result from frequent alcohol use during the first 8 weeks of pregnancy ([Floyd and associates, 1999](#)). Spontaneous abortion was increased even when alcohol was consumed "in moderation." [Kline and co-workers \(1980\)](#) reported that the abortion rate was doubled in women drinking twice weekly and trebled in women who consumed alcohol daily compared with nondrinkers. [Armstrong and colleagues \(1992\)](#) computed that abortion risk increased by an average of 1.3 for each drink per day. In contrast, [Cavallo and associates \(1995\)](#), in a prospective study of 546 women, reported that a low level of alcohol consumption during pregnancy was not associated with a significant risk for abortion. Somewhat worrisome is the fact that in one cross-sectional study from the Centers for Disease Control and Prevention, [Floyd and associates \(1999\)](#) found that half of all pregnant women in the study drank alcohol during the 3 months preceding pregnancy recognition and 5 percent drank moderate to heavy levels!

CAFFEINE. Coffee consumption at greater than four cups per day appears to slightly increase the risk of abortion ([Armstrong and associates, 1992](#)). The risk appears to increase with increasing amounts. In a study by [Klebanoff and associates \(1999\)](#), maternal paraxanthine (a caffeine metabolite) levels were associated with a significant twofold risk of spontaneous abortion only if extremely high. These authors concluded that moderate consumption of caffeine was unlikely to be associated with spontaneous abortion.

RADIATION. In sufficient doses, radiation is a recognized abortifacient. As discussed in [Chapter 42](#), the human dose is not precisely known.

CONTRACEPTIVES. There is no evidence to support that oral contraceptives or spermicidal agents used in contraceptive creams and jellies are associated with an increased incidence of abortion. Intrauterine devices, however, are associated with an increased incidence of septic abortion after contraceptive failure ([Chap. 58, p. 1538](#)).

ENVIRONMENTAL TOXINS. In some studies abortion rates in exposed women were not increased ([Axelsson and Rylander, 1982](#)). [Rowland and associates \(1995\)](#) reported an increased risk for spontaneous abortion among dental assistants exposed to 3 or more hours of nitrous oxide in offices without scavenging equipment, but not in offices using such equipment. In a meta-analysis, [Boivin \(1997\)](#) concluded that there was an increased risk of spontaneous abortion for women occupationally exposed to anesthetic gases based on data from the prescavenging era.

In most instances, there is little information to indict any specific environmental agent; however, there is evidence that arsenic, lead, formaldehyde, benzene, and ethylene oxide may cause abortion ([Barlow and Sullivan, 1982](#)). Video display terminals and exposure to the accompanying electromagnetic fields do not increase the risk of abortion ([Schnorr and co-workers, 1991](#)). Short-waves and ultrasound also do not increase the risk ([Taskinen and colleagues, 1990](#)).

IMMUNOLOGICAL FACTORS. Much attention has focused on the immune system as important in recurrent pregnancy loss. Two primary pathophysiological models that have evolved are the autoimmune theory (immunity against self) and the alloimmune theory (immunity against another person).

AUTOIMMUNE FACTORS. It has been determined from compiled studies that approximately 15 percent of over 1000 recurrent pregnancy loss patients have recognized autoimmune factors ([Kutteh and Pasquarette, 1995](#)). The most significant antibodies have specificity against negatively charged phospholipids and are most commonly detected by testing for lupus anticoagulant (LAC) and anticardiolipin antibody (ACA). Women with both a history of early fetal loss and high levels of antibodies may suffer a 70 percent miscarriage recurrence ([Dudley and Branch, 1991](#)). Pooling studies totaling 1500 women with recurrent loss yields an average incidence of 17 percent for anticardiolipin antibody and 7 percent for the lupus anticoagulant. In contrast, only 1 to 3 percent of normal obstetrical patients are found to have either of these ([Harris and Spinnato, 1991](#); [Lockwood and colleagues, 1989](#)). In a prospective study of 860 women screened for anticardiolipin antibody in the first trimester, [Yasuda and colleagues \(1995\)](#) reported that 7 percent were positive. Spontaneous abortion occurred in 25 percent of the antibody-positive group compared with 10 percent of the negative group. In another recent study, however, [Simpson and associates \(1998\)](#) found no association between early pregnancy loss and the presence of either anticardiolipin antibody or lupus anticoagulant. Despite these controversies with early abortion, there is a consensus regarding increased midtrimester pregnancy losses and the antiphospholipid antibody syndrome ([Blumenfeld and Brenner, 1999](#); [Cowchock, 1997](#); [Simpson and associates, 1998](#)).

The lupus anticoagulant is an immunoglobulin (IgG, IgM, or both) that interferes with one or more of the phospholipid-dependent tests of in vitro coagulation. The term is a misnomer because it is associated with clinically important increases in thromboembolic events. Importantly, the lupus anticoagulant is most often diagnosed in patients who do not meet the diagnostic criteria for lupus.

Antiphospholipid antibodies are acquired antibodies targeted against a phospholipid. They can be of the IgG, IgA, or IgM isotype. The mechanism of pregnancy loss in these women is thought to involve placental thrombosis and infarction. One mechanism may involve the inhibition of prostacyclin release ([Fig. 33-4](#)). This product of endothelial cells is a potent vasodilator and inhibitor of platelet aggregation. On the other hand, platelets produce thromboxane A₂, a vasoconstrictor and platelet aggregator. These antibodies therefore may reduce prostacyclin production, facilitating a thromboxane dominant milieu that leads to thrombosis. In addition, they have been shown to inhibit protein C activation.

Investigators have proposed various treatments for the antiphospholipid antibody syndrome, including low-dose aspirin, prednisone, heparin, and intravenous

immunoglobulin ([Coulam, 1995](#)). These treatments are thought to counteract the adverse action of antibodies by affecting both the immune and coagulation systems. [Cowchock and colleagues \(1992\)](#) performed a randomized trial comparing prednisone to low-dose heparin therapy in 20 women with antibodies and recurrent pregnancy loss. Live-birth rates were equal (75 percent) for both groups. However, those women receiving a glucocorticoid demonstrated a significantly greater incidence of maternal and fetal morbidity. [Kutteh \(1996\)](#) described 50 such women who were treated with either heparin and low-dose aspirin or aspirin alone. Heparin was initiated at 5000 units subcutaneously twice daily with a positive pregnancy test and titrated according to the partial thromboplastin time and platelet count. Although 76 percent of women in the heparin plus aspirin group delivered viable infants, only 44 percent of those treated with aspirin alone had a live birth. Maternal and obstetrical complications were low in both groups. Recent data indicate that antibodies bind directly to heparin in vitro and function in a similar way in vivo, thereby decreasing the adverse effects of the antibodies ([Ermel and associates, 1995](#)).

[Branch and associates \(2000\)](#) conducted a placebo-controlled pilot study of immune globulin for the treatment of the antiphospholipid antibody syndrome during pregnancy and found that intravenous immune globulin did not improve pregnancy outcomes above that achieved with heparin and low-dose aspirin.

ALLOIMMUNE FACTORS. A number of women with recurrent pregnancy loss have been diagnosed as having an alloimmune cause. They have received a variety of therapies targeted at stimulating maternal immune tolerance of fetal material. Diagnosis of an alloimmune factor has centered on several tests:

1. Maternal and paternal HLA comparison.
2. Assessment of maternal serum for the presence of cytotoxic antibodies to paternal leukocytes.
3. Maternal serum testing for blocking factors for maternal-paternal mixed lymphocyte reactions.

In essence, those couples determined to have significant HLA-type homology, or in which the women were found to have minimal antipaternal antibodies, were judged to represent an alloimmune disorder.

The validity of this model remains doubtful. For example, human HLA sharing clearly does not preclude successful pregnancies ([Ober and co-workers, 1983](#)). Most importantly, other studies have compared HLA sharing frequency in couples with recurrent losses with those with reproductive success and observed no differences ([Bellingard, 1995](#); [Houwert-de Jong, 1989](#); [Sargent, 1988](#); and their associates). Although some investigators have found the presence of lymphocytotoxic antibodies and mixed lymphocyte culture inhibitors to be associated with women with successful pregnancies, [Coulam \(1992\)](#) has conclusively shown these to be a function of the duration and number of pregnancies rather than a reason for pregnancy loss. Furthermore, the results of these three tests were found to have no predictive value in assessing risks for subsequent pregnancy outcome in a population of women with recurrent losses ([Cowchock and Smith, 1992](#)).

Notwithstanding the uncertainties surrounding the most prevalent hypotheses of alloimmune causes of recurrent pregnancy loss, a number of studies have described outcomes following therapy to improve the maternal immune milieu. The majority of these women received either paternal leukocytes or pooled human immunoglobulin. [Fraser and associates \(1993\)](#) performed meta-analysis of 19 case series and concluded that immunotherapy does not significantly improve pregnancy outcome. A retrospective worldwide observational study and meta-analysis on allogeneic leukocyte immunization therapy for recurrent pregnancy loss in over 400 cases demonstrated marginal improvement for immunized women ([Coulam and colleagues, 1994](#)). The considerable expense and potential morbidity associated with immunization therapy make full disclosure of relevant information and informed consent important ([Bux and co-workers, 1992](#); [Katz and associates, 1992](#)).

Some physicians have infused pooled human immunoglobulin as an alternative to paternal lymphocyte therapy. A prospective, double-blind, placebo-controlled trial using intravenous gamma globulin to treat women with recurrent loss demonstrated an improvement in women receiving this treatment versus placebo ([Coulam, 1995](#)). In another prospective study of 47 women with a history of three or more unexplained pregnancy losses, [Stricker and associates \(2000\)](#) reported that low-dose intravenous immunoglobulin (IVIG) was beneficial in improving pregnancy outcome. Of the 24 women receiving IVIG therapy who subsequently became pregnant, 22 had a term pregnancy. There were 11 women who refused IVIG therapy and seven subsequently became pregnant but all had first-trimester spontaneous abortions.

INHERITED THROMBOPHILIA. There have been numerous reports of an association of spontaneous abortions and inherited thrombophilias ([Blumenfeld, 1999](#); [Girling, 1998](#); [Nelen, 1997](#); [Ridker, 1998](#); [Souza, 1999](#); [Younis, 2000](#) and all their associates). As discussed in [Chapter 49 \(p. 1330\)](#), other pregnancy complications have also been associated with these thrombophilias ([Table 33-2](#)). In a study of 78 consecutive women with two or more first- or second-trimester losses, [Younis and associates \(2000\)](#) reported that 38 percent versus 8 percent of controls had activated protein C resistance and 19 percent versus 6 percent of controls had factor V Leiden mutation. [Nelen and colleagues \(2000\)](#) reported that elevated serum homocysteine levels were also a risk factor. [Blumenfeld and Brenner \(1999\)](#) recently reviewed thrombophilia-associated pregnancy wastage.

The optimal treatment for the various thrombophilias during pregnancy is unclear, but heparin (including low molecular weight heparin) appears to be efficacious for the treatment of antithrombin III deficiency as well as protein C and S deficiency. Aspirin plus heparin seems to be efficacious for treatment of factor V Leiden mutation and antiphospholipid syndrome ([Blumenfeld and Brenner, 1999](#)).

AGING GAMETES. [Guerrero and Rojas \(1975\)](#) found an increased incidence of abortion relative to successful pregnancies when insemination occurred 4 days before or 3 days after the time of shift in basal body temperature. They concluded, therefore, that aging of the gametes within the female genital tract before fertilization increased the chance of abortion. [Dickey and colleagues \(1992\)](#) reported that infertility patients over 35 had a higher incidence of *small amnionic sac syndrome* and an increased incidence of euploidic abortion. Whether ovulation induction or in vitro fertilization result in aging of gametes prior to implantation is not known.

LAPAROTOMY. There is no evidence that surgery performed during early pregnancy causes increased abortions ([Chap. 42, p. 1144](#)). For example, ovarian tumors and pedunculated myomas are generally removed without interfering with pregnancy. Peritonitis increases the likelihood of abortion.

PHYSICAL TRAUMA. Trauma that failed to interrupt the pregnancy is often forgotten. Only the particular event apparently related temporally to abortion is remembered. Most spontaneous abortions, however, occur some time after death of the embryo or fetus.

UTERINE DEFECTS ACQUIRED UTERINE DEFECTS. Even large and multiple uterine leiomyomas usually do not cause abortion. When associated with abortion, their location is apparently more important than their size ([Chap. 35, p. 927](#)). Uterine synechiae (Asherman syndrome) are caused by destruction of large areas of endometrium by curettage. This in turn results in amenorrhea and recurrent abortions believed to be due to insufficient endometrium to support implantation. The diagnosis can be made by a hysterosalpingogram that shows characteristic multiple filling defects, but the most accurate and direct diagnosis is made by hysteroscopy ([Raziel and colleagues, 1994](#)). [Romer \(1994\)](#) reported that the incidence of intrauterine adhesions diagnosed by hysteroscopy was about the same after the first incomplete or missed abortion (20 percent), but was significantly higher in women with recurrent abortions (approximately 50 percent). Recommended treatment is lysis of the adhesions via hysteroscopy and placement of an intrauterine contraceptive device to prevent recurrence. Continuous high-dose estrogen therapy is also recommended by some practitioners for 60 to 90 days. [March and Israel \(1981\)](#) reported that abortions decreased from 80 to 15 percent with such therapy.

DEVELOPMENTAL UTERINE DEFECTS. These defects are the consequence of abnormal müllerian duct formation or fusion; or they may occur spontaneously or be induced by in utero exposure to diethylstilbestrol ([Chap. 35](#)). Some types, such as uterine septa, may be associated with abortions. [Porcu and associates \(2000\)](#) described pregnancy outcomes in 63 women with a septate uterus. They all underwent hysteroscopic resection of the septa because of repeat pregnancy loss or abnormal fetal presentation. There were 26 term live births following this procedure. In a recent review, [Homer and associates \(2000\)](#) reported that hysteroscopic septoplasty resulted in improved pregnancy outcome in women with repeated pregnancy loss.

INCOMPETENT CERVIX. The term *incompetent cervix* is applied to a discrete obstetrical entity. It is characterized by painless cervical dilatation in the second trimester or perhaps early in the third trimester, with prolapse and ballooning of membranes into the vagina, followed by rupture of membranes and expulsion of an immature fetus. Unless effectively treated, this sequence tends to repeat in each pregnancy.

Numerous methods have been described in nonpregnant women to make the diagnosis, usually by documenting a more widely dilated internal cervical os than is normal. Methods have included hystero-graphy, pull-through techniques of inflated catheter balloons, and acceptance without resistance at the internal os of specifically sized cervical dilators ([Ansari and Reynolds, 1987](#)). During pregnancy, attempts have been made with moderate success to predict premature cervical dilation using ultrasonic techniques ([Michaels and associates, 1989](#)). [Iams and co-workers \(1995\)](#) performed a cross-sectional study of cervical length measured by transvaginal ultrasonography in women with a prior preterm delivery, those with cervical incompetence, and normal controls delivered at term. Gestational age at the

first preterm delivery was significantly correlated with cervical length in the pregnancy evaluated at each gestational age between 20 and 30 weeks. [Andrews and associates \(2000\)](#), in a study of 53 women with ultrasound evaluation prior to 20 weeks, reported an association of short cervical lengths or funneling of the internal cervical os and early spontaneous preterm births. Several authors have reported on the use of transfundal pressure during transvaginal ultrasound evaluation of the cervix as an aid in the detection of asymptomatic incompetent cervix ([Guzman and colleagues, 1997a, 1997b, 1998](#); [Rocco and Garrone, 1999](#)).

[Kurup and Goldkrand \(1999\)](#), in a study comparing elective, emergent, or urgent cerclage, concluded that ultrasound was useful in identifying women with subtle changes in the cervix who would benefit from urgent cerclage. Ultrasound has also been utilized to demonstrate an increase in cervical length after prophylactic or therapeutic cerclage ([Althuisius and co-workers, 1999](#); [Funai and colleagues, 1999](#)). The use of magnetic resonance imaging in the diagnosis of incompetent cervix was recently reported by [Maldjian and associates \(1999\)](#).

There is little doubt that ultrasound, especially transvaginal, is a useful adjunct for the diagnosis of cervical shortening or funneling of the internal os and in the early detection of cervical incompetence. The diagnosis, however, remains difficult in most women and is still often based on clinical examination and history.

ETIOLOGY. Although the cause of cervical incompetence is obscure, previous trauma to the cervix—especially in the course of dilatation and curettage, conization, cauterization, or amputation—appears to be a factor in many cases. In other instances, abnormal cervical development, including that following exposure to diethylstilbestrol in utero, plays a role ([Chap. 35, p. 918](#)).

TREATMENT. The treatment of cervical incompetence is surgical, consisting of reinforcement of the weak cervix by some type of purse-string suture. Bleeding, uterine contractions, or ruptured membranes are usually contraindications to surgery.

PREOPERATIVE EVALUATION. Cerclage should generally be delayed until after 14 weeks so that early abortions due to other factors will be completed. There is no consensus as to how late in pregnancy the procedure should be performed. The more advanced the pregnancy, the more likely surgical intervention will stimulate preterm labor or membrane rupture. For these reasons, some clinicians prefer bed rest rather than cerclage some time after midpregnancy. We usually do not perform cerclage after 24 to 26 weeks.

[Aarts and associates \(1995\)](#) provided a review of late second-trimester cerclage, commonly known as an *emergency cerclage*. They concluded that emergency cerclage can be of benefit in some women, but that the incidence of complications, especially infection, is high. According to [Schorr and Morales \(1996\)](#), bulging membranes are associated with significantly increased failure rates. [Caruso and associates \(2000\)](#) reported their experience with emergency cerclage in 23 women with a dilated cervix and protruding membranes (gestational age 17 to 27 weeks). There were 11 live-born infants and they concluded that the success of the procedure was unpredictable. In a 10-year review of 75 emergency cerclages, [Chasen and Silverman \(1998\)](#) reported that 65 percent of the women delivered at 28 weeks or later, and half delivered at 37 weeks or greater. Only 44 percent of those with bulging membranes at the time of cerclage reached 28 weeks. Amnioreduction at the time of emergency cerclage may improve pregnancy prolongation ([Locatelli and associates, 1999](#)).

Sonography to confirm a living fetus and to exclude major fetal anomalies is done prior to cerclage. Obvious cervical infection should be treated, and cultures for gonorrhea, chlamydia, and group B streptococci are recommended. For at least a week before and after surgery, there should be no sexual intercourse.

If there is a question as to whether cerclage should be performed, the woman is placed at decreased physical activity. Proscription of intercourse is essential, and frequent cervical examinations should be conducted to assess cervical effacement and dilatation. Weekly ultrasonic surveillance of the lower uterine segment between 14 and 27 weeks may prove useful in some women ([Guzman and associates, 1998](#); [Michaels and colleagues, 1989](#)). Unfortunately, rapid effacement and dilatation develop even with such precautions ([Witter, 1984](#)).

CERCLAGE PROCEDURES. Three types of operations are commonly used during pregnancy. One is a simple procedure recommended by [McDonald \(1963\)](#) and illustrated in [Figure 33-5](#). The second is the more complicated [Shirodkar operation \(1955\)](#). The third is the modified Shirodkar procedure shown in [Figure 33-6](#). There is less trauma and blood loss with both the McDonald and modified Shirodkar procedures than with the original Shirodkar procedure.

In many cases, filling the bladder with 600 mL of saline through an indwelling Foley catheter will serve to push the fetus and membranes upward from the ballooning lower segment. Some clinicians recommended placement of a 30-mL balloon Foley catheter through the cervix and inflating the balloon with saline to deflect the amniotic sac cephalad.

Success rates approaching 85 to 90 percent are achieved with both McDonald and modified Shirodkar techniques ([Caspi and associates, 1990](#); [Kuhn and Pepperell, 1977](#)). Thus, there appears to be little reason for performing the more complicated original Shirodkar procedure. The modified Shirodkar procedure is often reserved for previous McDonald cerclage failures and structural cervical abnormalities. Success rates are higher when cervical dilatation was minimal and membrane prolapse was absent.

Transabdominal cerclage placed at the level of the uterine isthmus has been recommended in some instances, especially in cases of anatomical defects of the cervix or failed transvaginal cerclage ([Cammarano and colleagues, 1995](#); [Gibb and Salaria, 1995](#); [Herron and Parer, 1988](#)). The procedure requires laparotomy for placement of the suture and another laparotomy for its removal, for delivery of the fetus, or both. The potential for trauma and other complications initially and subsequently is much greater with this procedure than with the vaginal procedures. [Turnquest and colleagues \(1999\)](#) recently described fetal salvage in 9 of 11 women with abdominal cerclage.

COMPLICATIONS. [Charles and Edward \(1981\)](#) identified complications, especially infection, to be much less frequent when cerclage was performed by 18 weeks. When performed much after 20 weeks, there was a high incidence of membrane rupture, chorioamnionitis, and intrauterine infection. With clinical infection, the suture should be cut, and labor induced.

There is no evidence that prophylactic antibiotics prevent infection, or that progestational agents or β -mimetic drugs are of any adjunctive value ([Thomason and co-workers, 1982](#)). In the event that the operation fails and signs of imminent abortion or delivery develop, it is urgent that the suture be released at once; failure to do so may result in grave sequelae. Rupture of the uterus or cervix may be the consequence of vigorous uterine contractions with the ligature in place. Membrane rupture during suture placement or within the first 48 hours of surgery is considered by some to be an indication to remove the cerclage. [Kuhn and Pepperell \(1977\)](#) reported that when the membranes rupture in the absence of labor, the likelihood of serious fetal or maternal infection is increased appreciably if the suture is left in situ and delivery is delayed. Still, the range of management options spans from observation, to removal of the cerclage with observation, to removal of the cerclage and labor induction ([Barth, 1995](#)). There are insufficient data upon which to base any firm recommendation, and the optimal management of such patients remains controversial ([O'Connor and associates, 1999](#)).

Following the Shirodkar operation, the suture can be left in place if it remains covered by mucosa, and cesarean delivery performed near term. Conversely, the Shirodkar suture may be removed and vaginal delivery permitted.

PATERNAL FACTORS. Little is known about paternal factors in the genesis of spontaneous abortion. Certainly, chromosomal translocations in sperm can lead to abortion. [Kulcsar and associates \(1991\)](#) found adenovirus or herpes simplex virus in nearly 40 percent of semen samples obtained from sterile men. The viruses were detected in latent form in 60 percent of the cells, and the same viruses were found in abortuses.

CATEGORIES AND TREATMENT OF SPONTANEOUS ABORTION

It is convenient to consider the clinical aspects of spontaneous abortion under five subgroups: threatened, inevitable, incomplete, missed, and recurrent abortion.

THREATENED ABORTION. The clinical diagnosis of threatened abortion is presumed when any bloody vaginal discharge or bleeding appears during the first half of pregnancy. It is an extremely commonplace occurrence, and one out of four or five women has vaginal spotting or heavier bleeding during early gestation. Of those women who bleed in early pregnancy, approximately half will abort. The bleeding of threatened abortion frequently is slight, but it may persist for days or weeks. Unfortunately, an increased risk of suboptimal pregnancy outcome in the form of preterm delivery, low birthweight, and perinatal death persists ([Batsofin and associates, 1984](#); [Funderburk and colleagues, 1980](#)). Importantly, the risk of a malformed infant does not appear to be increased.

Some bleeding about the time of expected menses may be physiological. Cervical lesions are likely to bleed in early pregnancy, especially after intercourse. Polyps presenting at the external cervical os as well as decidual reaction in the cervix tend to bleed in early gestation. A significant clinical point is that lower abdominal pain and persistent low backache do not accompany bleeding from these benign causes.

Because most physicians consider any bleeding in early pregnancy to be a sign of threatened abortion, any treatment of so-called threatened abortion has a considerable likelihood of success. Most women who actually are threatening to abort will ultimately do so no matter what is done. If, however, bleeding is attributable to one of the unrelated causes mentioned previously, it is likely to disappear, regardless of treatment.

If an intrauterine device is still present and the "string" is visible, the device should be removed for reasons cited in [Chapter 58 \(p. 1539\)](#).

Bleeding usually begins first, and cramping abdominal pain follows a few hours to several days later. The pain of abortion may be anterior and clearly rhythmic; it may be a persistent low backache, associated with a feeling of pelvic pressure; or it may be a dull, midline, suprapubic discomfort. Whichever form the pain takes, prognosis for pregnancy continuation in the presence of bleeding and pain is poor. Higher perinatal mortality rates are observed in women whose pregnancies were complicated early by threatened abortion.

Each woman should be examined for there is always the possibility that the cervix already is dilated and abortion is inevitable, or there is a serious complication such as extrauterine pregnancy or torsion of an unsuspected ovarian cyst. She may be kept at home in bed with analgesia given to help relieve the pain. If the bleeding persists, she should be reexamined and the hematocrit rechecked. If blood loss is sufficient to cause anemia or hypovolemia, evacuation of the pregnancy is generally indicated.

Women with threatened abortion have been treated with progesterone intramuscularly or with a wide variety of synthetic progestational agents orally or intramuscularly. Unfortunately, there evidence of effectiveness is lacking. "Success" from the use of these agents often results in no more than a missed abortion.

Occasionally, slight bleeding may persist for weeks. It then becomes essential to decide whether there is any possibility of continuation of the pregnancy. Vaginal sonography, serial serum quantitative chorionic gonadotropin (hCG) levels, and serum progesterone values, measured alone or in various combinations, have proven helpful in ascertaining if a live intrauterine pregnancy is present. [Fossum and associates \(1988\)](#) reported that a fetal sac can usually be seen using vaginal sonography between 33 and 35 days from the last menstrual period ([Table 33-3](#)). This was associated with a chorionic gonadotropin level of about 1000 mIU/mL. Thus, if a gestational sac can be seen and serum hCG² is less than 1000 mIU/mL, the gestation is not likely to survive. If any doubt exists, however, serial gonadotropin levels should be measured.

[Al-Sebai and associates \(1995\)](#) reported that a single progesterone measurement had an 88 percent sensitivity and specificity in predicting a live versus dead intrauterine fetus or a tubal pregnancy. [Stovall and associates \(1992\)](#) reported that only about 1 percent of abnormal pregnancies (spontaneous incomplete abortions and ectopic pregnancies) have a serum progesterone level of 25 ng/mL or greater. A serum progesterone value of less than 5 ng/mL was associated with a dead conceptus, but this did not localize the pregnancy as uterine or extrauterine. [Hahlin and colleagues \(1990\)](#) reported that no live intrauterine pregnancy had a progesterone level less than 10 ng/mL; and 88 percent of ectopic pregnancies and 83 percent of spontaneous abortions had lower values. Therefore, with a fetal sac clearly visible, a gonadotropin level of less than 1000 mIU/mL, and a serum progesterone value of less than 5 ng/mL, there almost certainly is not an intrauterine pregnancy.

Sonographic demonstration of a distinct, well-formed gestational ring with central echoes from the embryo implies that the products of conception are reasonably healthy ([Table 33-3](#)). A gestational sac with no central echoes from an embryo or fetus implies strongly, but does not prove, death of the conceptus. When abortion is inevitable, mean gestational sac diameter is frequently smaller than appropriate for gestational age. All viable intrauterine pregnancies are visible by transvaginal ultrasonography by 41 days' gestation ([Lipscomb and colleagues, 2000](#)). Moreover, by approximately 45 days after the last menses and thereafter, fetal heart action should be discernible using real-time ultrasound. [Emerson and associates \(1992\)](#) and [Pellerito and colleagues \(1992\)](#) reported excellent results in identifying live intrauterine gestations using vaginal color and pulsed Doppler flow imaging techniques.

After death of the conceptus, the uterus should be emptied. All tissue passed should be examined to determine whether the abortion is complete. Unless all of the fetus and placenta can be positively identified, curettage may be required. Vaginal probe or abdominal ultrasound may assist in this decision-making process. If significant amounts of material are retained within the uterine cavity, curettage is recommended by most clinicians. Ectopic pregnancy should always be considered in the differential diagnosis of threatened abortion. This is especially so if the gestational sac or fetus are not identified. Frozen section of the curettings may further assist with diagnosis.

Women who are D negative with a threatened abortion probably should receive anti-D immunoglobulin ([Chap. 39, p. 1067](#)). [Von Stein and associates \(1992\)](#) reported that more than 10 percent of such women had significant fetomaternal hemorrhage.

INEVITABLE ABORTION. Inevitability of abortion is signaled by gross rupture of the membranes in the presence of cervical dilatation. Under these conditions, abortion is almost certain. Rarely, a gush of fluid from the uterus during the first half of pregnancy is without serious consequence. The fluid may have collected previously between the amnion and chorion. Most often, however, either uterine contractions begin promptly, resulting in expulsion of the pregnancy, or infection develops.

With obvious membrane rupture during the first half of pregnancy, the possibility of salvaging the pregnancy is very unlikely. If in early pregnancy the sudden discharge of fluid, suggesting ruptured membranes, occurs before any pain or bleeding, the woman may be put to bed and observed for further leakage of fluid, bleeding, cramping, or fever. If after 48 hours there has been no further escape of amniotic fluid, no bleeding or pain, and no fever, she may get up and, except for any form of vaginal penetration, continue her usual activities. If, however, the gush of fluid is accompanied or followed by bleeding and pain, or if fever ensues, abortion should be considered inevitable and the uterus emptied.

INCOMPLETE ABORTION. The fetus and placenta are likely to be expelled together in abortions occurring before 10 weeks, but separately thereafter. When the placenta, in whole or in part, is retained in the uterus, bleeding ensues sooner or later, to produce the main sign of incomplete abortion. With abortions that are more advanced, bleeding occasionally may be massive to the point of producing profound hypovolemia.

In instances of incomplete abortion, it is often unnecessary to dilate the cervix before curettage. In many cases, the retained placental tissue simply lies loose in the cervical canal and can be lifted from an exposed external os with ovum or ring forceps. Suction curettage, as described later, is effective for evacuating the uterus. A woman with a more advanced pregnancy, or a woman who is bleeding heavily, should be hospitalized and the retained tissue removed without delay. Hemorrhage from incomplete abortion is occasionally severe but rarely fatal. Fever is not a contraindication to curettage once appropriate antibiotic treatment has been started (p. 877).

[Nielsen and Hahlin \(1995\)](#) performed a randomized study comparing expectant management with curettage for spontaneous abortions less than 13 weeks. Spontaneous resolution of pregnancy occurred within 3 days in 80 percent of women treated conservatively, although vaginal bleeding lasted on the average one day longer. Complications were similar between the groups.

MISSED ABORTION. This is defined as retention of dead products of conception in utero for several weeks. The rationale for an exact time period is not clear, and it serves no useful clinical purpose. In the typical instance, early pregnancy appears to be normal, with amenorrhea, nausea and vomiting, breast changes, and growth of the uterus. After fetal death, there may or may not be vaginal bleeding or other symptoms denoting a threatened abortion. For a time, the uterus seems to remain stationary in size, but mammary changes usually regress. The woman is likely to lose a few pounds. Thereafter, it becomes apparent that the uterus not only has ceased to enlarge but also has become smaller. Many women have no symptoms during this period except persistent amenorrhea. If the missed abortion terminates spontaneously, and most do, the process of expulsion is the same as in any abortion. If retained several weeks after death, it becomes a shriveled sac containing a macerated fetus ([Fig. 33-7](#)). [Egarter and associates \(1995\)](#) reported that gemeprost vaginal suppositories (prostaglandin E₁) were effective in the termination of first-trimester missed abortions in 77 percent of women.

Occasionally, after prolonged retention of the dead fetus, serious coagulation defects develop. This is more likely when the gestation reached the second trimester before fetal death. The woman may note troublesome bleeding from the nose or gums and especially from sites of slight trauma. The pathogenesis and treatment of coagulation defects and any attendant hemorrhage in instances of prolonged retention of a dead fetus are considered in [Chapter 25 \(p. 659\)](#).

The reason some abortions do not terminate after fetal death is not clear. The use of potent progestational compounds to treat threatened abortion, however, may contribute to this. [Smith and co-workers \(1978\)](#) observed that 73 percent of women with threatened abortion given hormonal treatment did abort, but on the average 20 days later. In women who received no hormonal support, 67 percent aborted at a mean of 5 days.

RECURRENT ABORTION. This has been defined by various criteria of number and sequence, but probably the most generally accepted definition refers to three or more consecutive spontaneous abortions. Repeated spontaneous abortions are likely to be chance phenomena in the majority of cases. Accepting an independent risk of miscarriage occurrence to be 15 percent, a second loss could be calculated to occur at a rate of 2.3 percent and a third loss in 0.34 percent of women. In a study of women doctors, the occurrences of one, two, and three miscarriages were reported to be 10.4, 2.3, and 0.34 percent, respectively ([Alberman, 1988](#)). Approximately 1 to 2 percent of women of reproductive age will experience three or more spontaneous, consecutive abortions, and as many as 5 percent will have two or more recurrent abortions ([Blumenfeld and Brenner, 1999](#)).

Epidemiologically, there is some uniformity in the proportion of recurrent pregnancy loss with chromosomal anomalies. Despite this, however, there are significant discrepancies when compared with the relative prevalence of other categories. There are several reasons to explain this: First, differences in definition make direct comparisons between various studies questionable. For example, some authors included women with only two losses into their analysis. Second, methods used to assign women to various diagnostic categories differ. Complicating this issue is that many diagnoses under consideration are debatable, both as to the criteria used and to their actual contribution to pregnancy loss. Third, the intensity of evaluation applied prior to categorizing a woman as "unexplained" varied among these studies. In general, the majority of studies have observed that women with three or more miscarriages more commonly are determined to have a chromosomal anomaly, endocrinological disorder, or an altered immune system ([Table 33-4](#)).

PROGNOSIS. With the exception of antiphospholipid antibodies and an incompetent cervix, the apparent "cure rate" after as many as three consecutive spontaneous abortions will range between 70 and 85 percent regardless of treatment. That is, the loss rate will be higher, but not a great deal higher, than that anticipated for pregnancies in general. In fact, [Warburton and Fraser \(1964\)](#) reported that the likelihood of recurrent abortion was 25 to 30 percent regardless of the number of previous abortions. [Poland and associates \(1977\)](#) noted that if a woman had previously delivered a live-born infant, the risk for each recurrent abortion was approximately 30 percent. If, however, the woman had no live-born infants and had experienced at least one spontaneous fetal loss, the risk of abortion was 46 percent. Women with three or more spontaneous abortions are at increased risk in a subsequent pregnancy for preterm delivery, placenta previa, breech presentation, and fetal malformation ([Thom and colleagues, 1992](#)).

INDUCED ABORTION

Induced abortion is the *medical or surgical termination of pregnancy before the time of fetal viability*. In 1996, a total of 1,221,585 legal abortions were reported to the [Centers for Disease Control and Prevention \(1999\)](#). Approximately 20 percent of these women were 19 years of age or less and the majority were less than 25 years of age, white, and unmarried ([Centers for Disease Control and Prevention, 2000](#)). About 88 percent of abortions were performed before 13 weeks, 55 percent before 8 weeks, and 16 percent at 6 weeks or less.

LEGAL ASPECTS. Until the United States [Supreme Court decision of 1973](#), only therapeutic abortions could be performed legally in most states. The most common legal definition of therapeutic abortion until then was termination of pregnancy before the period of fetal viability for the purpose of saving the life of the mother. A few states extended their laws to read "to prevent serious or permanent bodily injury to the mother" or "to preserve the life or health of the woman." Some states allowed abortion if pregnancy was likely to result in the birth of an infant with grave malformations.

The stringent abortion laws in effect until 1973 were of fairly recent origin. Abortion before quickening—the first definite perception of fetal movement, which most often occurs between 16 and 20 weeks' gestation—was either lawful or widely tolerated in both the United States and Great Britain until 1803. In that year, as part of a general restructuring of British criminal law, a statute was enacted that made abortion before quickening illegal. The Roman Catholic Church's traditional condemnation of abortion did not receive the ultimate sanction of universal law (excommunication) until 1869 ([Piipal and Norwich, 1969](#)).

It was not until 1821 that Connecticut enacted the nation's first abortion law. Subsequently, throughout the United States, abortion became illegal except to save the life of the mother. Because therapeutic abortion to save the life of the woman is rarely necessary or definable, it follows that the great majority of such operations previously performed in this country went beyond the letter of the law. [Borgmann and Jones \(2000\)](#) have extensively reviewed legal issues in providing abortions.

INDICATIONS. Some indications for therapeutic abortion are discussed with the diseases that commonly lead to the operation. Well-documented indications are persistent heart disease after previous cardiac decompensation and advanced hypertensive vascular disease. Another is invasive carcinoma of the cervix. The [American College of Obstetricians and Gynecologists \(1987\)](#) established guidelines for therapeutic abortion:

- When continuation of pregnancy may threaten the life of the woman or seriously impair her health. In determining whether or not there is such a risk to health, account may be taken of her total environment, actual or reasonably foreseeable.
- When pregnancy has resulted from rape or incest. In this case, the same medical criteria should be employed in evaluation of the woman.
- When continuation of pregnancy is likely to result in the birth of a child with severe physical deformities or mental retardation. Issues such as maternal [HIV-1³](#) infection are less clear-cut but problematic ([Araneta and colleagues, 1992](#)).

ELECTIVE (VOLUNTARY) ABORTION

Elective or voluntary abortion is the interruption of pregnancy before viability at the request of the woman but not for reasons of impaired maternal health or fetal disease. Most abortions done today fall into this category; in fact, there is approximately one elective abortion for every three live births in the United States.

LEGALITY. It was only about 25 years ago when elective abortion was again legalized in the United States. Several Supreme Court decisions are noteworthy in the history of abortion.

ROE VERSUS WADE. The legality of elective abortion was established by the United States [Supreme Court in its 1973](#) decision in *Roe v Wade*. It defined the extent to which states might regulate abortion:

- (a) For the stage prior to approximately the end of the first trimester, the abortion decision and its effectuation must be left to the medical judgment of the attending physician.
- (b) For the stage subsequent to approximately the end of the first trimester, the State, in promoting its interest in the health of the mother, may, if it chooses, regulate the abortion procedures in ways that are reasonably related to maternal health.
- (c) For the stage subsequent to viability, the State, in promoting its interest in the potential of human life, may, if it chooses, regulate, and even proscribe, abortion, except where necessary, in appropriate medical judgment, for the preservation of the life or health of the mother.

WEBSTER VERSUS REPRODUCTIVE HEALTH SERVICES. Since the *Roe v Wade* decision, many different pieces of legislation, both state and national, have been introduced, and some enacted, to regulate or even dismantle its three provisions. All such attempts were unsuccessful until the United States [Supreme Court ruled in the 1989](#) *Webster v Reproductive Health Services* that states could place restrictions interfering with provision of abortion services on such items as waiting periods, specific informed consent requirements, parental/spousal notification, and hospital requirements. Based upon this decision, numerous challenges have arisen to limit a woman's choice and access to abortion services.

PLANNED PARENTHOOD OF SOUTHEASTERN PENNSYLVANIA VERSUS ROBERT P. CASEY. In [1992, the United States Supreme Court](#) considered whether a state could require, prior to an abortion, a woman's informed consent, a 24-hour waiting period, spousal consent, parental consent in the case of a minor, and a physician's description of the fetus and the abortion technique to be employed. In a 5 to 4 decision, the court upheld a state's right to require all these except spousal consent. The court also reconsidered and reaffirmed the *Roe v Wade* decision by a 5 to 4 vote.

STENBERG VERSUS CARHART. The [United States Supreme Court in 2000](#) considered whether the state of Nebraska, as represented by Attorney General Don Stenberg, could by state law prevent the performance of so-called "partial birth abortions," and specifically those performed by Dr. Leroy Carhart. The court, in a 5 to 4 decision, struck down the Nebraska law. The court ruled that the Nebraska law was too broad, and that such a prohibition could jeopardize abortions that involve more common surgical procedures. The court also noted that the Nebraska law "would place some women at unnecessary risk" because it did not include a health exception.

HILL VERSUS COLORADO. In this 6 to 4 decision rendered also in 2000, the United States Supreme Court upheld the 1993 Colorado statute that is used to regulate speech-related conduct within 100 feet of the entrance to any health-care facility. The specific portion of the statute that was challenged by Leila J. Hill and others dealt with the provision that made it unlawful to "knowingly approach" within 8 feet of another person without that person's consent "for the purpose of passing a leaflet or handbill to, displaying a sign to, or engaging in oral protest, education, or counseling with such other person. . . ."

The Colorado law had been enacted to prevent the disruption of normal functions at medical facilities by protests conducted for any reason. The Supreme Court's decision to uphold the Colorado law does not prevent protests against abortion facilities, but it certainly reduces the likelihood of confrontations between patients and demonstrators. That is, the court noted that the Colorado law insured "the right to be left alone" and did not violate the First Amendment because the law is "content neutral."

COUNSELING BEFORE ELECTIVE ABORTION. There are only three choices available to the woman considering an abortion. These are continued pregnancy with its risks and responsibilities; continued pregnancy with its risks and arranged adoption; or the choice of abortion with its risks. In any event, knowledgeable and compassionate counselors are invaluable. For instance, women who delay abortion decisions to later gestational ages have been shown to exhibit greater disturbances in the basic sense of self as noted in indications of gender/sexual conflict and lower achievement or striving orientation ([Cancelmo and associates, 1992](#)).

ABORTION TECHNIQUES

Abortion can be performed either medically or surgically. In a randomized comparison of the efficacy and acceptability of these techniques, [Creinin \(2000\)](#) reported that medical abortion seemed to be slightly less costly than surgical techniques. [Paul and colleagues \(1999\)](#) have provided detailed summaries for each method shown in [Table 33-5](#).

Prior to an elective abortion, if bacterial vaginosis is found, the woman should be treated with metronidazole to reduce the postoperative infection rate ([Larsson and colleagues, 1992](#)). Vaginal application of 2 percent clindamycin cream for 3 days reduces postabortion pelvic infection fourfold compared with placebo ([Larsson and co-workers, 2000](#)). Treatment of D-negative women after abortion with anti-D immunoglobulin is recommended, because about 5 percent of D-negative women become sensitized after an abortion ([Chap. 39, p. 1066](#)).

[Goldstein and associates \(1994\)](#) emphasized the utility of both ultrasound and immediate tissue examination in 674 women undergoing elective first-trimester abortion. Each woman was scanned with an empty bladder using the transabdominal technique. If no gestational sac was seen, endovaginal sonography was performed. All specimens underwent modified gross examination at 33 times magnification and tissue was sent for histopathological analysis. Transabdominal sonogram demonstrated uterine gestational tissue in 612 women (91 percent) and 595 of these were less than 12 weeks. There were 17 women (2.5 percent) who were 13 weeks or greater. In 62 women (9 percent) with no sac seen transabdominally, endovaginal ultrasound showed 34 uterine and two unruptured ectopic pregnancies. Of the remaining women, chorionic villi (17) and decidua without villi (4) were seen on tissue examination. Of the latter four, two had rising serum hCG^4 levels and were diagnosed with ectopic pregnancy, and two with falling levels were managed expectantly.

SURGICAL TECHNIQUES FOR ABORTION

The pregnancy may be removed surgically through an appropriately dilated cervix or transabdominally by either hysterotomy or hysterectomy.

DILATATION AND CURETTAGE. Surgical abortion is performed by first dilating the cervix and then evacuating the pregnancy by mechanically scraping out the contents (sharp curettage), by vacuum aspiration (suction curettage), or both. The technique for early manual vacuum has been recently reviewed by [MacIsaac and Jones \(2000\)](#). The likelihood of complications—including uterine perforation, cervical laceration, hemorrhage, incomplete removal of the fetus and placenta, and infection—increases after the first trimester. For this reason, curettage or vacuum aspiration should be performed before 14 weeks.

After 16 weeks, dilatation and evacuation (D & E) is performed. This consists of wide cervical dilatation followed by mechanical destruction and evacuation of fetal parts. With complete removal of the fetus, a large-bore vacuum curette is used to remove the placenta and remaining tissue. A dilatation and extraction (D & X) is similar to a D & E⁵ except that with a D & X⁶, part of the fetus is first extracted through the dilated cervix to facilitate the procedure.

In the absence of maternal systemic disease, pregnancies are usually terminated by curettage or by evacuation or extraction without hospitalization. When abortion is not performed in a hospital setting, it is imperative that capabilities for effective cardiopulmonary resuscitation be available, and that immediate access to hospitalization be possible.

HYGROSCOPIC DILATORS. Trauma from mechanical dilatation can be minimized by using a device to slowly dilate the cervix. These devices draw water from cervical tissues and also are used for preinduction cervical ripening ([Chap. 20, p. 473](#)). Laminaria tents are commonly used to help dilate the cervix ([Fig. 33-8](#)). They are made from the stems of *Laminaria digitata* or *Laminaria japonica*, a brown seaweed. The stems are cut, peeled, shaped, dried, sterilized, and packaged according to size (small, 3 to 5 mm diameter; medium, 6 to 8 mm; and large, 8 to 10 mm). The strongly hygroscopic laminaria are thought to act by drawing water from proteoglycan complexes, causing them to dissociate and thereby allowing the cervix to soften and dilate.

Synthetic hygroscopic dilators have also been used. *Lamicel* is a polyvinyl alcohol polymer sponge impregnated with anhydrous magnesium sulfate ([Nicolaidis and co-workers, 1983](#)). [Stornes and Rasmussen \(1991\)](#) reported that although both lamical tents and gemeprost pessaries were effective for cervical dilatation preparatory to first-trimester abortions, further dilatation was significantly easier after gemeprost.

Dilapan is made of hydrogel polymer, and while it was used for some time, it is not available now in the United States. It has been claimed that it dilates the cervix more rapidly than dilators made of traditional seaweed ([Blumenthal, 1988](#); [Chvapil and co-workers, 1982](#)). [Patsner \(1996\)](#) found same-day Dilapan insertion successful in preparing the cervix for dilatation and evacuation for second-trimester abortion. [Hern \(1994\)](#) compared Dilapan with laminaria in 1001 women as overnight dilators. Although both were equally effective dilators, women receiving the Dilapan were at least twice as likely to experience problems in cervical dilatation or problems resulting from poor dilatation or disintegration of the device than women who used the seaweed preparation.

An interesting dilemma is presented by the woman who has an osmotic dilator placed overnight preparatory to elective abortion, but who then changes her mind. Among seven first-trimester and 14 second-trimester pregnancies in which this occurred, the dilator was removed and 14 had term deliveries, two had preterm deliveries, and one had a spontaneous abortion 2 weeks later ([Schneider and associates, 1991](#)). None suffered infectious morbidity, including three un-treated women with cervical cultures positive for chlamydia.

TECHNIQUE FOR INSERTION. The cleansed cervix is grasped anteriorly with a tenaculum. The cervical canal is carefully sounded, without rupturing the membranes, to identify its length. A laminaria of appropriate size is then inserted so that the tip rests just at the level of the internal os using a uterine packing forceps or a radium capsule forceps ([Fig. 33-8](#)). Later, usually after 4 to 6 hours, the laminaria will have swollen and thereby dilated the cervix sufficiently to allow easier mechanical dilatation and curettage. The laminaria may cause cramping.

PROSTAGLANDINS. Rather than using a hygroscopic dilator to effect cervical softening, prostaglandin pessaries (suppositories) have been inserted into the vagina against the cervix 3 hours or so before attempting dilatation. [Chen and Edler \(1983\)](#) reported good results from applying 1 mg of prostaglandin E₁ methyl ester. Several newer prostaglandin products have been used to induce labor or to efface the cervix prior to labor induction. Many of these same products have also been used to prepare the cervix prior to mechanical dilatation for induction of abortion. These prostaglandins are also discussed in [Chapter 20 \(p. 471\)](#).

TECHNIQUE FOR DILATATION AND CURETTAGE. The anterior cervical lip is grasped with a toothed tenaculum. A local anesthetic such as 5 mL of 1 or 2 percent lidocaine is injected bilaterally into the cervix. Alternatively, a paracervical block may be used.

The uterus is sounded carefully to identify the status of the internal os and to confirm uterine size and position. The cervix is further dilated with Hegar or Pratt dilators until a vacuum aspirator suction curet of appropriate diameter can be inserted. As shown in [Figure 33-9](#), the fourth and fifth fingers of the hand introducing the dilator should rest on the perineum and buttocks as the dilator is pushed through the internal os. This provides a further safeguard against uterine perforation.

Suction curettage then is used to aspirate pregnancy products. The vacuum aspirator is moved over the surface systematically in order eventually to cover all the uterine cavity. Once this is done and no more tissue is aspirated, then gentle sharp curettage is done if it is thought that any placenta or fetal fragments remain. A sharp curet is more efficacious, and its dangers need not be greater than those of the dull instrument. Uterine perforations rarely occur on the downstroke of the curet,

but they may occur when any instrument is introduced into the uterus. As shown in [Figure 33-10](#), manipulations should be carried out with the thumb and forefingers only.

In cases advanced past 16 weeks, the fetus is extracted, usually in parts, using Sopher or similar forceps and other destructive instruments. These late abortions are unpleasant for medical and nursing personnel and more dangerous for the woman undergoing the procedure. The risks of uterine perforation and laceration are increased due to the larger fetus and the thinner uterine walls.

It is reemphasized that morbidity, immediate and remote, will be kept to a minimum if:

1. The cervix is adequately dilated without trauma before attempting to remove the fetus and gestational tissues.
2. Removal of the pregnancy is accomplished without perforating the uterus.
3. All pregnancy tissue is removed.

UTERINE PERFORATION. Accidental uterine perforation may occur during sounding of the uterus, dilatation, or curettage. The incidence of uterine perforation associated with elective abortion varies. Two important determinants of this complication are the skill of the physician and the position of the uterus, with a much greater likelihood of perforation if the uterus is retroverted. Accidental uterine perforation is recognized easily, as the instrument passes without hindrance further than it should have. Observation may be sufficient therapy if the uterine perforation is small, as when produced by a uterine sound or narrow dilator.

Considerable intra-abdominal damage can be caused by instruments passed through a uterine defect into the peritoneal cavity. This is especially true for suction and sharp curets. In this circumstance, laparotomy to examine the abdominal contents, especially the bowel, is the safest course of action. Unrecognized bowel injury causes severe peritonitis and sepsis ([Kambiss and associates, 2000](#)). We have also cared for a woman transferred to us after much of her right ureter had been removed at the time of attempted abortion using suction curettage! Similar cases have been observed by others ([Keegan and Forkowitz, 1982](#)).

Some women may develop cervical incompetence or uterine synechiae following dilatation and curettage. The possibility of these complications should be explained to those contemplating abortion. In general, their risk is very slight. Unfortunately, more advanced abortion performed by curettage may induce sudden, severe consumptive coagulopathy, which can prove fatal.

MENSTRUAL ASPIRATION. Aspiration of the endometrial cavity using a flexible 5- or 6-mm Karman cannula and syringe within 1 to 3 weeks after a missed menstrual period has been referred to as menstrual extraction, menstrual induction, instant period, traumatic abortion, and mini-abortion. Problems include the woman not being pregnant, the implanted zygote being missed by the curet, failure to recognize an ectopic pregnancy, and rarely, uterine perforation.

A positive pregnancy test will eliminate a needless procedure on a nonpregnant woman whose period has been delayed for other reasons. [Maclsaac and Jones \(2000\)](#) recommend the following technique for identifying placenta in the aspirate. First, the syringe contents are placed in a clear plastic container and examined with back lighting. Tap water is used to wash the tissue held in a strainer. The tissue is immersed in clear water. Placenta is macroscopically soft, fluffy, feathery, and villous. A magnifying lens or culposcope provides visualization. If there is doubt as to whether the tissue is placenta or decidua, microscopic examination of a small piece under a cover glass with high-light contrast will allow differentiation. Placental villi are obvious.

LAPAROTOMY. In a few circumstances, abdominal hysterotomy or hysterectomy for abortion is preferable to either curettage or medical induction. If significant uterine disease is present, hysterectomy may provide ideal treatment. If sterilization is to be performed, either hysterotomy with tubal ligation or hysterectomy on occasion may be indicated. At times, hysterotomy or hysterectomy becomes necessary because of failure of a medical induction during the second trimester.

MEDICAL INDUCTION OF ABORTION

Throughout history, many naturally occurring substances have been tried as abortifacients by women desperate not to be pregnant. Most often, serious systemic illness or even death has been the result rather than abortion. Even today, there are only a few effective, safe abortifacient drugs.

OXYTOCIN. Successful induction of second-trimester abortion is possible with high doses of oxytocin administered in small volumes of intravenous fluids. One regimen we have found effective is to add 10 1-mL ampules of oxytocin (10 IU/mL) to 1000 mL of lactated Ringer solution. This solution contains 100 mU oxytocin per mL. An intravenous infusion is started at 0.5 mL/min (50 mU/min). The rate of infusion is increased at 15- to 30-minute intervals up to a maximum rate of 2 mL/min (200 mU/min). If effective contractions are not established at this infusion rate, the concentration of oxytocin is increased in the infused solution. It is safest to discard all but 500 mL of the remaining solution, which contains a concentration of 100 mU oxytocin per mL. To this 500 mL is added an additional five ampules of oxytocin. The resulting solution now contains 200 mU/mL, and the rate of infusion is reduced to 1 mL/min (200 mU/min). A resumption of a progressive rate increase is commenced up to a rate of 2 mL/min (400 mU/min) and left at this rate for an additional 4 to 5 hours, or until the fetus is expelled.

Similar regimens have been shown to be highly effective by [Winkler \(1991\)](#) and [Owen \(1992\)](#) and their associates. In a retrospective comparison of prostaglandin E₂ (PGE₂) vaginal suppositories and high-dose oxytocin, [Winkler and colleagues \(1991\)](#) reported successes of 93 percent and 91 percent, respectively. The mean duration of labor was 13.1 hours with PGE₂ and 8.2 hours with oxytocin. The mean dose of PGE₂ was 65 mg and of oxytocin was 200 units. Side effects were limited to the PGE₂ group, with nausea (46 percent), vomiting (37 percent), fever (64 percent), and diarrhea (20 percent).

In a subsequent randomized trial, [Owen and co-workers \(1992\)](#) concluded that concentrated oxytocin is a satisfactory alternative to prostaglandin E₂ for midtrimester abortion. The same group also compared concentrated oxytocin plus low-dose prostaglandin with prostaglandin E₂ vaginal suppositories for second trimester terminations ([Owen and Hauth, 1996](#)). The women in the prostaglandin-only group received a 20-mg PGE₂ vaginal suppository every 4 hours, and those in the combined group received a 10-mg PGE₂ suppository every 6 hours. The success rate was 81 versus 89 percent, but the side effects were significantly higher for the vaginal PGE₂-only group. In a more recent trial, the Alabama group compared vaginal misoprostol (200 µg vaginally every 12 hours) with a regimen of concentrated oxytocin plus 10-mg PGE₂ suppositories every 6 hours ([Owen and Hauth, 1999](#)). They concluded that misoprostol vaginal tablets in this dose were not satisfactory for second-trimester pregnancy termination.

With concentrated oxytocin, careful attention must be directed to the frequency and intensity of uterine contractions, because each increase in infusion rate markedly increases the amount of oxytocin infused. If the initial induction is unsuccessful, serial inductions on a daily basis for 2 to 3 days are almost always successful. The chance of a successful induction with high-dose oxytocin is enhanced greatly by the use of hygroscopic dilators such as laminaria tents inserted the night before.

INTRA-AMNIONIC HYPEROSMOTIC SOLUTIONS. In order to effect abortion during the second trimester, 20 to 25 percent saline or 30 to 40 percent urea have been injected into the amniotic sac to stimulate uterine contractions and cervical dilatation. These techniques are used infrequently in the United States, and according to the [American College of Obstetricians and Gynecologists \(1987\)](#), they have been replaced by dilatation and evacuation. Benefits of the latter cited included speed, lower cost, and less pain and emotional trauma.

In a study from Thailand, among 125 pregnancies undergoing midtrimester termination using hypertonic saline, the mean induction-to-delivery time was 31.7 hours ([Herabutya and O-Prasertsawat, 1994](#)). Retained placenta developed in 63 percent and pyrexia in 39 percent. In a study from India, [Allahbadia \(1992\)](#) reported success rates of 96 percent in pregnancies ranging from 14 to 20 weeks when 200 mL of 20 percent saline was instilled. This compared favorably with a success rate of 90 percent with intramuscular PGF_{2α}, and 100 percent with extra-amnionic instillation of 5 percent povidone-iodine mixed with normal saline.

Hypertonic saline may result in serious complications, including death ([Jasnosz and colleagues, 1993](#)). Other complications include:

1. Hyperosmolar crisis following entry of hypertonic saline into the maternal circulation.
2. Cardiac failure.
3. Septic shock.
4. Peritonitis.

5. Hemorrhage.
6. Disseminated intravascular coagulation.
7. Water intoxication.

HYPEROSMOTIC UREA. Urea, 30 to 40 percent, dissolved in 5 percent dextrose solution, has been injected into the amniotic sac, followed by intravenous oxytocin at about 400 mU/min. Urea plus oxytocin is as efficacious an abortifacient as hypertonic saline, but is less likely to be toxic. Urea plus prostaglandin F_{2a} injected into the amniotic sac is similarly effective.

PROSTAGLANDINS. Because of shortcomings of other medical methods of inducing abortion, prostaglandins and their analogues are used extensively to terminate pregnancies, especially in the second trimester. Compounds commonly used are prostaglandin E₂, prostaglandin F_{2a}, and certain analogues, especially 15-methylprostaglandin F_{2a} methyl ester, PGE₁-methyl ester (gemeprost), and misoprostol. Mechanisms of action of the prostaglandins are considered in detail in [Chapter 20 \(p. 471\)](#).

TECHNIQUE. Prostaglandins can act effectively on the cervix and uterus when:

1. Placed in the vagina as a suppository or pessary immediately adjacent to the cervix.
2. Administered as a gel through a catheter into the cervical canal and lowermost uterus extraovularly.
3. Injected intramuscularly.
4. Injected into the amniotic sac by amniocentesis.
5. Taken orally.

Various treatment regimens are outlined in [Table 33-6](#).

[Christin-Maitre and colleagues \(2000\)](#) provided a recent update on the medical termination of pregnancy. They reviewed numerous studies regarding the efficacy and side effects of prostaglandins and methotrexate utilized alone or in various combinations. They also reviewed the efficacy and side effects of mifepristone utilized with a prostaglandin. [Kahn and associates \(2000\)](#) provided a meta-analysis regarding medical abortion with mifepristone and misoprostol, mifepristone with other prostaglandins, and methotrexate with misoprostol. They concluded that these regimens had high levels of success for early gestations. Parenteral approaches reduce appreciably, but do not eliminate, the unpleasant systemic effects, especially gastrointestinal, that accompany oral administration. Repeated doses of prostaglandin are often required and hygroscopic cervical dilators are often used concurrently.

Effectiveness of the various treatment regimens has ranged from 86 to 95 percent. Induction-to-delivery intervals ranged from 4 hours to more than 48 hours. In one study of 932 second-trimester terminations using gemeprost, the median induction-to-abortion interval was 18 hours in nulliparas and 15 hours in parous women ([Thong and associates, 1992](#)).

Prostaglandin vaginal suppositories applied to the cervix are also used in a lower dose during the first and early second trimesters to ripen or soften and dilate the cervix before curettage or as an adjunct for mifepristone termination ([Healy and Evans, 1994](#)). The safety of late induced abortion after a previous cesarean delivery using prostaglandins or mifepristone was reported by [Boulot and associates \(1993\)](#). At a mean gestational age of almost 24 weeks, vaginal evacuation was achieved in 20 of 23 women. At hysterotomy in the three treatment failures, one uterine rupture was found and successfully repaired. [Chapman and colleagues \(1996\)](#) reported a uterine rupture rate of 3.8 percent in 79 women undergoing termination by induction at a mean age of 21 weeks.

MIFEPRISTONE (RU 486). This oral antiprogesterone has been used to effect abortions in early gestation, either alone or in combination with oral prostaglandins ([Baird and colleagues, 1992](#); [el-Refaey and associates, 1995](#); [Newhall and Winikoff, 2000](#); [World Health Organization Task Force, 1994](#)). The effectiveness of the drug as an abortifacient is based upon its high receptor affinity for progesterone-binding sites ([Healy and colleagues, 1983](#)). A single 600-mg dose of RU 486 administered prior to 6 weeks results in an 85 percent abortion rate. In first trimester nondeveloping pregnancies, a single dose of 600-mg of mifepristone induced expulsion in 82 percent of women ([Lelaidier and co-workers, 1993](#)).

[Ulmann and associates \(1992\)](#) reported their results from over 16,000 women in whom RU 486 was given followed by a prostaglandin analogue for medical termination. Overall success rate was 95 percent, with no difference regarding the nature or dose of prostaglandin used. Median duration of bleeding was 8 days and it was 12 days or less in 90 percent of women. Bleeding necessitated vacuum aspiration or curettage in 0.8 percent of cases. Transfusion was required in 1 per 1000 women.

As discussed in [Chapter 58 \(p. 1548\)](#), RU 486 is also highly effective for emergency postcoital contraception if given within 72 hours ([Glasier and associates, 1993](#)). After 72 hours, the agent is progressively less effective. The addition of various oral, vaginal, or injected prostaglandins to this regimen results in abortion rates over 95 percent.

Side effects of RU 486 include nausea, vomiting, and gastrointestinal cramping. The major associated risk is hemorrhage due to partial expulsion of the pregnancy and due to intra-abdominal hemorrhage from an early unsuspected ectopic pregnancy. The duration of vaginal bleeding is approximately 2 weeks after RU 486 alone and approximately 1 to 2 weeks after RU 486 is given with a prostaglandin.

EPOSTANE. This 3 β -hydroxysteroid dehydrogenase inhibitor block the synthesis of endogenous progesterone. If administered within 4 weeks of the last menstrual period, the drug will induce an abortion in approximately 85 percent of women ([Crooij and associates, 1988](#)). Clinical responses are likely related to circulating endogenous progesterone levels. Nausea is a frequent side effect, and hemorrhage is a risk if the abortion is incomplete. Other antiprogestins such as ZK 98,734 are under study, and appear to be promising for induction of early abortion ([Swahn and colleagues, 1994](#)).

CONSEQUENCES OF ELECTIVE ABORTION

MATERNAL MORTALITY. Legally induced abortion is a relatively safe surgical procedure, especially when performed during the first 2 months of pregnancy. The risk of death from abortion performed during the first 2 months is about 0.6 per 100,000 procedures ([Berg and co-workers, 1996](#); [Centers for Disease Control, 1986](#); [Grimes, 1994](#)). The relative risk of dying as the consequence of abortion is approximately doubled for each 2 weeks of delay after 8 weeks' gestation. [Atrash and colleagues \(1988\)](#) reported that the proportion of abortion-related deaths caused by general anesthesia had increased from 8 percent in 1975 to 29 percent in 1985. This likely reflects an absolute decrease in deaths from nonanesthetic complications. [LeBolt and co-workers \(1982\)](#) estimated that during the 1970s, overall risk of death from legal abortion was 15 percent of the risk from childbirth. Indeed, in 1987 six maternal deaths were reported among 1.3 million legal abortions ([Grimes, 1994](#)). In his recent review, [de Swiet \(2000\)](#) emphasized that prior to the United Kingdom Abortion Act in 1968, 40 percent of maternal deaths were due to criminal abortion. In 1994 through 1996, only 4 percent of deaths were related to abortion, and none were illegal.

IMPACT ON FUTURE PREGNANCIES. [Hogue \(1986\)](#), in a scholarly review of the impact of elective abortion upon subsequent pregnancy outcome, summarized data from more than 200 publications. She emphasized that consideration must be given for the method of inducing abortion, and that women chosen as controls should be nulliparous because parous women had a reduced risk of complications in subsequent pregnancies.

Fertility is not altered by an elective abortion. A possible exception is the small risk from pelvic infection. Vacuum aspiration results in no increased incidence of midtrimester spontaneous abortions, preterm deliveries, or low-birthweight infants in subsequent pregnancies. Dilatation and curettage, however, in primigravidas results in an increased risk for subsequent ectopic pregnancy, midtrimester abortion, and low-birthweight infants.

Subsequent ectopic pregnancies are not increased if the first termination is done by vacuum aspiration. Possible exceptions are in women with preexisting chlamydial infection or those who develop postabortion infection. Multiple elective abortions do not increase the incidence of preterm delivery and low-birthweight infants ([Mandelson and associates, 1992](#)). Placenta previa was reported to be increased following elective abortion ([Barrett and associates, 1981](#)). [Hogue \(1986\)](#) discounted

this study because of failure to control for maternal age.

Induced midtrimester abortions apparently carry little risk to subsequent pregnancies if injection techniques are used. There are not enough procedure-specific data available to permit valid conclusions regarding the risks to future pregnancies following any midtrimester abortion.

SEPTIC ABORTION

Serious complications of abortion have most often been associated with criminal abortion. Severe hemorrhage, sepsis, bacterial shock, and acute renal failure have all developed in association with legal abortion but at a very much lower frequency. Metritis is the usual outcome, but parametritis, peritonitis, endocarditis, and septicemia may all occur ([Vartian and Septimus, 1991](#)). In 300 septic abortions at Parkland Hospital, a positive blood culture was found in a fourth. Almost two thirds were anaerobic bacteria and coliforms were also common. Other organisms reported as causative of septic abortion include *Haemophilus influenzae*, *Campylobacter jejuni*, and group A streptococcus ([Denton and Clarke, 1992](#); [Dotters and Katz, 1991](#); [Pinhas-Hamiel and associates, 1991](#)). Treatment of infection includes prompt evacuation of the products of conception along with broad-spectrum antimicrobials given intravenously. If sepsis and shock supervenes, then supportive care is essential as discussed in [Chapter 43 \(p. 1167\)](#). Septic abortion has also been associated with disseminated intravascular coagulopathy ([Chap. 25, p. 657](#)).

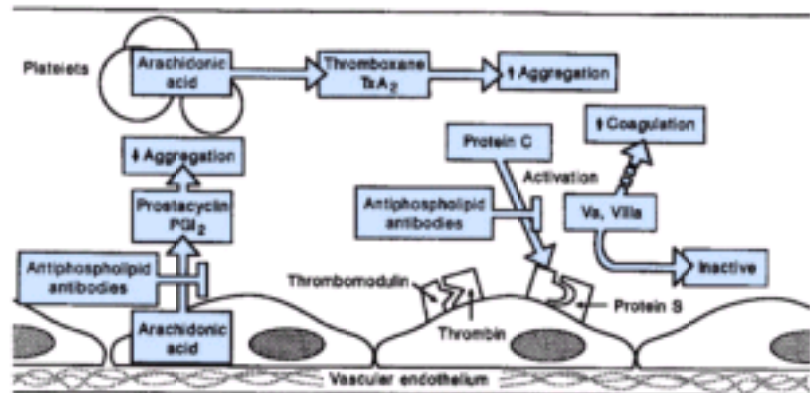

FIGURE 33-4.

Possible mechanisms of antiphospholipid antibody-induced thrombosis. Three potential mechanisms are shown: (1) Endothelial cells normally convert plasma membrane arachidonic acid into prostacyclin, which is released into the circulation and prevents platelet aggregation. Antiphospholipid antibodies may predispose to thrombosis by inhibiting endothelial cells from producing prostacyclin. (2) Platelets normally convert plasma membrane arachidonic acid into thromboxane, which is released and induces platelet aggregation. Antiphospholipid antibodies may increase thrombosis by enhancing thromboxane release. (3) During clotting, thrombin forms a complex on the surface of endothelial cells with its receptor, thrombomodulin. The thrombin/thrombomodulin complex is enzymatically active and can activate circulating protein C. The activated protein C binds with protein S on the surface of endothelial cells (and platelets). The protein C/protein S complex degrades circulating activated components of the clotting cascade, factors Va and VIIIa. If factors Va and VIIIa were allowed to remain in the circulation, they would increase coagulation activity of the blood. (From [Rote, 1989](#), with permission.)

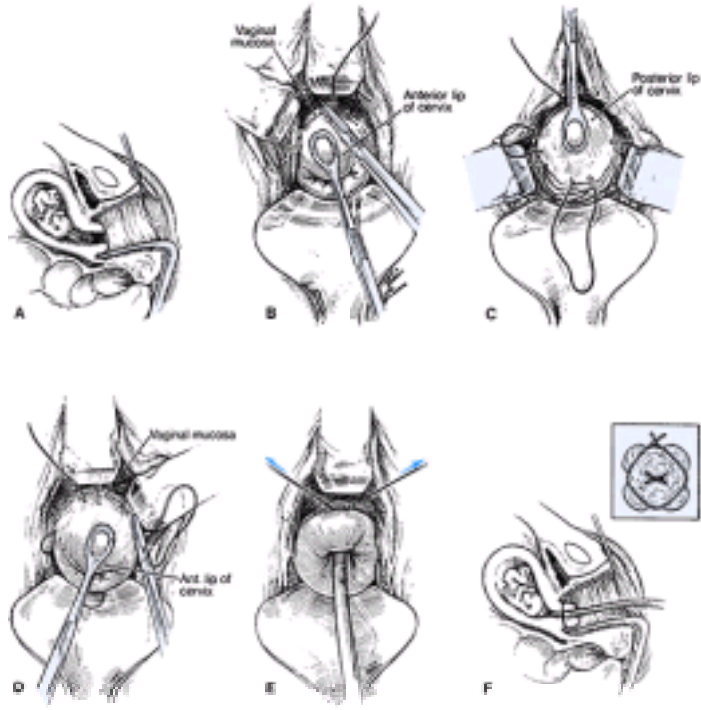

FIGURE 33-5.

Incompetent cervix treated with McDonald cerclage procedure. **A.** Somewhat dilated cervical canal and beginning prolapse of membranes (*arrow*). **B.** Start of the cerclage procedure with a suture of #2 monofilament being placed superiorly in the body of the cervix very near the level of the internal os. **C.** Continuation of suture placement in the body of the cervix so as to encircle the os. **D.** Completion of encirclement. **E.** The suture is tightened around the cervical canal sufficiently to reduce the diameter of the canal to 5 to 10 mm. In the illustration the *small* dilator has been placed just through the level of ligation to maintain patency of the canal when the suture is tied. A second suture similarly placed but somewhat higher may be of value, especially if the first is not in close proximity to the internal os. **F.** The effect of the suture placement on the cervical canal is apparent.

34. Ectopic Pregnancy

The blastocyst normally implants in the endometrial lining of the uterine cavity. Implantation anywhere else is an ectopic pregnancy. More than 1 in every 100 pregnancies in the United States is ectopic and over 95 percent of ectopic pregnancies involve the oviduct. The risk of death from an extrauterine pregnancy is greater than that for a vaginal delivery or an induced abortion. Moreover, prognosis for a successful subsequent pregnancy is reduced in these women. With earlier diagnosis, both maternal survival and conservation of reproductive capacity are enhanced.

GENERAL CONSIDERATIONS

ETIOLOGY AND PATHOGENESIS

There are a number of risk factors that lead to tubal damage and dysfunction. While there is overlap, these can be generalized as mechanical and functional factors (Table 34-1).

MECHANICAL FACTORS. These factors prevent or retard passage of the fertilized ovum into the uterine cavity. Prior tubal surgery, either to restore patency or to perform sterilization, confers the highest risk (Ankum, 1996; Hendrix, 1998; Mol, 1995, and their colleagues). After one previous ectopic pregnancy, the chance of another is 7 to 15 percent (Ankum and colleagues, 1996; Coste and associates, 1991). The increased risk likely is due to previous salpingitis which causes agglutination of the mucosal arborescent folds with luminal narrowing or formation of blind pockets (Sherman and co-workers, 1990). Reduced ciliation due to infection also may contribute to tubal implantation. According to the American College of Obstetricians and Gynecologists (1998), prior pelvic inflammatory disease, especially that caused by *Chlamydia trachomatis*, is the most common risk factor. Bjartling and colleagues (2000) showed that peak salpingitis rates in Malmö, Sweden, mirrored the peak ectopic pregnancy rates. Peritubal adhesions subsequent to postabortal or puerperal infection, appendicitis, or endometriosis may cause tubal kinking and narrowing of the lumen (Coste and associates, 1991). These may be associated with the slightly increased risk of ectopic pregnancy following previous induced abortion (Tharaux-Deneux and co-workers, 1998). In utero exposure to diethylstilbestrol predisposes to developmental tubal abnormalities, especially diverticula, accessory ostia, and hypoplasia. Finally, previous cesarean delivery has been linked to a small increase in ectopic pregnancy risk (Hemminki and Merilainen, 1996).

FUNCTIONAL FACTORS. Some tubal factors delay passage of the fertilized ovum into the uterine cavity. Altered tubal motility may follow changes in serum levels of estrogens and progesterone, likely from upregulation of adrenergic receptors in smooth muscle (Jacobson and associates, 1987). An increased incidence of ectopic pregnancies has been reported with use of progestin-only oral contraceptives (Ory, 1981); with use of intrauterine devices—with and without progesterone (Sivin, 1991); after use of postovulatory high-dose estrogens to prevent pregnancy—the "morning after pill" (Chap. 58, p. 1546; Morris and Van Wageningen, 1973); and after ovulation induction. The rate of tubal ectopic pregnancy has also been reported to be significantly increased in women with luteal phase defects (Guillaume and colleagues, 1995), with cigarette smoking (Phillips and colleagues, 1992; Saraiya and associates, 1998), and with vaginal douching (Kendrick and co-workers, 1997).

ASSISTED REPRODUCTION. The increase in ectopic pregnancies with assisted reproduction is likely related to tubal factors that cause infertility. Tubal pregnancy is increased following gamete intrafallopian transfer (GIFT) and in vitro fertilization (IVF) (Coste and associates, 1991; Guirgis and Craft, 1991). The Society for Assisted Reproductive Technology and the American Society of Reproductive Medicine (1998) cited the 1995 incidence to be 2.8 percent for these pregnancies.

"Atypical" implantations are more common following assisted reproductive techniques. Chen and associates (1998) reported 11 ectopic gestations following 1014 IVF¹ cycles, and 3 of 11 were cornual implantations. Similarly, extratubal as well as heterotypic tubal pregnancies are also increased after these procedures (Botta and co-workers, 1995; Glassner and colleagues, 1990; Marcus and associates, 1995; Pisarska and Carson, 1999). Berliner and associates (1998) described a triplet heterotypic pregnancy following ovulation induction and intrauterine insemination. Heterotypic cervical and ovarian pregnancy also have been reported (Bayati and associates, 1989; DeMuylder and co-workers, 1994).

Abdominal pregnancy has been reported following gamete intrafallopian transfer and in vitro fertilization (Balmaceda and associates, 1993; Ferland and associates, 1991; Vignali and co-workers, 1990). Cervical pregnancy may be increased after in vitro fertilization (Bennett, 1993; Ginsberg, 1994; Pattinson, 1994; Peleg, 1994, and their colleagues). Finally, ovarian pregnancy also may be increased after in vitro fertilization (Marcus and Brinsden, 1995).

FAILED CONTRACEPTION. With any form of contraceptive, the actual number of ectopic pregnancies is decreased because pregnancy occurs less often. In some contraceptive failures, however, there is an increased incidence of ectopic compared with uterine pregnancies. Examples include some forms of tubal sterilization and in women using intrauterine devices or taking progestin-only minipills (Sivin, 1991).

As shown in Table 34-1, pregnancy following tubal sterilization has an ectopic pregnancy rate that is increased ninefold. The highest rates follow laparoscopic fulguration. Yamada and Kasamatsu (2000) recently described a woman who developed a tubal pregnancy in each tube at different times following puerperal tubal sterilization. Tubal pregnancy may occasionally follow hysterectomy. Isaacs and colleagues (1996) reviewed 36 such cases, and in 24 instances, a recently fertilized ovum was trapped in the oviduct at the time of hysterectomy. In the 12 cases remote from hysterectomy (1 to 11 years), sperm migrated from a fistulous communication in the vaginal vault.

EPIDEMIOLOGY

There has been a marked increase in both the absolute number and rate of ectopic pregnancies in the United States in the past two decades. The actual number has increased out of proportion to population growth.

The incidence of ectopic pregnancy for nonwhite women is higher in every age category than for whites, and this disparity increases with age (Fig. 34-1). Overall, in 1989 a nonwhite woman had a 1.4 times increased risk for ectopic pregnancy compared with a white woman (Goldner and associates, 1993). The combined factors of race and increasing age are at least additive. For example, nonwhite women 35 to 44 years of age were five times more likely to have an ectopic pregnancy than white women aged 15 to 24 years.

As shown in Table 34-2, the rate of ectopic pregnancy per 1000 reported pregnancies increased fourfold from 1970 to 1992. This increase was greater for nonwhite than white women, and for both, the incidence increased with age. Put another way, in 1992, almost 2 percent of all pregnancies were ectopic. Importantly, ectopic pregnancy accounted for 10 percent of all pregnancy-related deaths (Centers for Disease Control and Prevention, 1995; Koonin and colleagues, 1997).

The apparent fall in the number of ectopic pregnancies after 1989 as shown in Table 34-2 unfortunately is not real. For example, the number in 1992 was 108,800 rather than 55,200. This difference is because of contemporaneous ambulatory management of very early ectopic pregnancies. Medical therapy usually does not require hospitalization. Therefore, accurate figures are currently obtained through the National Hospital Ambulatory Medical Care Survey (NHAMCS), along with inpatient statistics from the National Hospital Discharge Survey (NHDS).

CAUSES FOR INCREASED ECTOPIC PREGNANCY RATES. The reasons for increased ectopic pregnancies in the United States are not entirely clear. Similar increases have been reported from Eastern Europe, Scandinavia, and Great Britain. Some likely causes include:

1. Increased prevalence of sexually transmitted tubal infection (Brunham and associates, 1992; Maccato and colleagues, 1992).
2. Earlier diagnosis with sensitive assays for chorionic gonadotropin and transvaginal ultrasound—in some, resorption would occur before diagnosis in the past.
3. Popularity of contraception that prevents intrauterine but not extrauterine pregnancies.
4. Unsuccessful tubal sterilizations.
5. Induced abortion followed by infection.
6. Increased use of assisted reproductive techniques.

7. Tubal surgery, including prior salpingotomy for tubal pregnancy as well as tuboplasty.

MORTALITY

Deaths from ectopic pregnancy in the United States decreased from 63 in 1970, to 46 in 1980, and to 30 in 1987. Unfortunately, the proportion of all maternal deaths attributed to ectopic pregnancy increased from 8 percent in 1970 to 11 percent in the 3-year period ending 1990 ([Koonin and associates, 1997](#)). As shown in [Figure 34-2](#), the death rate has plateaued for white women and for black women since 1986. The case-fatality rate, however, decreased 10-fold, from 35.5 per 10,000 ectopic pregnancies in 1970 to 3.8 per 10,000 in 1989. Ectopic pregnancy remains a leading cause of maternal mortality in the United States, and is the most common cause of maternal mortality in the first trimester ([Centers for Disease Control and Prevention, 1995](#)).

The dramatic decrease in deaths from ectopic pregnancies is probably due to improved diagnosis and management. For example, massive hemorrhage causing death was often the result of abdominal and interstitial tubal pregnancies, which were likely to become symptomatic later in gestation. An important consideration for improvement is the markedly high mortality rate in 15- to 19-year-old nonwhite women ([Nederlof and colleagues, 1990](#)). This almost certainly is due in part to lack of early care.

ANATOMICAL CONSIDERATIONS

The fertilized ovum may develop in any portion of the oviduct, giving rise to ampullary, isthmic, and interstitial tubal pregnancies (see [Fig. 3-16](#), p. 47). In rare instances, the fertilized ovum may be implanted in the fimbriated extremity. The ampulla is the most frequent site, and the isthmus the next most. Interstitial pregnancy accounts for only about 3 percent of all tubal gestations. From these primary types, certain secondary forms of tubo-abdominal, tubo-ovarian, and broad ligament pregnancies occasionally develop.

ZYGOTE IMPLANTATION. The fertilized ovum promptly burrows through the epithelium and the zygote comes to lie in the muscular wall because the tube lacks a submucosa. At the periphery of the zygote is a capsule of rapidly proliferating trophoblast, which invades and erodes the subjacent muscularis. At the same time, maternal blood vessels are opened, and blood pours into the spaces lying within the trophoblast or between it and the adjacent tissue.

Although decidual cells usually can be recognized, the tube normally does not form an extensive decidua. Tubal wall in contact with the zygote offers only slight resistance to invasion by the trophoblast, which soon burrows through it, opening maternal vessels ([Fig. 34-3](#)). The embryo or fetus in an ectopic pregnancy is often absent or stunted.

UTERINE CHANGES. The uterus undergoes some of the changes associated with early normal pregnancy, including softening of the cervix and isthmus and an increase in size. Even so, of 1125 women with a proven ectopic pregnancy, 75 percent had a normal-sized uterus ([Stabile and Grudzinskas, 1990](#)). Thus, lack of uterine changes do not exclude an ectopic pregnancy.

The degree to which the endometrium is converted to decidua is variable. The finding of uterine decidua without trophoblast suggests ectopic pregnancy but is not absolute. In 1954, [Arias-Stella](#) described, as had others before him, these changes. Enlarged epithelial cells with nuclei that are hypertrophic, hyperchromatic, lobular, and irregularly shaped. Cytoplasm may be vacuolated and foamy, and occasional mitoses are found. These endometrial changes—the *Arias-Stella reaction*—are not specific for ectopic and may occur with a normal implantation.

External bleeding—seldom severe—is seen commonly in cases of tubal pregnancy and is uterine in origin from degeneration and sloughing of the uterine decidua. Soon after embryonic death, the decidua degenerates and is usually shed in small pieces. Occasionally it is cast off intact, as a decidual cast of the uterine cavity. Absence of decidual tissue, however, does not exclude an ectopic pregnancy. [Romney and co-workers \(1950\)](#) identified secretory endometrium in 40 percent of cases of ectopic pregnancy, proliferative in 30 percent, and menstrual in 6 percent, while decidua was present in only 20 percent.

NATURAL HISTORY OF TUBAL PREGNANCY

TUBAL ABORTION

The frequency of tubal abortion depends in part upon the implantation site. Tubal abortion is common in ampullary tubal pregnancy, whereas rupture is the usual outcome with isthmic pregnancy. The immediate consequence of tubal hemorrhage is further disruption of the connection between the placenta and membranes and the tubal wall. If placental separation is complete, all of the products of conception may be extruded through the fimbriated end into the peritoneal cavity. At this point, hemorrhage may cease and symptoms eventually disappear.

Some bleeding usually persists as long as products remain in the oviduct. Blood slowly trickles from the tubal fimbria into the peritoneal cavity and typically pools in the rectouterine cul-de-sac. If the fimbriated extremity is occluded, the fallopian tube may gradually become distended by blood, forming a hematosalpinx.

After incomplete tubal abortion, pieces of the placenta or membranes may remain attached to the tubal wall and, after becoming surrounded by fibrin, give rise to a placental polyp. The process is similar to that in the uterus after an incomplete abortion.

TUBAL RUPTURE

The invading, expanding products of conception may rupture the oviduct at any of several sites. Before sophisticated methods to measure chorionic gonadotropin were available, many cases of tubal pregnancy ended during the first trimester by intraperitoneal rupture. As a rule, whenever there is tubal rupture in the first few weeks, the pregnancy is situated in the isthmic portion of the tube. When the fertilized ovum is implanted well within the interstitial portion, rupture usually occurs later.

Rupture is usually spontaneous, but it may be caused by trauma associated with coitus or a bimanual examination. With intraperitoneal rupture, the entire conceptus may be extruded from the tube, or if the rent is small, profuse hemorrhage may occur without extrusion. In either event, the woman commonly shows signs of hypovolemia. If an early conceptus is expelled essentially undamaged into the peritoneal cavity, it may reimplant almost anywhere, establish adequate circulation, survive, and grow. This outcome is most unlikely, however, because of damage during the transition. The conceptus, if small, may be resorbed or, if larger, may remain in the cul-de-sac for years as an encapsulated mass or even become calcified to form a *lithopedion*.

ABDOMINAL PREGNANCY. If only the fetus is extruded at the time of rupture, the effect upon the pregnancy will vary depending on the extent of injury sustained by the placenta. The fetus dies if the placenta is damaged appreciably, but if the greater portion of the placenta retains its tubal attachment, further development is possible. The fetus may then survive for some time, giving rise to an abdominal pregnancy. Typically, in such cases, a portion of the placenta remains attached to the tubal wall and the periphery grows beyond the tube and implants on surrounding structures.

BROAD-LIGAMENT PREGNANCY. When original zygote implantation is toward the mesosalpinx, rupture may occur at the portion of the tube not immediately covered by peritoneum, and the gestational contents may be extruded into a space formed between the folds of the broad ligament. This is designated an intraligamentous or broad-ligament pregnancy.

INTERSTITIAL PREGNANCY. Implantation within the tubal segment that penetrates the uterine wall results in an interstitial or cornual pregnancy ([Fig. 34-4](#)). These account for about 3 percent of all tubal gestations. There is variable asymmetry of the uterus that is often difficult to distinguish from a uterine pregnancy. Hence, early diagnosis is more frequently overlooked than in other types of tubal implantation. Because of the greater distensibility of the myometrium covering the tube, rupture occurs later, usually between 8 and 16 weeks. Hemorrhage may rapidly prove fatal because the implantation site is located between the ovarian and uterine arteries. In fact, tubal pregnancies in which the woman dies before she can reach the hospital often fall into this group ([Dorfman and associates, 1984](#)). Because of the large uterine defect, hysterectomy is commonly necessary. Despite this, [Moon and colleagues \(2000\)](#) reported 24 women with an interstitial pregnancy treated by endoscopic surgery.

MULTIFETAL ECTOPIC PREGNANCY

HETEROTYPIC ECTOPIC PREGNANCY. Tubal pregnancy may be accompanied by a coexisting uterine gestation. Such a heterotypic pregnancy is quite difficult to diagnose clinically. Typically, laparotomy is performed because of a tubal pregnancy. At the same time, the uterus is congested, softened, and somewhat enlarged.

Although these features are suggestive of uterine pregnancy, they are commonly induced by tubal pregnancy. Using ultrasound, gestational products are demonstrable within the uterine cavity in practically all instances of heterotypic pregnancy.

Until recently, heterotypic pregnancies were rare with an incidence of 1 per 30,000 pregnancies ([Glassner and associates, 1990](#)). Currently, because of assisted reproduction, the incidence is likely 1 in 7000 overall, and following ovulation induction it may be as high as 1 in 900 ([Glassner and associates, 1990](#)). In vitro fertilization and embryo transfer also increases the incidence ([Dimitry and colleagues, 1990](#); [Marcus and associates, 1995](#)). According to [Pisarska and Carson \(1999\)](#), almost 12 percent of pregnancies following assisted reproduction are heterotypic.

A heterotypic pregnancy is more likely, and should be considered:

1. After assisted reproduction techniques.
2. With persistent or rising chorionic gonadotropin levels after dilatation and curettage for an induced or spontaneous abortion.
3. When the uterine fundus is larger than menstrual dates.
4. With more than one corpus luteum.
5. With absence of vaginal bleeding in the presence of signs and symptoms of an ectopic pregnancy.
6. When there is ultrasound evidence of uterine and extrauterine pregnancy ([Kouyoumdjian and Kirkpatrick, 1990](#); [Nugent, 1992](#)).

[Sherer and associates \(1995\)](#) reported a heterotypic quadruplet pregnancy after in vitro fertilization and embryo transfer complicated by a ruptured interstitial pregnancy at 8 weeks. Cases of cervical and ovarian heterotypic pregnancy have been described ([Bayati and associates, 1989](#); [Hirose and associates, 1994](#); [Peleg and colleagues, 1994](#)).

MULTIFETAL TUBAL PREGNANCY. Twin tubal pregnancy has been reported with both embryos in the same tube, as well as with one in each tube. Simultaneous pregnancy in both fallopian tubes is the rarest form of double-ovum twinning. Quadruplet tubal pregnancy in the same oviduct was described by [Fujii and associates \(1981\)](#).

TUBO-UTERINE, TUBO-ABDOMINAL, AND TUBO-OVARIAN PREGNANCIES. A tubo-uterine pregnancy results from the gradual extension into the uterine cavity of products of conception that originally implanted in the interstitial portion of the tube. Tubo-abdominal pregnancy is derived from a tubal pregnancy in which the zygote, originally implanted near the fimbriated end of the tube, gradually extends into the peritoneal cavity. In such circumstances, the portion of the fetal sac projecting into the peritoneal cavity may form troublesome adhesions to surrounding organs. Both of these conditions are very uncommon.

A tubo-ovarian pregnancy occurs when the fetal sac is adherent partly to tubal and partly to ovarian tissue. Such cases arise from zygote development in a tubo-ovarian cyst or in a tube, the fimbriated extremity of which was adherent to the ovary or soon after fertilization. Rarely, the fetus and placenta may achieve appreciable size before rupture.

CLINICAL AND LABORATORY FEATURES OF TUBAL PREGNANCY

Clinical manifestations of a tubal pregnancy are diverse and depend on whether rupture has occurred. Earlier presentation and more precise diagnostic technology have enabled identification before there is rupture in most cases. Usually, the woman does not suspect pregnancy, or thinks that she is normally pregnant, or that she is aborting a uterine pregnancy.

In what used to be considered "classical" cases, normal menstruation is replaced by variably delayed slight vaginal bleeding, or "spotting." Suddenly, the woman is stricken with severe lower abdominal pain, frequently described as sharp, stabbing, or tearing in character. Vasomotor disturbances develop, ranging from vertigo to syncope. There is tenderness on abdominal palpation, and vaginal examination, especially cervical motion, causes exquisite pain. The posterior vaginal fornix may bulge because of blood in the cul-de-sac, or a tender, boggy mass may be felt to one side of the uterus. Symptoms of diaphragmatic irritation, characterized by pain in the neck or shoulder, especially on inspiration, develop in perhaps 50 percent of women with sizable intraperitoneal hemorrhage.

The diagnosis of such cases with rupture is not difficult to make. Even though symptoms and signs of ectopic pregnancy often range from indefinite to bizarre, most women are now seeking care before this classical clinical picture develops. Every reasonable effort is made to diagnose the condition before catastrophic events occur.

SYMPTOMS AND SIGNS

PAIN. Symptoms are related to whether the ectopic pregnancy has ruptured. According to [Pisarska and colleagues \(1998\)](#), women at high risk should be screened early and before they become symptomatic. For others, the most frequently experienced symptoms of ectopic pregnancy are pelvic and abdominal pain (95 percent) and amenorrhea with some degree of vaginal spotting or bleeding (60 to 80 percent). With more advanced gestation, [Dorfman and associates \(1984\)](#) reported that gastrointestinal symptoms (80 percent) and dizziness or light-headedness (58 percent) were common. With rupture, pain may be anywhere in the abdomen. Pleuritic chest pain may occur from diaphragmatic irritation caused by the hemorrhage.

ABNORMAL MENSTRUATION. About a fourth of women do not report amenorrhea; they mistake uterine bleeding that frequently occurs with tubal pregnancy for true menstruation. When endocrine support for the endometrium declines, bleeding is usually scanty, dark brown, and may be intermittent or continuous. Although profuse vaginal bleeding is suggestive of an incomplete abortion rather than an ectopic gestation, such bleeding is occasionally seen with tubal gestations.

ABDOMINAL AND PELVIC TENDERNESS. Exquisite tenderness on abdominal and vaginal examination, especially on motion of the cervix, is demonstrable in over three fourths of women with ruptured or rupturing tubal pregnancies. Such tenderness, however, may be absent prior to rupture.

UTERINE CHANGES. Because of placental hormones, in about 25 percent of cases, the uterus grows during the first 3 months of a tubal gestation to nearly the same size as it would with a normal pregnancy ([Stabile and Grudzinskas, 1990](#)). Its consistency may be similar as long as the fetus is alive. The uterus may be pushed to one side by an ectopic mass, or if the broad ligament is filled with blood, the uterus may be greatly displaced. Uterine decidual casts are passed by only 5 to 10 percent of women. Their passage may be accompanied by cramps similar to those with a spontaneous abortion.

BLOOD PRESSURE AND PULSE. Before rupture, vital signs generally are normal. Early responses to moderate hemorrhage may range from no change in vital signs to a slight rise in blood pressure, or a vasovagal response with bradycardia and hypotension. Blood pressure will fall and pulse rise only if bleeding continues and hypovolemia becomes significant.

Even with modern diagnostic methods, women with a ruptured ectopic pregnancy may present with hypovolemia and shock. [Stabile and Grudzinskas \(1990\)](#) reviewed several reports totaling almost 2400 women with surgically confirmed ectopic pregnancy. Almost a fourth presented in shock, but this proportion ranged from 1 to 50 percent in various series.

TEMPERATURE. After acute hemorrhage, the temperature may be normal or even low. Temperatures up to 38°C may develop, but higher temperatures are rare in the absence of infection. Fever is important in distinguishing a ruptured tubal pregnancy from some cases of acute salpingitis.

PELVIC MASS. On bimanual examination, a pelvic mass is palpable in about 20 percent of women. Its size ranges between 5 and 15 cm, and such masses are often soft and elastic. With extensive infiltration of blood into the tubal wall, the mass may be firm. It is almost always either posterior or lateral to the uterus. Pain and tenderness often preclude identification of the mass by palpation.

In some cases, there is gradual disintegration of the tubal wall followed by slow leakage of blood into the lumen, peritoneal cavity, or both. Signs of active hemorrhage are absent, and even mild symptoms may subside. Gradually, however, trickling blood collects in the pelvis, more or less walled off by adhesions, and a pelvic hematocele results. In some cases, this is eventually absorbed, and the patient recovers without operation. In others, it may rupture into the peritoneal cavity, or it

may become infected and form an abscess.

CULDOCENTESIS. This is a simple technique for identifying hemoperitoneum. The cervix is pulled toward the symphysis with a tenaculum, and a long 16- or 18-gauge needle is inserted through the posterior fornix into the cul-de-sac. If present, fluid can be aspirated; however, failure to do so is interpreted only as unsatisfactory entry into the cul-de-sac and does not exclude an ectopic pregnancy, either ruptured or unruptured. Fluid-containing fragments of old clots, or bloody fluid that does not clot, are compatible with the diagnosis of hemoperitoneum resulting from an ectopic pregnancy. If the blood subsequently clots, it may have been obtained from an adjacent perforated blood vessel rather than from a bleeding ectopic pregnancy.

LABORATORY TESTS

Measurement of hemoglobin, hematocrit, and leukocyte count, as well as serum levels of chorionic gonadotropin and progesterone, are useful in certain cases if their limitations are understood.

HEMOGLOBIN, HEMATOCRIT, AND LEUKOCYTE COUNT. After hemorrhage, depleted blood volume is restored toward normal by hemodilution over the course of a day or longer. Even after substantive hemorrhage, therefore, hemoglobin or hematocrit readings may at first show only a slight reduction. For the first few hours after an acute hemorrhage, a decrease in **hemoglobin or hematocrit level while the woman is under observation is a more valuable index of blood loss than is the initial reading.**

The degree of leukocytosis varies considerably in ruptured ectopic pregnancy. In about half of women, it is normal, but in the remainder, varying degrees of leukocytosis up to 30,000/uL may be documented.

CHORIONIC GONADOTROPIN ASSAYS. Ectopic pregnancy cannot be diagnosed by a positive pregnancy test alone. The key issue, however, is whether the woman is pregnant. In virtually all cases of ectopic gestation, human chorionic gonadotropin (β -hCG) can be detected in serum, but usually at markedly reduced concentrations compared with normal pregnancy.

URINARY PREGNANCY TESTS. Urine tests are most often latex agglutination inhibition slide tests with sensitivities for chorionic gonadotropin in the range of 500 to 800 mIU/mL. Their simplicity is offset by only a 50 to 60 percent chance of being positive with an ectopic pregnancy. Even when tube-type tests are used, detection of chorionic gonadotropin is within 150 to 250 mIU/mL, and the test is positive only in 80 to 85 percent of ectopic pregnancies. Tests using enzyme-linked immunosorbent assays (ELISA) are sensitive to 10 to 50 mIU/mL, and are positive in 95 percent of ectopic pregnancies.

SERUM β -hCG ASSAYS. Radioimmunoassay is the most precise method, and virtually any pregnancy can be detected. In fact, because of the sensitivity of this assay, a pregnancy may be confirmed before there are grossly visible changes in the fallopian tube. Absence of pregnancy can be established only when there is a negative assay for serum gonadotropin that has a sensitivity of 5 to 10 mIU/mL. Because a single positive serum assay does not exclude an ectopic pregnancy, several different methods have been devised to use serial quantitative serum values to establish the diagnosis. These may be used alone, but more commonly are used in conjunction with sonography.

SERUM PROGESTERONE. A single progesterone measurement can often be used to establish that there is a normally developing pregnancy. A value exceeding 25 ng/mL excludes ectopic pregnancy with 97.5 percent sensitivity ([Lipscomb and co-workers, 1999a](#); [Pisarska and colleagues, 1998](#); [Stoval and associates, 1992](#)). Values less than 5 ng/mL suggest that the fetus-embryo is dead, but not its location. Progesterone levels between 5 and 25 ng/mL—unfortunately common—are inconclusive ([McCord and colleagues, 1996](#)).

According to [DeCherney \(1996\)](#), 10 percent of women with a normal pregnancy have serum progesterone values less than 25 ng/mL. [Hahlin and co-workers \(1990\)](#) reported that no woman with a uterine pregnancy had progesterone levels less than 10 ng/mL, while 88 percent of those with ectopic pregnancies and 83 percent of those with spontaneous abortions had lower values.

ULTRASOUND IMAGING

ABDOMINAL SONOGRAPHY. Identification of pregnancy products in the fallopian tube is difficult using abdominal sonography. If a gestational sac is clearly identified within the uterine cavity, it is unlikely an ectopic pregnancy coexists. Moreover, with sonographic absence of a uterine pregnancy, a positive pregnancy test, fluid in the cul-de-sac, and an abnormal pelvic mass, ectopic pregnancy is almost certain ([Romero and associates, 1988](#)). Unfortunately, ultrasonic findings suggestive of early uterine pregnancy may be apparent in some cases of ectopic pregnancy. The sonographic appearance of a small sac (very early pregnancy) or a collapsed sac (dead fetus) may actually be a blood clot or decidual cast ([Coleman and colleagues, 1985](#)). A uterine pregnancy is usually not recognized using abdominal ultrasound until 5 to 6 menstrual weeks or 28 days after timed ovulation ([Batzer and co-workers, 1983](#)). Conversely, demonstration of an adnexal or cul-de-sac mass by sonography is not necessarily helpful. Corpus luteum cysts and matted bowel sometimes look like tubal pregnancies sonographically. Identification with sonography of fetal heart action clearly outside the uterine cavity, however, provides firm evidence of an ectopic pregnancy ([Fig. 34-5](#)).

VAGINAL SONOGRAPHY. Sonography with a vaginal transducer can be used to detect uterine gestation as early as 1 week after missed menses when the serum β -hCG level is greater than 1500 mIU/mL. In a study by [Barnhart and colleagues \(1994\)](#), an empty uterus with a serum β -hCG concentration of 1500 mIU/mL or higher was 100 percent accurate in identifying an ectopic pregnancy.

Vaginal sonography is also used to detect adnexal masses. This, however, can be misleading, and ectopic pregnancies may be missed when a tubal mass is small or obscured by bowel ([Cacciatore and colleagues, 1990](#)). [Sadek and Schiatz \(1995\)](#) reported that the sensitivity and specificity of vaginal ultrasound for ectopic pregnancy was 96 and 99 percent, respectively, when free peritoneal fluid was identified. With visualization of a tubal mass, these were 81 and 99 percent, respectively.

Vaginal sonography results in earlier and more specific diagnoses of uterine pregnancy. With a serum β -hCG level of 1000 mIU/mL, 50 percent of gestational sacs are seen ([DeCherney, 1996](#)). Criteria include identification of a 1- to 3-mm or larger gestational sac, eccentrically placed in the uterus, and surrounded by a decidual-chorionic reaction. A fetal pole within the sac is diagnostic, especially when accompanied by fetal heart action.

Vaginal sonography, such as shown in [Figures 34-6](#) and [34-7](#), can be used alone to diagnose ectopic pregnancy in more than 90 percent of cases ([Cacciatore and co-workers, 1990](#)). Accurate clinical diagnosis is based upon two possibilities:

1. Uterine pregnancy is identified as described.
2. Or, an empty uterus and an ectopic pregnancy are seen based upon visualization of an adnexal mass separate from two clearly identified ovaries.

The mass must be complex, or contain a gestational saclike adnexal ring with or without a fetal pole (fetal echoes or yolk sac).

Without these criteria, the study may be nondiagnostic. A heterotypic pregnancy is an exception ([Hirsch and associates, 1992](#)). In the event of a nondiagnostic study, most clinicians favor serial sonography along with serial β -hCG measurements because the change in concentration is important ([Tay and colleagues, 2000](#)). In some cases, laparoscopy or laparotomy may be necessary.

VAGINAL COLOR AND PULSED DOPPLER ULTRASOUND. This technique consists of identifying a uterine or extrauterine site of vascular color in a characteristic placental shape, the so-called *ring-of-fire* pattern, and a high-velocity low-impedance flow pattern that is compatible with placental perfusion. If this pattern is seen outside the uterine cavity, which is also "cold" with respect to blood flow, the diagnosis of ectopic pregnancy is apparent.

The technique significantly improves the correct diagnosis of a live uterine pregnancy as well as an ectopic pregnancy or incomplete abortion ([Emerson and colleagues, 1992](#); [Pellerito and co-workers, 1992](#)). It has been used successfully to diagnose cervical pregnancy and to monitor its regression following methotrexate therapy ([Chao and colleagues, 1993](#); [Roussis and co-workers, 1992](#)). Unfortunately, the equipment is expensive and interpretation is complex.

DIAGNOSIS OF ECTOPIC PREGNANCY

During the past decade, as modern refinements for identification of ectopic pregnancy have evolved, the majority—perhaps 80 percent—are diagnosed before

rupture. Coincidentally, the death rate has decreased appreciably ([Fig. 34-2](#)). A number of diagnostic algorithms have been proposed and are described next.

QUANTITATIVE SERUM β -hCG PLUS SONOGRAPHY

When pregnancy is diagnosed in a hemodynamically stable woman suspected of having an ectopic pregnancy, subsequent management is based upon serial serum β -hCG values and sonography. When the β -hCG value is less than 1500 mIU/mL and there is an empty uterus with vaginal sonography, no definitive diagnosis can be made. While a positive assay for serum β -hCG can confirm a pregnancy as early as 8 days after fertilization, a uterine gestational sac cannot be reliably identified with vaginal ultrasound until 28 days after conception, or about 6 weeks of amenorrhea. This time between 8 and 28 days is called the *20-day window* ([Daus and colleagues, 1989](#)). During this time, the woman may abort, she may continue her pregnancy and develop a normal gestational sac, or she may develop evidence of an ectopic pregnancy.

[Kadar and Romero \(1987\)](#) confirmed earlier work demonstrating that in women with normal pregnancies, mean doubling time for β -hCG in serum was approximately 48 hours, and the lowest normal value for this increase was 66 percent ([Table 34-3](#)). They calculated this number by subtracting the initial value for β -hCG from the 48-hour value and dividing the result by the initial value, which is multiplied by 100 to obtain a percentage. They found that more reliable values could be obtained at 48-hour intervals. They concluded that failure to maintain this rate of increased β -hCG production, along with an empty uterus, was suggestive for an ectopic pregnancy. This plan delays surgery at least 48 hours. Moreover, the test would still falsely identify 15 percent of normal women as likely to have an ectopic pregnancy and falsely identify 13 percent of women with an ectopic pregnancy as normal.

SURGICAL DIAGNOSIS

CURETTAGE. Differentiation between threatened or incomplete abortion and a tubal pregnancy may be accomplished in many instances by office curettage. [Stovall and colleagues \(1992\)](#) recommend curettage in suspected cases of incomplete abortion versus ectopic pregnancy when serum progesterone is less than 5 ng/mL, β -hCG levels are rising abnormally (less than 2000 mU/mL), and a uterine pregnancy is not seen using transvaginal sonography. If an embryo, fetus, or placenta is identified, the diagnosis is apparent. When none of these is identified, tubal pregnancy is a probability and further follow-up is done using serial β -hCG levels and sonography.

LAPAROSCOPY. Advantages of diagnostic laparoscopy include:

1. A definitive diagnosis in most cases.
2. A concurrent route to remove the ectopic mass using operative laparoscopy.
3. A direct route to inject chemotherapeutic agents into the ectopic mass.

Complete visualization of the pelvis may be impossible if there is pelvic inflammation or active bleeding. At times, identification of an early unruptured tubal pregnancy may be difficult, even if the tube is fully visualized.

LAPAROTOMY. This is preferred when the woman is hemodynamically unstable, or if laparoscopy is not feasible. Laparotomy should not be delayed while laparoscopy is performed in a woman with obvious abdominal hemorrhage that requires immediate definitive treatment. Laparoscopy is more cost-effective, and there is a shorter postoperative recovery ([Gray and colleagues, 1995](#)).

TREATMENT AND PROGNOSIS OF TUBAL PREGNANCY

In the past, salpingectomy was usually done to remove a damaged, bleeding oviduct. Over the past two decades, technical advances with earlier diagnosis and treatment of high-risk women have allowed definitive management of an unruptured ectopic pregnancy even before there are clinical symptoms. Importantly, early diagnosis, while contributing to a higher incidence, has made many cases of ectopic pregnancy amenable to medical therapy. Indeed, according to [Pisarska and colleagues \(1998\)](#), ectopic pregnancy is evolving into a medical disorder. [Mol and associates \(1999\)](#) evaluated costs for 100 women in a randomized study to compare salpingostomy with methotrexate therapy. They reported that medical therapy costs were lower if confirmatory laparoscopy was not performed. [Lecuru and colleagues \(2000\)](#) analyzed costs in a nonrandomized prospective evaluation of 59 women treated by methotrexate or laparoscopic salpingectomy. The cost for surgical therapy was more than twice than for methotrexate. [Morlock and colleagues \(2000\)](#) used decision-analysis of published data and calculated cost savings of \$3000 in 1998 for methotrexate therapy for each resolved ectopic pregnancy.

SURGICAL MANAGEMENT

Subsequent pregnancy and lower recurrent ectopic pregnancy rates are observed in women in whom surgery is performed prior to rupture. Laparoscopy is preferred over laparotomy unless the woman is unstable ([Tulandi and Saleh, 1999](#)). Even though reproductive outcome—including rates of uterine and recurrent ectopic pregnancies—is similar, laparoscopy is more cost effective and has a shorter recovery time—1.3 versus 3.1 days ([Tay and colleagues, 2000](#)).

Tubal surgery for ectopic pregnancy is considered *conservative* when there is tubal salvage. Examples include salpingostomy, salpingotomy, and fimbrial expression of the ectopic. *Radical surgery* is defined by salpingectomy. Shown in [Table 34-4](#) are four retrospective studies of fertility subsequent to surgical treatment. The rates of uterine and recurrent ectopic pregnancies are not different when conservative procedures were compared with salpingectomy.

SALPINGOSTOMY. This procedure is used to remove a small pregnancy that is usually less than 2 cm in length and located in the distal third of the fallopian tube ([Fig. 34-8](#)). A linear incision, 10 to 15 mm in length or less, is made on the antimesenteric border immediately over the ectopic pregnancy. The products usually will extrude from the incision and can be carefully removed or flushed out. Small bleeding sites are controlled with needlepoint electrocautery or laser, and the incision is left unsutured to heal by secondary intention. This procedure is readily performed through a laparoscope and currently is the "gold standard" of surgical methods used for an unruptured ectopic pregnancy ([Tulandi and Saleh, 1999](#)).

SALPINGOTOMY. The procedure is the same as for salpingostomy except that the incision is closed with 7-0 Vicryl or similar suture. According to [Tulandi and Saleh \(1999\)](#), there is no difference in prognosis with or without suturing.

SALPINGECTOMY. Tubal resection can be performed through an operative laparoscope and may be used for both ruptured and unruptured ectopic pregnancies. It is performed if the fallopian tube is extensively diseased or damaged ([Tay and associates, 2000](#)). When removing the oviduct, it is advisable to excise a wedge no more than the outer third of the interstitial portion of the tube. This so-called *cornual resection* is done in an effort to minimize the rare recurrence of pregnancy in the tubal stump. Even with cornual resection, a subsequent interstitial pregnancy may not be prevented ([Kalchman and Meltzer, 1966](#)).

In some women with an interstitial pregnancy, hysterectomy is necessary to stop life-threatening hemorrhage. Conversely, [Moon and co-workers \(2000\)](#) described 24 women with an interstitial pregnancy who were successfully treated by endoscopic surgery. In 15 of these, the endoloop technique was used.

SEGMENTAL RESECTION AND ANASTOMOSIS. Resection of the mass and tubal anastomosis is sometimes used for an unruptured isthmic pregnancy. This procedure is used because salpingostomy may cause scarring and subsequent narrowing of the small lumen ([Stangel and associates, 1976](#)). After the tubal segment is exposed, the mesosalpinx beneath the tube is incised, and the tubal isthmus containing the ectopic mass is resected. The mesosalpinx is sutured, thus reapproximating the tubal stumps. The segments of the tube are then apposed to one another in layers with interrupted 7-0 Vicryl sutures, preferably using magnification. Three sutures are used in the muscularis and three in the serosa, with strict attention to avoid the tubal lumen.

PERSISTENT TROPHOBLAST. Following salpingostomy or salpingectomy, serum β -hCG levels usually fall quickly and are at about 10 percent of preoperative values by day 12 ([Hajenius and colleagues, 1995](#); [Vermesh and associates, 1988](#)). Persistent ectopic pregnancy is the result of incomplete removal of trophoblast. It is the most common complication of salpingostomy, with a frequency of 5 to 20 percent ([Graczykowski and Mishell, 1997](#)). [Yao and Tulandi \(1997\)](#) summarized almost 700 tubal pregnancies removed at laparoscopy, and persistent pregnancy was identified in 8 percent. The number was 4 percent in 230 women undergoing laparotomy. Because of these high rates, [Spandorfer and co-workers \(1997\)](#) studied the predictive value of a day 1 serum hCG value. If the level at this time had decreased to less than 50 percent of that done preoperatively, then persistent ectopic trophoblast was rare.

According to [Seifer \(1997\)](#), factors that increase the risk of persistent ectopic include:

1. Small pregnancies, viz, less than 2 cm.
2. Early therapy, viz, before 42 menstrual days.
3. β -hCG serum levels exceeding 3000 mIU/mL.
4. Implantation medial to the salpingostomy site.

To avoid persistent ectopic pregnancy, some clinicians choose to give single-dose prophylactic methotrexate (1 mg/kg) to women in these high-risk categories. In either case, with persistent or increasing values, the choice of reexploration or methotrexate chemotherapy must be made.

MEDICAL MANAGEMENT

METHOTREXATE. [Tanaka and associates \(1982\)](#) were first to recommend use of methotrexate for interstitial pregnancy. Subsequently, [Miyazaki \(1983\)](#) and [Ory and colleagues \(1986\)](#) reported its use as first-line therapy for ectopic pregnancies. Since these initial reports, there have been numerous reports describing successful treatment of all varieties of ectopic pregnancies using a number of methotrexate regimens. Indeed, as experience was gained, medical treatment became comparable with the "gold standard" of salpingostomy ([Buster and Pisarska, 1999](#)). Despite this, there still may be reluctance to use medical therapy for fear of subsequent tubal rupture ([Kucera and associates, 2000](#); [Lipscomb and colleagues, 2000](#)).

In the largest single-center series, [Lipscomb and colleagues \(1999a\)](#) reported a 91 percent success rate in 350 women given methotrexate therapy. Of these, 283 women were given a single dose of methotrexate, 60 women two doses, six women three doses, and one woman four doses. In a randomized trial from the Netherlands by [Hajenius and colleagues \(1997\)](#), comparable results were described with systemic methotrexate and laparoscopic salpingostomy.

Active intra-abdominal hemorrhage is a contraindication to chemotherapy. The size of the ectopic mass is also important, and [Pisarska and colleagues \(1998\)](#) recommend that methotrexate not be used if the pregnancy is more than 4 cm. Success is greatest if the gestation is less than 6 weeks, the tubal mass is not more than 3.5 cm in diameter, the fetus is dead, and the β -hCG is less than 15,000 mIU ([Lipscomb and colleagues, 1999a](#); [Stovall, 1995](#)). According to the [American College of Obstetricians and Gynecologists \(1998\)](#), other contraindications include breast feeding, immunodeficiency, alcoholism, liver or kidney disease, blood dyscrasias, active pulmonary disease, and peptic ulcer.

PATIENT SELECTION. Candidates for methotrexate therapy must be hemodynamically stable with a normal hemogram and normal liver and renal function. They are instructed that:

1. Medical therapy fails in 5 to 10 percent of cases, and this rate is higher in pregnancies past 6 weeks gestation or with a tubal mass greater than 4 cm in diameter.
2. Failure of medical therapy results in re-treatment, either medically or with elective surgery, or if tubal rupture occurs—a 5 percent chance—emergency surgery.
3. If treated as an outpatient, rapid transportation must be available.
4. Signs and symptoms of tubal rupture such as vaginal bleeding, abdominal and pleuritic pain, weakness, dizziness, or syncope must be reported promptly.
5. Sexual intercourse is prohibited until after serum β -hCG is undetectable.
6. No alcohol is consumed.
7. Multivitamins with folic acid should not be taken.

DOSE AND ADMINISTRATION. Methotrexate is an antineoplastic drug that acts as a folic acid antagonist and is highly effective against rapidly proliferating trophoblast. Its use is discussed in greater detail in [Chapter 32 \(p. 846\)](#). The two general schemes used for methotrexate administration for ectopic pregnancy are shown in [Table 34-5](#). While single-dose treatment is easier to administer and monitor than variable-dose methotrexate therapy, it is associated with a higher failure rate, defined as persistent ectopic pregnancy ([Table 34-6](#)). This likely is related to the pharmacokinetics of methotrexate. [Creinin and Krohn \(1997\)](#) reported that with 50 or 60 mg/m² given intramuscularly, serum levels peaked within 2 hours and were undetectable by 72 hours.

Most methotrexate regimens studied include a dose of 50 mg/m². Recently, [Yalcinkaya and colleagues \(2000\)](#) compared 50 mg/m² with 25 mg/m² in a randomized study of clinically stable patients. Their preliminary results show that either dose resulted in similar outcomes. Importantly, the need for a second injection was about the same (25 to 30 percent) for each group.

MONITORING METHOTREXATE TOXICITY. Although toxicity may be severe, fortunately, most regimens have been associated with minimal laboratory changes and symptoms. [Kooi and Kock \(1992\)](#) reviewed 16 studies that reported side effects that all resolved in 3 to 4 days after methotrexate was discontinued. The most common were liver dysfunction (12 percent), stomatitis (6 percent), and gastroenteritis (1 percent); however, one woman had bone marrow depression. Case reports also describe life-threatening neutropenia and fever, transient drug-induced pneumonitis, and alopecia ([Buster and Pisarska, 1999](#)).

MONITORING EFFICACY OF THERAPY. Various placental protein and steroid hormones have been used to monitor trophoblastic function (and mass) following medical and surgical therapy for ectopic pregnancies. The most widely used is serial serum β -hCG determinations, but values frequently continue to rise until day 4 after methotrexate therapy ([Lipscomb and colleagues, 2000](#)).

After methotrexate administration, β -hCG usually disappears from plasma between 14 and 21 days ([Fig. 34-9](#)). [Lipscomb and colleagues \(1998\)](#) treated 287 women successfully and found the average time to resolution (< 15 mIU/mL) was 34 days. The longest time was 109 days. As shown in [Table 34-5](#), monitoring single-dose therapy calls for repeat serum β -hCG determinations at 4 and 7 days. With variable-dose methotrexate, serum concentrations are measured at 48-hour intervals until they fall more than 15 percent. After successful treatment, weekly serum β -hCG determinations are measured until less than 5 mIU/mL. Outpatient surveillance is preferred, but if there is any question of safety, the woman is hospitalized. Failure is judged when there is no decline in β -hCG level, there is persistence of the ectopic mass, or there is any intraperitoneal bleeding.

PERSISTENT ECTOPIC PREGNANCY. Failure of initial medical or surgical therapy usually can be resolved with methotrexate therapy. About 20 percent of women given single-dose methotrexate will need a second dose ([Lipscomb and associates, 2000](#)). Aggregate studies shown in [Table 34-6](#) suggest comparable efficacy—93 percent—of conservative surgery and variable-dose methotrexate. In the only randomized trial, however, [Hajenius and colleagues \(1997\)](#) observed persistent trophoblast in only 4 percent of women given variable-dose methotrexate compared with 20 percent of women undergoing salpingostomy.

Persistent pregnancy is suspected in women with abdominal pain. This is problematic because 65 to 75 percent of women given methotrexate will have increasing pain beginning several days after therapy. This **separation pain** generally is mild and relieved by nonnarcotic analgesics. For 20 percent of 258 patients with pain severe enough to require evaluation in the clinic or emergency room, [Lipscomb and colleagues \(1999b\)](#) reported that 10 of 53 ultimately underwent surgical exploration. Careful clinical observation, along with vaginal sonography and serum β -hCG determinations, is warranted.

Rupture of persistent ectopic pregnancy is the most catastrophic form of primary therapy failure. Its incidence is not known for certain, but Graczykowski and Seifer (1999) estimate it to be about 25 percent. [Lipscomb and associates \(1998\)](#) described a 14-day mean time to rupture, but one woman had tubal rupture 32 days after single-dose methotrexate therapy.

Reproductive outcomes after treatment for persistent ectopic pregnancy were reviewed by [Seifer and colleagues \(1994\)](#). At 36-month follow-up, 60 percent of 32 women trying had a successful uterine pregnancy. There were no recurrent ectopic pregnancies reported. These data are comparable to those shown in [Table 34-6](#) for successes following primary medical or surgical therapy.

OTHER TREATMENTS ACTINOMYCIN. [Neary and Rose \(1995\)](#) reported that a 5-day course of intravenous *actinomycin* resulted in complete resolution of an ectopic pregnancy in a woman who had failed methotrexate therapy. [Fishman and associates \(1998\)](#) reported successful treatment of a diaphragmatic pregnancy with

thoroscopic excision and actinomycin chemotherapy.

DIRECT INJECTION. A number of cytotoxic drugs have been injected directly into the ectopic mass, either by laparoscopy or transvaginally by culdocentesis. Treatment with methotrexate by salpingocentesis usually is a single 50-mg injection, but as little as 5 mg has been used successfully ([Fernandez and colleagues, 1995](#)). [Natofsky and associates \(1999\)](#) reviewed 406 ectopic pregnancies treated by salpingocentesis. In the majority, methotrexate was injected and the success rate was 81 percent. This is much lower than the 93 percent success rate with either conservative surgery or variable-dose methotrexate as determined by [Pisarska and colleagues \(1998\)](#).

[Paulsson and colleagues \(1995\)](#) reported their results of laparoscopic injection of **prostaglandin F_{2a}** into 127 ectopic pregnancies. While 85 to 90 percent effective, prostaglandin therapy caused cardiac arrhythmias, transient hypertension, pulmonary edema, and atrioventricular block.

Tubal pregnancy injection with **hyperosmolar glucose** has also been reported to be successful for unruptured ectopic pregnancies ([Yeko and associates, 1995](#)).

Because of the much lower success rate and side effects with direct injection, coupled with the need for laparoscopic guidance, these techniques are not used widely.

EXPECTANT MANAGEMENT. Some practitioners choose to observe very early tubal pregnancies that are associated with stable or falling serum β -hCG levels. As many as a third of women with ectopic pregnancies will present with declining β -hCG levels ([Shalev and colleagues, 1995](#)). [Stovall and Ling \(1992\)](#) restrict this to women with these criteria:

1. Decreasing serial β -hCG levels.
2. Tubal pregnancies only.
3. No evidence of intraabdominal bleeding or rupture using vaginal sonography.
4. Diameter of the ectopic mass not greater than 3.5 cm.

[Trio and colleagues \(1995\)](#) reported spontaneous resolution of ectopic pregnancy in 49 of 67 women (73 percent) treated expectantly. This was more likely if the initial serum β -hCG level was less than 1000 mIU/mL. In a study of 60 women observed initially with expectant management, [Shalev and associates \(1995\)](#) reported spontaneous resolution in 28 women (48 percent).

ANTI-D IMMUNE GLOBULIN. If the woman is d-negative but not yet sensitized to d-antigen, then anti-d immunoglobulin should be administered.

ABDOMINAL PREGNANCY

Almost all cases of abdominal pregnancy follow early rupture or abortion of a tubal pregnancy into the peritoneal cavity. Primary peritoneal implantation of the fertilized ovum is very rare, and six well-documented cases have been reported ([Thomas and co-workers, 1991a](#)). The Centers for Disease Control estimated that the incidence of abdominal pregnancy is 1 in 10,000 live births ([Atrash and co-workers, 1987](#)). At Parkland Hospital, where ectopic pregnancy is common, advanced abdominal pregnancy is rare and encountered in perhaps 1 in 25,000 births.

Typically, the growing placenta, after penetrating the oviduct wall, maintains its tubal attachment but gradually encroaches upon and implants in the neighboring serosa. Meanwhile, the fetus continues to grow within the peritoneal cavity. Occasionally, the placenta is found in the general region of the oviduct and over the posterior aspect of the broad ligament and uterus ([Fig. 34-10](#)). In other cases, after tubal rupture, the conceptus reimplants elsewhere in the peritoneal cavity. In some cases a prior cesarean incision will rupture early in pregnancy to give rise to a pregnancy under the vesico-uterine peritoneal fold ([Marcus and colleagues, 1999](#)). We recently encountered a woman whose pregnancy had ruptured through a prior vertical cesarean incision at some point remote from delivery. The placenta remained implanted in the lower uterine segment and repeat cesarean delivery near term disclosed the abdominal pregnancy with the healthy fetus outside of the uterus.

The incidence of abdominal pregnancy is increased after gamete intrafallopian transfer, in vitro fertilization, and induced abortion ([Ferland and associates, 1991](#); [Pisarska and Carson, 1999](#)). Endometriosis, tuberculosis, and intrauterine devices may also contribute to an increased incidence ([Borlum and Blom, 1988](#); [Durukan and co-workers, 1990](#)).

FETAL OUTCOME

Fetal salvage in an abdominal pregnancy is exceedingly precarious, and the great majority succumb. In a world literature review, [Ware \(1948\)](#) cited a perinatal loss of 75 percent, but this figure may have been falsely low because of the tendency to report cases with good outcomes. Some authors report an incidence of a malformed fetus as high as 50 percent. In his extensive review of abdominal pregnancies since the year 1809, [Stevens \(1993\)](#) found that survival of infants born after 30 weeks was 63 percent. Moreover, fetal malformations and deformations were only 20 percent. The most common deformations were facial and/or cranial asymmetry and various joint abnormalities. The most common malformations were limb deficiency and central nervous system malformations. Even the lack of amniotic fluid surrounding the fetus is not always associated with fetal lung hypoplasia ([Dubinsky and colleagues, 1994](#)).

Some clinicians await fetal viability with in-hospital expectant management if pregnancy is diagnosed after 24 weeks, ([Cartwright and associates, 1986](#); [Hage and colleagues, 1988](#)). Such management carries a risk for sudden, life-threatening, intraabdominal bleeding. Because of this risk, termination of pregnancy is generally indicated when abdominal pregnancy is diagnosed. In cases where amniotic fluid volume is minimal or absent, and in cases less than 24 weeks, conservative treatment is rarely justified because fetal survival is extremely poor.

If the fetus dies after reaching a size too large to be resorbed, it may undergo suppuration, mummification, or calcification. Bacteria may gain access to the gestational products, particularly when they are adherent to intestine, resulting in suppuration. Eventually, the abscess ruptures, and if the woman does not die of peritonitis and septicemia, fetal parts may be extruded through the abdominal wall or more commonly into the intestine or bladder ([Emembolu, 1989](#)). Mummification and formation of a lithopedion occasionally ensue, and calcified products of conception may be carried for years. There are instances in which a period of 20 to 50 years elapsed before removal of a lithopedion at operation or autopsy. Much more rarely, the fetus is converted into a yellowish, greasy mass to which the term adipocere is applied. The various bizarre terminations of abdominal pregnancy have been discussed, with illustrative cases graphically described by [King \(1954\)](#).

DIAGNOSIS

Because early rupture or abortion of a tubal pregnancy is the usual antecedent of an abdominal pregnancy, in retrospect, a suggestive history can usually be obtained. Abnormalities likely to be recalled include spotting or irregular bleeding along with abdominal pain that usually was most prominent in one or both lower quadrants. [Costa and associates \(1991\)](#) presented an excellent and extensive review of this subject.

Women with an abdominal pregnancy are likely to be uncomfortable but not sufficiently so to warrant thorough evaluation. Nausea, vomiting, flatulence, constipation, diarrhea, and abdominal pain may each be present in varying degrees. Multiparas may state that the pregnancy does not "feel right." Late in pregnancy, fetal movements may cause pain.

Abnormal fetal positions can frequently be palpated, but the ease of palpating fetal parts is not a reliable sign. Fetal parts sometimes feel exceedingly close to the examining fingers even in normal pregnancies, especially in thin, multiparous women. Abdominal massage over the pregnancy does not stimulate the mass to contract as it almost always does with advanced intrauterine pregnancy. As depicted in [Figure 34-10](#), the cervix is usually displaced, depending in part on the fetal position, and it may dilate but appreciable effacement is unusual. The uterus may be outlined over the lower part of the pregnancy mass. Small parts or the fetal head may occasionally be palpated through the fornices and identified as clearly outside the uterus.

LABORATORY TESTS. An unexplained transient anemia early in pregnancy may accompany the initial tubal rupture or abortion. Almost all other laboratory values, including those reflecting fetal well-being, are normal until fetal demise occurs. An otherwise unexplained increase in serum alpha-fetoprotein value suggests the possibility of abdominal pregnancy ([Bombard, 1994](#); [Costa, 1991](#); [el Kareh, 1993](#); [Jackson, 1993](#), and their associates). Interestingly, despite two elevated maternal serum alpha-fetoprotein values, amniotic fluid alpha-fetoprotein was normal in the abdominal pregnancy reported by [Jackson and colleagues \(1993\)](#). Doppler waveform analyses also have been reported to be normal in abdominal gestations ([Hage and co-workers, 1988](#); [Kirkinen and colleagues, 1988](#)).

OXYTOCIN STIMULATION. [Cross and co-workers \(1951\)](#) emphasized that oxytocin stimulation could be a valuable aid to diagnose abdominal pregnancy. If no uterine activity is detected using a sensitive strain gauge applied over the products of conception while oxytocin is infused, the diagnosis of extrauterine pregnancy may be suspected. [Hertz and co-workers \(1977\)](#) could detect no uterine activity while infusing oxytocin in excess of 50 mU/min because the empty uterus was posterior to the fetus. If the uterus were anterior, as in [Figure 34-10](#), it might contract in response to oxytocin and possibly lead to the false diagnosis of intrauterine pregnancy.

[Orr and associates \(1979\)](#) reported that before the diagnosis of an abdominal pregnancy was made, the uterus contracted in response to oxytocin, and an oxytocin challenge test was interpreted as negative on two occasions. Nonstress testing has been normal in most series, and as noted earlier, contraction stress testing may lead to varying results depending upon placental location ([Costa and associates, 1991](#)).

SONOGRAPHY. Ultrasonic findings with an abdominal pregnancy most often do not allow an unequivocal diagnosis to be made. In some suspected cases, however, these findings may be diagnostic. For example, if the fetal head is seen to lie immediately adjacent to the maternal bladder with no interposed uterine tissue, a specific diagnosis can be made ([Kurtz and associates, 1982](#)). Even with ideal conditions, however, a sonographic diagnosis of abdominal pregnancy is missed in half of cases ([Costa and associates, 1991](#)).

[Akhan and colleagues \(1990\)](#) reported the following sonographic criteria to be suggestive of abdominal pregnancy:

1. Visualization of the fetus separate from the uterus.
2. Failure to visualize uterine wall between the fetus and urinary bladder.
3. Close approximation of fetal parts to the maternal abdominal wall.
4. Eccentric position (relation of fetus to uterus) or abnormal fetal attitude (relation of fetal parts to one another) and visualization of extrauterine placental tissue.

The consensus is that sonography is not a definitive diagnostic procedure for abdominal pregnancy ([Anquaco and colleagues, 1994](#); [Sherer and associates, 1994](#)).

MAGNETIC RESONANCE IMAGING. This technique has been used to confirm abdominal pregnancy following a suspicious sonographic examination. The technique appears to be very accurate and specific ([Harris and associates, 1988](#); [Wagner and Burchardt, 1995](#)). Even so, in our institutions, abdominal pregnancy has been incorrectly diagnosed as a placenta previa, and an intrauterine pregnancy with degenerating fibroids has been misdiagnosed as an abdominal pregnancy.

COMPUTED TOMOGRAPHY. [Costa and associates \(1991\)](#) maintain that computed tomography is superior to magnetic resonance imaging, but its use is limited because of the concern for fetal radiation. In cases of fetal demise, computed tomography may be diagnostic and should be considered ([Glew and Sivanesaratnam, 1989](#)).

TREATMENT

Surgery for abdominal pregnancy may precipitate torrential hemorrhage, and it is essential to have adequate blood immediately available. Preoperatively, two intravenous infusion systems, each capable of delivering large volumes of fluid at a rapid rate, should be functioning. Techniques for monitoring the adequacy of the circulation should be employed, as described in [Chapter 25 \(p. 652\)](#). Whenever time allows, a mechanical bowel preparation should be done.

The massive hemorrhage that often ensues with surgery for abdominal pregnancy is related to the lack of constriction of hypertrophied opened blood vessels after placental separation. Partial placental separation occasionally occurs spontaneously and mandates laparotomy. Even if the fetus has been dead for several weeks, bleeding may still be torrential.

MANAGEMENT OF THE PLACENTA. Because placental removal always carries the risk of hemorrhage, blood vessels supplying the placenta should be ligated before its removal. Partial separation can develop spontaneously or, more likely, in the course of the operation while attempting to locate the exact site of placental attachment. Therefore, it is best to avoid unnecessary exploration of surrounding organs. In general, the infant should be delivered, the cord severed close to the placenta, and the abdomen closed.

Unfortunately, if left in the abdominal cavity, the placenta commonly causes infection, abscesses, adhesions, intestinal obstruction, and wound dehiscence ([Bergstrom and colleagues, 1998](#); [Martin and associates, 1988](#)). Reversible maternal hydronephrosis may also develop ([Weiss and Stone, 1994](#)). [Piering and colleagues \(1993\)](#) described persistent preeclampsia for 99 postpartum days until the placenta was removed! The woman was normotensive before pregnancy and again after placental removal. Although the complications of leaving the placenta are troublesome and usually lead to subsequent laparotomy, they may be less grave than the hemorrhage that sometimes results from placental removal during initial surgery.

If the placenta is left, its involution may be monitored using ultrasound and a variety of placental hormones. Serum β -hCG levels have been shown to be accurate ([France and Jackson, 1980](#); [Martin and associates, 1990](#)). In many cases, placental function rapidly declines, and the placenta is resorbed. In a case described by [Belfar and associates \(1986\)](#), placental resorption took over 5 years! Methotrexate use is controversial. It has been recommended to hasten involution but may cause accelerated placental destruction with accumulation of necrotic tissue and infection with abscess formation ([Rahman and associates, 1982](#)).

ARTERIAL EMBOLIZATION. Percutaneous femoral artery catheterization and pelvic angiography, followed by embolization of specific bleeding sites is discussed in [Chapter 25 \(p. 646\)](#). This technique has been lifesaving in instances of massive pelvic hemorrhage ([Kivikoski and associates, 1988](#); [Martin and colleagues, 1990](#)). [Kerr and associates \(1993\)](#) advocate preoperative transcatheter embolization followed by surgical intervention.

MATERNAL PROGNOSIS. Maternal mortality is increased substantially compared with normal pregnancy. With appropriate preoperative planning, however, maternal mortality has been reduced from approximately 20 percent to less than 5 percent in the past 20 years ([Stevens, 1993](#)). Morbidity in surviving women is excessive in many cases ([Costa and colleagues, 1991](#); [Martin and associates, 1988](#); [Martin and McCall, 1990](#)).

OVARIAN PREGNANCY

Ectopic pregnancy implanted in the ovary is rare. In 1878, Spiegelberg formulated criteria for diagnosis of ovarian pregnancy:

1. The tube on the affected side must be intact.
2. The fetal sac must occupy the position of the ovary.
3. The ovary must be connected to the uterus by the ovarian ligament.
4. Definite ovarian tissue must be found in the sac wall.

[Bobrow and Winkelstein \(1956\)](#) reviewed 154 cases that satisfied these criteria. [Hallatt \(1982\)](#) described 25 cases of primary ovarian pregnancy, and [Grimes and co-workers \(1983\)](#) reported 24 more.

Traditional risk factors for tubal pregnancy are similar for ovarian ectopic pregnancy. Concurrent use of an intrauterine contraceptive device seems to be inordinately associated with ovarian pregnancy ([Golan and associates, 1991](#); [Pisarska and Carson, 1999](#)). [Gray and Ruffolo \(1978\)](#) described four instances of ovarian pregnancy in which the women conceived with a copper-7 device in situ.

Although the ovary can accommodate itself more readily than the tube to the expanding pregnancy, rupture at an early period is the usual consequence. Nonetheless, there are recorded cases in which ovarian pregnancy went to term, and a few infants survived. [Williams and associates \(1982\)](#), while attempting a cesarean delivery because of a fetal transverse lie at 41 weeks, found an ovarian pregnancy. The infant, who weighed about 3500 g, survived. The ovary, placenta, and membranes were resected, and the severed right ureter was reimplanted in the bladder. [Belfar and colleagues \(1991\)](#) reported ultrasound diagnosis in a case where the infant

survived.

DIAGNOSIS. Findings are likely to mimic those of a tubal pregnancy or a bleeding corpus luteum. Serious bleeding is seen in about a third of cases. At surgery, early ovarian pregnancies are likely to be considered corpus luteum cysts or a bleeding corpus luteum. The increased use of vaginal ultrasound has resulted in the more frequent diagnosis of unruptured ovarian pregnancies ([Marcus and Brinsden, 1993](#); [Sidek and colleagues, 1994](#)). Early diagnosis of an intact ovarian pregnancy allows for a medical approach.

MANAGEMENT. The classical management for ovarian pregnancies has been surgical. Early bleeding for small lesions has been managed by ovarian wedge resection or cystectomy ([Schwartz and colleagues, 1993](#)). In the presence of larger lesions, ovariectomy is most often performed. Recently, laparoscopy has been used to resect or to perform laser ablation of ovarian pregnancies ([Carter and colleagues, 1993](#); [Goldenberg and associates, 1994](#)). Finally, methotrexate has been used successfully to treat unruptured ovarian pregnancies ([Chelmow, 1994](#); [Raziel, 1993](#); [Shamma, 1992](#), and their associates).

CERVICAL PREGNANCY

In the past, cervical pregnancy was a rare form of ectopic gestation. [Dees \(1966\)](#) estimated the incidence to be 1 in 18,000 pregnancies. In our experience, it is even less common. The incidence is increasing, again in part due to assisted reproduction, but especially after in vitro fertilization and embryo transfer ([Ginsburg, 1994](#); [Pattinson, 1994](#); [Peleg, 1994](#), and their associates). According to [Pisarska and Carson \(1999\)](#), prior dilatation and curettage precedes 70 percent of cases.

In a typical case, the endocervix is eroded by trophoblast, and the pregnancy proceeds to develop in the fibrous cervical wall ([Fig. 34-11](#)). The duration of pregnancy is dependent upon the site of embryo implantation. The higher it is implanted in the cervical canal, the greater is its capacity to grow and cause hemorrhage.

Painless vaginal bleeding is present in 90 percent of cervical pregnancies, and a third of these have massive hemorrhage ([Ushakov and colleagues, 1996](#)). Only a fourth had abdominal pain with bleeding. As pregnancy progresses, a distended, thin-walled cervix with the external os partially dilated may be evident. Above the cervical mass, a slightly enlarged uterine fundus may be palpated. [Gabbe and co-workers \(1975\)](#) reported two women with high fever that initially was attributed to septic abortion. Cervical pregnancy rarely goes beyond 20 weeks, and usually is surgically terminated because of bleeding. A case of cervical-isthmic pregnancy has been reported to advance to term ([Jelsema and Zuidema, 1992](#)).

Thus, identification of cervical pregnancy is based upon a high degree of clinical suspicion confirmed with sonography ([Frates and colleagues, 1994](#); [Kligman and associates, 1995](#)). Sonographic findings include an empty uterus and a gestation filling the cervical canal ([Fig. 34-12](#)). If any doubt remains, magnetic resonance imaging most often confirms the diagnosis, as shown in [Figure 34-13](#) ([Bader-Armstrong and associates, 1989](#); [Rafal and co-workers, 1990](#)). We have used color Doppler to determine extent of the implantation.

[Rubin and co-workers \(1983\)](#) have described pathological criteria that establish the diagnosis of cervical pregnancy:

1. Cervical glands must be present opposite placental attachment.
2. Attachment of placenta to cervix must be intimate.
3. The placenta must be below the entrance of uterine vessels or below the peritoneal reflection on the anteroposterior uterine surfaces.
4. Fetal elements must not be present in the uterine corpus.

SURGICAL MANAGEMENT

In the past, hysterectomy was often the only choice available because of profuse hemorrhage that accompanied attempts at removal of the cervical pregnancy. Even with hysterectomy, hemorrhage was excessive, and urinary tract injury frequent due to the enlarged barrel-shaped cervix.

CERCLAGE. [Bernstein and associates \(1981\)](#) and [Bachus and colleagues \(1990\)](#) successfully managed cervical pregnancy by placing a heavy silk ligature around the cervix similar to a McDonald cerclage (see [Chap. 27, p. 713](#)). We do not recommend this.

FOLEY CATHETER. [Nolan and associates \(1989\)](#) and [Thomas and co-workers \(1991b\)](#) recommend placement of hemostatic cervical sutures at 3 and 9 o'clock. Suction curettage is then performed, followed immediately by insertion of a Foley catheter into the cervical canal. The 30-mL catheter bulb is inflated, and the vagina is packed tightly with gauze to further tamponade bleeding. A suction catheter tip may be left above the vaginal packing to ensure adequate drainage and to monitor blood loss.

ARTERIAL EMBOLIZATION. [Lobel and colleagues \(1990\)](#), [Saliken and co-workers \(1994\)](#), and others have reported success with selective preoperative uterine artery embolization using Gelfoam (see [Chap. 25, p. 646](#)).

MEDICAL MANAGEMENT

To avoid the risks of uncontrolled hemorrhage, methotrexate and other drug treatments have been successfully used. Currently, surgical techniques are generally used only when chemotherapy fails or in emergency situations when a woman, usually undiagnosed, presents with life-threatening acute hemorrhage ([Wolcott and associates, 1988](#)).

The general rules for methotrexate use were described earlier in the chapter (p. 897). The drug has been injected directly into the gestational sac with or without potassium chloride to induce fetal death; it has been given systemically in single high-dose therapy with folinic acid rescue; it has been given in lower-dose prolonged courses; it has been given as a single low-dose regimen; and finally, it has been given in various combinations, usually intra-amnionically after failure of systemic therapy ([Dotters, 1995](#); [Kaplan, 1990](#); [Marcovici, 1994](#); [Roussis, 1992](#); [Timor-Tritsch, 1994](#), and their colleagues). Pregnancies of greater than 6 weeks' duration generally require induction of fetal death (usually with potassium chloride) or high-dose and prolonged methotrexate therapy. [Kung and Chang \(1999\)](#) reviewed 62 cases treated with methotrexate. Women in whom the fetus was alive (35 cases) had a higher failure rate with single-dose methotrexate. Almost 45 percent of these needed a surgical procedure compared with 4 percent in the group without a live fetus.

[Brand and associates \(1993\)](#) reported the successful treatment of a cervical pregnancy using actinomycin D. This is a logical approach, but confirmation is necessary before recommending this agent. [Segna and colleagues \(1990\)](#) reported successful treatment of a 6-week cervical pregnancy with etoposide, which is a semisynthetic derivative of podophyllotoxin.

OTHER SITES OF ECTOPIC PREGNANCY

Primary **splenic pregnancy** was reported by [Mankodi and associates \(1977\)](#). Findings that led to laparotomy included epigastric and left shoulder pain, hypotension, tachycardia, syncope, and pelvic tenderness. A rent in the hilar surface of the spleen prompted splenectomy and chorionic villi were identified microscopically. A similar case was reported by [Yackel and associates \(1988\)](#). A few cases of primary **hepatic pregnancy** have been described, including one with lithopedion formation ([Borlum and Blom, 1988](#); [De Almeida Barbosa and associates, 1991](#); [Schlatter and colleagues, 1988](#)). An upper **retroperitoneal pregnancy** was reported by [Ferland and associates \(1991\)](#) after in vitro fertilization and embryo transfer. Finally, [Fishman and co-workers \(1998\)](#) described implantation of a 6-week **diaphragmatic pregnancy** in a woman with abdominal and shoulder pain, dyspnea, and a hemothorax.

TABLE 34-1. Risk Factors for Ectopic Pregnancy

Risk Factor	Risk^a
High Risk	
Tubal corrective surgery	21.0
Tubal sterilization	9.3
Previous ectopic pregnancy	8.3
In utero DES exposure	5.6
Intrauterine device	4.5-45
Documented tubal pathology	3.8-21
Moderate Risk	
Infertility	2.5-21
Previous genital infection	2.5-3.7
Multiple partners	2.1
Slight Risk	
Previous pelvic/abdominal surgery	0.93-3.8
Smoking	2.3-2.5
Douching	1.1-3.1
Intercourse < 18 yr	1.6

DES = diethylstilbestrol.

^a Single values are common odds ratio from homogeneous studies; double values are range of values from heterogenous studies.

TABLE 34-2. Numbers and Rate of Reported Ectopic Pregnancies in the United States, 1970-1992

Year	Number ^a	Rates		Reported ^d Pregnancies
		Females 15 to 44 years ^b	Live Births ^c	
1970	17,800	—	—	4.5
1975	30,500	6.5	9.8	7.6
1980	52,200	9.9	14.5	10.5
1985	78,400	14.0	20.9	15.2
1989	88,400	—	—	16.0
1990	60,400	—	—	11.4
1992 ^e	55,200	—	—	10.6
1992 ^f	108,800	—	—	19.7
1993 ^g	53,000	—	—	—
1995 ^g	40,000	—	—	—
1996 ^g	37,000	—	—	—
1997 ^g	25,000	—	—	—

^a Rounded to nearest hundred.

^b Rate per 10,000 females.

^c Rate per 1000 live births.

^d Rate per 1000 reported pregnancies (live births, legal abortions, and ectopic).

^e Number and rate based upon conventional data reported from hospitals.

^f Number and rate based upon hospitalizations and ambulatory management of ectopic pregnancies.

^g Number based on National Hospital Discharge Survey.

From Centers for Disease Control and Prevention (1988, 1995, 1999); Goldner and colleagues (1993); and Nederlof and associates (1990).

TABLE 34-5. Methotrexate Therapy for Primary Treatment of Ectopic Pregnancy

Regimen	Follow-up
Single Dose ^a Methotrexate, 50 mg/m ² IM	Measure β -hCG days 4 and 7: If difference is \geq 15%, repeat weekly until $<$ 15 mIU/mL If difference $<$ 15%, repeat methotrexate dose and begin new day 1 If fetal cardiac activity present day 7, repeat methotrexate dose, begin new day 1 Surgical treatment if β -hCG levels not decreasing or fetal cardiac activity persist after three doses methotrexate

Variable Dose

Methotrexate, 1 mg/kg IM, days 1, 3, 5, 7 plus
Continue alternate-day injections until β -hCG levels decrease $>$ 15% in 48 h, or four doses methotrexate given

Leukovorin, 0.1 mg/kg IM, days 2, 4, 6, 8
Then, weekly β -hCG until $<$ 5.0 mIU/mL

IM = intramuscularly.

^a Preferred by editors.

Regimens from Buster and Pisarska (1999), Lipscomb and co-workers (1999b), and Pisarska and colleagues (1998, 1999).

35. Abnormalities of the Reproductive Tract

In some cases, pregnancy is complicated by abnormalities of the reproductive tract. In general, these are considered as developmental anomalies incurred during embryogenesis or they may be acquired and caused by events that usually occur during adulthood.

DEVELOPMENTAL REPRODUCTIVE TRACT ABNORMALITIES

A number of genitourinary defects from abnormal embryogenesis occur sporadically. Serious defects often result in significant fetal and maternal hazards. In some, even minor defects may result in an increased incidence of threatened abortion and abnormal fetal lie.

EMBRYOGENESIS OF THE REPRODUCTIVE TRACT

In order to understand the etiology of developmental abnormalities of the vagina, cervix, and uterus, it is important to first understand how the structures are formed. Briefly, development begins when the metanephric ducts emerge and connect with the cloaca between the third and fifth gestational weeks. Between the fourth and fifth weeks, two ureteric buds develop distally from the mesonephric ducts and begin to grow cephalad toward the mesonephros. Mullerian (paramesonephric) ducts form bilaterally between the developing gonad and the mesonephros. The mullerian ducts extend downward and laterally to the mesonephric ducts, and finally turn medially to meet and fuse together in the midline. The fused mullerian duct descends to the urogenital sinus to join the mullerian tubercle. **The close association between the mullerian and mesonephric ducts has clinical relevance, because damage to either duct system will most often be associated with damage to both—uterine horn, kidney, and ureter.**

The uterus is formed by the union of the two mullerian ducts at about the 10th week. Fusion begins in the middle and then extends caudally and cephalad. The characteristic uterine shape is now formed, with cellular proliferation at the upper portion and a simultaneous dissolution of cells at the lower pole, thus establishing the first uterine cavity. This cavity is at the lower pole with a thick wedge of tissue above. The upper thick wedge of tissue (septum) is dissolved slowly, creating the uterine cavity. This process is usually completed by the 20th week. Any failure to fuse the two mullerian ducts or failure to resorb the cavity between them results in separate uterine horns or some degree of persistent uterine septum.

The vagina forms between the urogenital sinus and the mullerian tubercle by a dissolution of the cell cord between the two structures. It is believed that this dissolution starts at the hymen and moves upward toward the cervix. Failure of this process will be associated with persistence of the cell cord, and vaginal agenesis or lesser abnormalities of this process will result in varying degrees of septum formation.

GENESIS AND CLASSIFICATION OF MULLERIAN ABNORMALITIES. Because fusion of the two mullerian ducts forms the vagina, cervix, and uterine body, the principal groups of deformities arising from three types of embryological defects can be classified as follows:

1. Defective canalization of the vagina results in a transverse vaginal septum, or in the most extreme form, absence of the vagina.
2. Unilateral maturation of the mullerian duct with incomplete or absent development of the opposite duct results in defects associated with upper urinary tract abnormalities.
3. The most common abnormality is absent or faulty midline fusion of the mullerian ducts. Complete lack of fusion results in two entirely separate uteri, cervixes, and vaginas. Incomplete tissue resorption between the two fused mullerian ducts results in a uterine septum.

Various classifications of these anomalies have been proposed, but none is completely satisfactory. One for mullerian duct abnormalities suggested by [Buttram and Gibbons \(1979\)](#) is based upon the failure of normal development. The classification separates a diversity of anomalies into groups with similar clinical characteristics, prognosis for pregnancy, and treatment ([Table 35-1](#)). The classification includes a category for abnormalities associated with fetal exposure to diethylstilbestrol (DES). Vaginal anomalies were not classified because they were not associated with fetal loss. Vaginal anomalies using their scheme were most often associated with uterine didelphys and bicornuate anomalies.

VULVAR ABNORMALITIES

Complete *atresia of the vulva*, or the lower portion of the vagina, unless corrected, precludes conception. More frequently, vulvar atresia is incomplete, resulting from adhesions or scars following injury or infection. The defect may present a considerable obstacle to delivery, but the resistance usually is overcome eventually by continued pressure exerted by the fetal head. This may result in deep perineal tears unless prevented by an adequate episiotomy.

VAGINAL ABNORMALITIES

Several developmental abnormalities of the vagina are possible:

1. *Single*. The normal vagina.
2. *Longitudinally septate*. More or less complete longitudinal septum.
3. *Double*. It is often difficult to distinguish the double from the completely septate vagina. The true double vagina includes a double introitus and resembles a double-barreled shotgun, with each passage terminating in a distinct, separate cervix. At times with double vaginas, one may end blindly.
4. *Transversely septate*. These result from faulty canalization of the united mullerian anlage rather than faulty longitudinal fusion. The septate vagina is usually discovered during routine pelvic examinations or by the woman who notices that vaginal tampons are not always effective in absorbing menses.

OBSTETRICAL SIGNIFICANCE OF VAGINAL ABNORMALITIES. In most cases, vaginal anomalies present few problems, but if so, they are usually obstruction to delivery.

SEPTAE AND STRICTURES. A complete longitudinal septum usually does not cause dystocia because the half of the vagina through which the fetus descends gradually dilates satisfactorily. An incomplete septum, however, occasionally interferes with descent. In these cases, the septum may become stretched around the presenting part as a band of varying thickness. Occasionally such septae are sufficiently resistant that either they must be divided or cesarean delivery must be performed.
